Kumar & Clark's Clinical Medicine

NINTH EDITION

Edited by

Professor Parveen Kumar CBE BSc MD DM(HC) FRCP(L&E) FRCPPath

Professor of Medicine and Education, Barts and The London School of Medicine and Dentistry, QMUL, and Honorary Consultant Physician and Gastroenterologist, Barts Health NHS Trust and Homerton University Hospital NHS Foundation Trust, UK

Dr Michael Clark MD FRCP

Honorary Senior Lecturer, Barts and The London School of Medicine and Dentistry, QMUL, and Princess Grace Hospital, UK
Editor, Online Content
Adam Feather FRCP FAcadMed
Senior Lecturer in Medical Education and Clinical Lead in Acute Medicine, The Royal London Hospital, Barts Health NHS Trust, UK

International Advisory Board

Preface to the Ninth Edition
  How to Use This Book

Section 1 Good medical practice

1 Ethics, law and communication
  Ethics and the Law
  Communication
2 Clinical pharmacology

Introduction

Why Do Patients Need Drugs?

The Choice of Drug

The Dose

Pharmacokinetics

Pharmacodynamics

Affordability and Cost-Effectiveness

Prescribing in Special Populations

Monitoring Drug Therapy

Adverse Drug Reactions

Drug Interactions

Inter-Individual Variability in Drug Response

Evidence-Based Medicine

Statistical Analyses

Information Sources

Significant websites

3 Palliative medicine and symptom control

Introduction and General Aspects

Symptom Control

Extending Palliative Care to People with Non-Malignant Disease

Palliative Care of the Frail Elderly

Care of the Dying

Further reading

Bibliography

Significant websites

4 Global health

Introduction
5 Environmental medicine

Disease and the Environment
Environmental Temperature
Heat Injury
Cold Injury
High Altitude
Diving
Drowning
Air Pollution
Ionizing Radiation
Electric Shock
Lightning Strike
Smoke
Noise
Bioterrorism/Biowarfare
6 Poisoning

Introduction

Clinical approach to the poisoned patient

Principles of Management of Poisoning

Specific Poisons

Significant websites

Section 2 Clinical sciences

7 Molecular cell biology and human genetics

Cell Biology

Human Genetics

Bibliography

Significant websites

8 The immune system and disease

Anatomy and Principles of the Immune System

Innate Immune System

Adaptive Immune System

Cell Migration

HLA Molecules and Antigen Presentation

The Immune System in Concert

Laboratory Investigations of the Immune System

Clinical Immunodeficiency

Type I (Immediate) Hypersensitivity and Allergic Disease

Autoimmune Disease

Organ Rejection in Clinical Transplantation
Immune-Based Therapies

9 Water, electrolytes and acid–base balance
   Water and Electrolytes
   Acid–Base Disorders
   Further reading
   Bibliography

10 Nutrition
   Introduction
   Water and Electrolyte Balance
   Dietary Requirements
   Protein–Energy Malnutrition
   Vitamins
   Minerals
   Nutrition and Ageing
   Obesity
   Nutritional Support
   Food Allergy and Food Intolerance
   Alcohol
   Bibliography
   Significant websites

Section 3 Clinical practice

11 Infectious diseases and tropical medicine
   Infection and Infectious Disease
   Viral Infections
   Transmissible Spongiform Encephalopathies (Prion Diseases)
   Bacterial Infections
Fungal Infections
Protozoal Infections
Helminthic Infections
Arthropod Ectoparasites

12 Sexually transmitted infections and human immunodeficiency virus
   Sexually Transmitted Infections
   Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome
   Bibliography

13 Gastrointestinal disease
   Introduction
   Clinical Approach to the Patient with Gastrointestinal Disease
   The Mouth
   The Salivary Glands
   The Pharynx and Oesophagus
   The Stomach and Duodenum
   Acute and Chronic Gastrointestinal Bleeding
   The Small Intestine
   Inflammatory Bowel Disease
   The Colon and Rectum
   Diarrhoea
   Functional Gastrointestinal Disorders
   The Acute Abdomen
   The Peritoneum
   Bibliography
   Significant websites

14 Liver disease
   Introduction
Anatomy of the Liver and Biliary System

Functions of the Liver

Clinical Approach to the Patient with Liver Disease

Jaundice

Hepatitis

Acute Hepatic Failure

Autoimmune Hepatitis

Drug-Induced Chronic Hepatitis

Chronic Hepatitis of Unknown Cause

Non-Alcoholic Fatty Liver Disease

Cirrhosis

Alcoholic Liver Disease

Budd–Chiari Syndrome

Hepatic Sinusoidal Obstruction Syndrome

Fibropolycystic Diseases

Liver Abscess

Other Infections of the Liver

Liver Disease in Pregnancy

Liver Tumours

Miscellaneous Conditions of the Liver

Drugs and the Liver

Bibliography

15 Biliary tract and pancreatic disease

The Gall Bladder and Biliary System

The Pancreas

16 Haematological disease

The Red Cell

The Spleen
17 Malignant disease

Cancer Treatment
Acute Oncology
Haematological Malignancies
Common Solid Tumour Treatment

18 Rheumatic disease

Introduction
Anatomy and Physiology of the Normal Joint
Clinical Approach to the Patient with Rheumatic Disease
Common Regional Musculoskeletal Problems
Chronic Pain Syndromes
Analgesic and Anti-Inflammatory Drugs for Musculoskeletal Problems
Disorders of collagen
Osteoarthritis
Inflammatory Arthritis
Rheumatoid arthritis
Infections of Joints
Autoimmune Rheumatic Diseases
Systemic Inflammatory Vasculitis
Arthritis in Children
Rheumatological Problems Seen in Other Diseases
Miscellaneous Arthropathies
19 Bone disease

Anatomy and Physiology of Bone
Clinical Approach to the Patient with Bone Disease
Osteoporosis
Osteonecrosis
Paget's Disease of Bone
Rickets and Osteomalacia
Bone Infections
Neoplastic Disease Of Bone
Other Bone Disorders
Bibliography
Significant websites

20 Kidney and urinary tract disease

Anatomy and Physiology of the Kidney and Urinary Tract
Clinical Approach to the Patient with Kidney and Urinary Tract Disease
The Glomerulus and Glomerular Disease
Kidney Involvement in Other Diseases
Hypertension and the Kidney
Other Vascular Disorders of the Kidney
Renal Calculi and Nephrocalcinosis
Urinary Tract Obstruction
Drugs and the Kidney
Urinary Tract Infection
Tubulointerstitial Nephritis
Acute Kidney Injury
Chronic Kidney Disease
Cystic Renal Disease
Tumours of the Kidney and Genitourinary Tract
Diseases of the Prostate Gland
The Urinary Tract in the Elderly

Bibliography

Significant websites

21 Neurological disease

Introduction

Clinical Approach to the Patient with Neurological Disease

Functional Neuroanatomy

Cranial Nerves

Motor Control Systems

Lower Motor Neurone Lesions

Sensory Pathways and Pain

Bladder Control and Sexual Dysfunction

Investigation of Neurological Disease

Unconsciousness and Coma

Stroke

Intracranial haemorrhage

Headache, Migraine and Facial Pain

Epilepsy and Loss of Consciousness

Movement Disorders

Neuroinflammatory Disorders

Nervous System Infection

Brain Tumours

Hydrocephalus

Traumatic Brain Injury

Spinal Cord Disease

Neurodegenerative Diseases

Congenital Disorders

Neurogenetic Disorders

Paraneoplastic Syndromes
22 Psychological medicine

Introduction
Clinical Approach to the Patient with a Psychiatric Disorder
Classification of Psychiatric Disorders
Aetiology of Psychiatric Disorders
Psychiatric Aspects of Physical Diseases
The Sick Role and Illness Behaviour
Functional Somatic Syndromes
Somatoform Disorders
Dissociative/Conversion Disorders
Sleep Difficulties
Mood (Affective) Disorders
Suicide and Self-Harm
Anxiety Disorders
Alcohol Misuse and Dependence
Drug Misuse and Dependence
Schizophrenia
Organic Mental Disorders
Eating Disorders
Sexual Disorders
Personality Disorders
Involuntary Detention or Commitment
Mental Capacity Act
Further reading
Significant websites
23 Cardiovascular disease
Cardiac Arrhythmias
Heart Failure
Coronary Artery Disease
Valvular Heart Disease
Infective Endocarditis
Congenital Heart Disease
Marfan Syndrome
Pulmonary Heart Disease
Myocardial and Endocardial Disease
Pericardial Disease
Systemic Hypertension
Peripheral Vascular Disease
Significant websites

24 Respiratory disease
Introduction
Anatomy of the Respiratory System
Physiology of the Respiratory System
Clinical Approach to the Patient with Respiratory Disease
Smoking
Diseases of the Upper Respiratory Tract
Diseases of the Lower Respiratory Tract
Asthma
Pneumonia
Tuberculosis
Diffuse Parenchymal Lung Diseases
Occupational Lung Disease
Lung Cysts
Tumours of the Respiratory Tract
Disorders of the Chest Wall and Pleura
Disorders of the Diaphragm
Mediastinal Lesions
Significant websites

25 Critical care medicine
Introduction
Clinical Approach to the Critically Ill Patient
Applied Cardiorespiratory Physiology
Disturbances of Acid–Base Balance
Shock, Sepsis and Acute Disturbances of Haemodynamic Function
Respiratory Failure
Acute Respiratory Distress Syndrome
Acute Kidney Injury
Neurocritical Care
Outcomes
Bibliography
Significant websites

26 Endocrine disease
Introduction
Clinical Approach to the Patient with Endocrine Disease
The Pituitary Gland and Hypothalamus
The Thyroid Axis
Reproduction and Sex
The Adrenal Axis
The Thirst Axis
Disorders of Calcium Metabolism
Other Endocrine Disorders
Bibliography
27 Diabetes mellitus

Introduction
Classification of Diabetes
Clinical Approach to the Patient with Diabetes
Management of Diabetes
Diabetic Metabolic Emergencies
Complications of Diabetes
Special Situations in Diabetes
Hypoglycaemia in the Non-Diabetic Patient

28 Lipid and metabolic disorders

Disorders of Lipid Metabolism
Inborn Errors of Carbohydrate Metabolism
Inborn Errors of Amino Acid Metabolism
Lysosomal Storage Diseases
Amyloidosis
The Porphyrias

29 Women's health

Introduction
The Life Course Approach
Miscarriage
Heavy Menstrual Bleeding
Abortion/Termination of Pregnancy
Urinary Incontinence
Domestic Abuse and Violence
Medical Problems in Pregnancy
Prescribing in Pregnancy

30 Ear, nose and throat and eye disease

Disorders of the Ear
Disorders of the Nose
Disorders of the Throat
Disorders of the Eye

31 Skin disease

Introduction
Structure and Function of the Skin
Clinical Approach to the Patient with Skin Disease
Infections
Papulo-Squamous/Inflammatory Rashes
Facial Rashes
Photodermatology
Erythroderma
Cutaneous Signs of Systemic Disease
Bullous Disease
Skin Tumours
Disorders of Blood Vessels and Lymphatics
Disorders of Collagen and Elastic Tissue
Disorders of Pigmentation
Disorders of the Nails
Disorders of Hair
Birth Marks/Neonatal Rashes
Drug Eruptions
Human Immunodeficiency Virus and the Skin
Principles of Topical Therapy

Bibliography

Notices
Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary. Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility. With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.
To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.
Acknowledgements

We would like to thank our many colleagues who have helped in the preparation of this edition by giving us useful advice, helping us to collect photographs and images and reading the manuscripts. A book of this size cannot be accomplished without the help and advice of many. In particular, we would like to acknowledge Peter Garrard, Monica Wolhuter and Susannah Leaver.

We are delighted to welcome several new contributors to this edition and we would like to thank the authors who have stepped down from the book after many years of commitment and loyalty:

- Caroline Byrne (Molecular biology)
- John Camm (Cardiology)
- Charles Clarke (Environmental medicine)
- Meredydd Harries (Special senses)
- Trevor Howlett (Endocrinology)
- Andrew Lister (Oncology)
- James Wainscoat (Haematology)
- David Watson (Critical care)

John Camm and Charles Clarke had been with us since the first edition! We were extremely saddened by the death of Andrew Burroughs (Liver Disease), who was a highly valued colleague and author.

We are very grateful to our specialist registrars, junior trainees and medical students across the world for their input and feedback.

Over the course of several editions, we have made many new friends and colleagues across the world. Our international travels give us much insight into the practice of medicine in different countries. We would like to thank the many colleagues who have escorted us through their hospitals and medical schools. We are extremely grateful to our International Advisory Board members who provide very helpful advice about their regions and contribute articles to the e-book. In particular we would like to thank Professor Janaka de Silva and Professor Senaka Rajapake for their advice, expertise and careful editing of these online contributions.

We are extremely grateful for the support of our publisher, Elsevier, whose staff has maintained a long-term commitment and loyalty to the book. Pauline Graham, our
commissioning editor, has now taken us through many editions and has been a constant support. Ailsa Laing, our development editor, has managed the day-to-day work on this edition with great patience and endless good humour. We would also very much like to acknowledge the production team: Anne Collett (production), Christian Bilbow (design), and Kim Benson (development editor for all the electronic content accompanying this book) who have all worked hard to create this extremely high-quality edition. We are also grateful for the meticulous work of the copy editor, Wendy Lee, and proofreader, Glenys Norquay. There are so many other people behind the scenes who have contributed in many ways, and we thank them all for their loyalty and hard work.

Finally, we would like to thank Jillian Linton for secretarial help and the Princess Grace Hospital, London for administrative assistance.
Online Special Topics

From the International Advisory Board

Chapter 5. Heat stroke and heat stress
   Samy A Azer

Chapter 6. Pesticide and plant poisoning
   H Janaka de Silva

Snake bite
   Christeine Ariaranee Gnanathasan, Rezvi Sheriff, Praveen Aggarwal

Chapter 10. Fluorosis
   F S Hough†, Karen Barnard

Vitamin B₁₂ and folic acid deficiency
   Vernon J Louw

Chapter 11. Brucellosis
   Suliman S Fedail

Cholera
   K Neelakanthan Viswanathan

Crimean–Congo haemorrhagic fever
   Somia Iqtadar

Dengue
   Somia Iqtadar

Diarrhoeas, including amoebiasis
   Samy A Azer

Ebola
   Somia Iqtadar

Infections caused by Rickettsiae, Orientiae and Coxiella
   Ranjan Premaratna

Leprosy
   Sandhya Kamath
Leptospirosis
   K Neelakanthan Viswanathan
Malaria
   Sandhya Kamath, Nilanthi R de Silva
Pyogenic meningitis
   Saad Shafqat, Anita Zaidi
Rabies
   K Neelakanthan Viswanathan
Rheumatic fever
   K Neelakanthan Viswanathan
Rift Valley fever
   Suliman S Fedail
Severe acute respiratory syndrome (SARS)
   Kar Neng Lai
Soil-transmitted helminths
   Nilanthi R de Silva
Vaccination for adults
   Richa Dewan
Visceral leishmaniasis
   K Neelakanthan Viswanathan, Han Ni
Clinical cases
   Abdullah Saadeh, Somia Iqtadar, K Neelakanthan Viswanathan, Han Ni
Chapter 12. HIV-associated immune reconstitution inflammatory syndrome (IRIS)
   Graeme Meintjes
HIV in resource-limited settings
   Marc Mendelson, Gary Maartens
HIV nephropathy
   Nicola Wearne
Thrombotic thrombocytopenic purpura (TTP) associated with HIV
   Vernon J Louw
Chapter 13. Tropical sprue
   Samy A Azer
Clinical case
   Samy A Azer
Chapter 14. Liver transplantation  
  Jennifer T Wells, Michael R Lucey

Chapter 18. Gout clinical case  
  Arup Kumar Kundu

Chapter 20. IgA nephropathy  
  Kar Neng Lai

Chapter 21. Arsenic poisoning  
  Arup Kumar Kundu

Neurocysticercosis  
  K Neelakantan Viswanathan, Han Ni, Anita Devi K Ravindran

Neurological manifestations of systemic disease  
  Udaya K Ranawaka

Neurology of toxins and envenoming  
  Udaya K Ranawaka

Tropical neurological infections  
  Udaya K Ranawaka

Clinical case  
  Abdullah Saadeh

Chapter 22. Trauma and its psychological impact  
  Nazish Imran

Chapter 23. Clinical cases  
  Nazish Imran

Non-communicable diseases in sub-Saharan Africa  
  Ntobeko A B Ntusi

Salt intake and cardiovascular disease  
  Mary-Anne Land, Ntobeko A B Ntusi

Myocarditis clinical case  
  Ntobeko A B Ntusi

Chapter 27. Diabetic ketoacidosis clinical case  
  Nabila A Abdella

Clinical Medicine is now approaching its 30th anniversary. It was first published in 1987 and is now firmly established as a companion to all medical students, young doctors and healthcare professionals. The book has been described as the ‘gold standard’ guide to clinical medicine and, with an excellent author team, we have striven to keep to these high standards.

There are several innovations in this edition. We have added two new chapters: Women's health and Global health. Women's health has been added to include women's disorders as well as those occurring in pregnancy. Global health has now entered the curricula in many medical schools in acknowledgement that inequalities and inadequacies of healthcare worldwide need to be vigorously tackled to improve the health of all people.

Infections travel fast across continents, as we have seen with the emergence of Ebola and Zika virus epidemics. To allow for fuller discussion of diseases posing particular problems in specific parts of the world, further short Special Topics have been written for the e-book by expert members of our International Advisory Board.

It is a difficult task to be both a comprehensive reference book and also be learner-friendly. However, we have taken much advice from our readers and sought to address this challenge in two main ways. In the print book we have redistributed information in several chapters to break down the content and facilitate learner engagement. Larger chapters have been subdivided. We have added diagrammatic overviews to all the appropriate systems-based chapters; headings have been put into colour to define whether the text relates to management, disease or basic science. In the e-book that accompanies your print copy, we have appointed a team of registrars, under the editorship of Adam Feather, to take on the task of providing online key learning outcomes, clinical tips, drug tips, videos, audio, extra images, and self-assessment to help learners of all levels to get what they need from the content. Keep checking your e-book to be advised of further developments, as we are also working to provide ‘scaled’ versions of the text online (which allow the reader to ‘zoom’ in or out for different levels of detail).

We very much hope you will enjoy reading this edition and find the information easily accessible for learning. Thank you all for your suggestions, which are always welcome.

Parveen Kumar, Mike Clark

How to Use This Book
The First Section contains general topics for the overall practice of medicine, and the Second
Section contains the basic sciences. Essentially these contain communication skills, general topics such as pharmacology, poisoning and global health, and the fundamental basics of science. These chapters can be read alone but can also be used as a reference for other chapters where a basic mechanism has been discussed.

The Third Section contains clinical chapters with the medical specialities for easy accessibility and to aid the day-to-day practice of medicine.

Chapter format

Each clinical chapter has its own anatomy, physiology and pathology for understanding the presentation of the problems of that speciality. This is followed, where appropriate, by clinical symptoms and signs in general. For the appropriate systems chapters a diagrammatic overview of the anatomy and physiology has been provided.

Individual diseases have an introduction, followed by pathogenesis, aetiology, clinical features, investigations, management and prognosis. These have colour codes to make them easy to follow:

- Conditions-related headings (e.g. ‘pernicious anaemia’)
- Disease-specific headings (e.g. ‘investigations’)
- Anatomy/physiology headings (e.g. ‘structure’)

Boxes

Boxes have been classified by the type of information they provide and have the following symbols:

- Pearls and Tips
- Table
- Emergency
- Information
- Differential diagnosis
- Frailty
- Practical

  Emergency Boxes are in red

E-Book enhancements

Click on icons throughout the e-Book to popup the added clinical and drug tips, images, key learning outcomes, videos, audio, extra images, and self-assessment, etc. Click on selected figures to open interactive versions.
Prescribing

We have used the Recommended International Non-proprietary Names (rINNs) for all drugs. In some diseases where a particular formulation of a drug is required, the proprietary name is used. Drugs have been spelled by their international names, e.g. bendroflumethazide and not bendrofluazide, and amfetamine and not amphetamine. For adrenaline and noradrenaline, we have added epinephrine and norepinephrine in brackets as these names are often used in emergency guidelines across the world.

Dosages have been given where appropriate but we recommend that all readers check with their national formularies for the exact dosages. We would strongly recommend that this is done every time you use a drug which is unfamiliar to you and not part of your daily practice.

Units of measurements

We have used the International System of Units (SI units) throughout the book. On occasion, if there is a possibility for confusion, we have also used non-SI-units and given a conversion factor.

Evidence based medicine

This is embedded within the book and not singled out as we feel it is a part of one's learning and the way we should practise medicine.

Ethics and the Law

Ethics

The practice of medicine is inherently moral:

- Biomedical expertise and clinical science have to be applied by and to people.
- Medical decisions are underpinned by values and principles.
- Potential courses of action will have implications that are often uncertain.
- Technological advancements sometimes have unintended or unforeseen consequences.
The profession has to agree on its collective purpose, aims and standards. People are much more than a collection of symptoms and signs – they have preferences, priorities, fears and hopes. Doctors too are much more than interpreters of symptoms and signs – they also have preferences, priorities, fears and hopes. Ethics is part of practice; it is a practical pursuit.

The study of the moral dimension of medicine is known as *medical ethics* in the UK and *bioethics* internationally. Becoming, and practising as, a doctor require an awareness of, and reflection on, one's ethical attitudes. All of us have personal values and moral intuitions. In the field of ethics, a necessary part of learning is to become aware of the assumptions on which these personal values are based, to reflect on them critically, and to listen and respond to challenging or opposing beliefs.

Ethics is commonly characterized as the consideration of big moral questions that preoccupy the media. Questions about cloning, stem cells and euthanasia are what many immediately think of when the words ‘medical ethics’ are used. However, ethics pervades all of medicine. The daily and routine workload is rife with ethical questions and dilemmas; introductions to patients, dignity on the wards, the use of resources in clinic, the choice of antibiotic and the medical report for a third party are as central to ethics as the issues that pervade the popular representation of this area.

The study and practice of ethics incorporate knowledge, cognitive skills such as reasoning, critique and logical analysis, and clinical skills. Abstract ethical understanding has to be integrated with other clinical knowledge and applied thoughtfully and appropriately in practice.

**Ethical practice: sources, resources and approaches**

Engaging with an ethical issue in clinical practice depends on:

• discerning the relevant moral question(s)
• looking at the relevant ethical theories and/or tools
• identifying applicable guidance (e.g. from a professional body)
• integrating the ethical analysis with an accurate account of the law (both national and international).

Personal views must be taken into account, but other perspectives should be acknowledged and supported by reasoning, and located in an accurate understanding of the current law and relevant professional guidance.

**Ethical theories and frameworks**

Key ethical theories are summarized in *Box 1.1*.

---

**Box 1.1**

**Key ethical theories**

• **Deontology**: a universally applicable rule or duty-based approach to morality, e.g. a
A deontologist would argue that one should always tell the truth, irrespective of the consequences.

- **Consequentialism**: an approach that argues that morality is located in consequences. Such an approach will focus on likely risks and benefits.

- **Virtue ethics**: an approach in which particular traits or behaviours are identified as desirable.

- **Rights theory**: an assessment of morality with reference to the justified claims of others. Rights are either ‘natural’ and arise from being human, or legal and therefore enforceable in court. Positive rights impose a duty on another to act, whilst negative rights prohibit interference by others.

- **Narrative ethics**: an approach that argues that morality is embedded in the stories shared between patient and clinician, and allows for multiple perspectives.

Many doctors find that ethical frameworks and tools that focus on the application of ethical theory to clinical problems are useful. Perhaps the best known is the ‘Four Principles’ approach, in which the principles are:

1. **Autonomy**: allowing ‘self-rule’, i.e. letting patients make their own choices and decide what happens to them
2. **Beneficence**: doing good, i.e. acting in a patient's best interests
3. **Non-maleficence**: avoiding harm
4. **Justice**: treating people equitably and fairly.

For some, a consistent process that incorporates the best of each theoretical approach is helpful. So, whatever the ethical question, one should:

- summarize the problem and state the moral dilemma(s)
- identify the assumptions being made or to be made
- analyse with reference to ethical principles, consequences, professional guidance and the law
- acknowledge other approaches and state the preferred approach with explanation.

People respond differently to ethical theories and approaches. Do not be afraid to experiment with ways of thinking about ethics. It is worthwhile understanding other ethical approaches, even in broad terms, as it helps in understanding how others might approach the same ethical problem, especially given the increasingly global context in which healthcare is delivered.

**Professional Guidance and Codes of Practice**

As well as ethical theories and frameworks, there are codes of practice and professional guidelines. For example, in the UK, the standards set out by the General Medical Council (GMC) are the basis on which doctors are regulated within the UK; if a doctor falls below the expectations of the GMC, disciplinary procedures may follow, irrespective of the harm caused
or whether legal action ensues. In other countries, similar professional bodies exist to license doctors and regulate healthcare. All clinicians should be aware of the regulatory framework and professional standards in the country within which they are practising.

Increasingly, ethical practice and professionalism are considered significant from the earliest days of medical study and training. In the UK, attention has turned to the standards expected of medical students. For example, in the UK, all medical schools are required to have ‘Fitness to Practise’ procedures. Students should be aware of their professional obligations from the earliest days of their admission to a medical degree. All medical schools are effectively vouching for a student's suitability for provisional registration at graduation.

Medical students commonly work with patients from the earliest days of their training and are privileged in the access they have to vulnerable people, confidential information and sensitive situations. As such, medical schools have particular responsibilities to ensure that students behave professionally and are fit to study, and eventually to practise, medicine.

The Hippocratic Oath, although well known, is outdated and something of an ethical curiosity, with the result that it is rarely, if ever, sworn. The symbolic value of taking an oath remains, however, and many medical schools expect students to make a formal commitment to maintain ethical standards.

### Further reading

### The Law

As it pertains to medicine, the law establishes boundaries for what is deemed to be acceptable professional practice. The law that applies to medicine is both national and international: for example, the European Convention on Human Rights (*Box 1.2*). Within the UK, along with other jurisdictions, both statutes and common law apply to the practice of medicine (*Box 1.3*).

#### Box 1.2

**European Convention on Human Rights: substantive rights that apply to evaluating good medical practice**

- Right to life (Article 2)
- Prohibition of torture, inhuman or degrading treatment or punishment (Article 3)
- Prohibition of slavery and forced labour (Article 4)
- Right to liberty and security (Article 5)
- Right to a fair trial (Article 6)
- No punishment without law (Article 7)
- Right to respect for private and family life (Article 8)
- Freedom of thought, conscience and religion (Article 9)
- Freedom of expression (Article 10)
- Right to marry (Article 12)
- Prohibition of discrimination (Article 14)

Box 1.3

**Statutes and common law**

**Statutes**

- Primary legislation made by the state, e.g. Acts of Parliament in the UK, such as the Mental Capacity Act 2005
- Secondary (or delegated) legislation: supplementary law made by an authority given the power to do so by the primary legislation
- Implementation (or statutory) guidance, e.g. the Mental Health Act Code of Practice

**Common law**

- Judicial decisions made in cases: these establish precedents that are then applied to future cases
- Precedent: whether a decision constitutes a precedent depends on which court made the decision – higher-level courts have authority over lower-level courts

The majority of cases involving healthcare arise in the civil system. Occasionally, a medical case is subject to criminal law: for example, when a patient dies in circumstances that could constitute manslaughter.

**Respect for Autonomy: Capacity and Consent**

**Capacity**

Capacity is at the heart of ethical decision-making because it is the gateway to self-determination *(Box 1.4)*. People are able to make choices only if they have capacity. The assessment of capacity is a significant undertaking; a patient's freedom to choose depends on it. If a person lacks capacity, it is meaningless to seek consent. In the UK, the Mental Capacity Act 2005 sets out the criteria for assessing whether a person has the capacity to make a decision (see Ch. 22, p. 930).
### Principles of self-determination

- Every adult has the right to make his/her own decisions and to be assumed to have capacity unless proved otherwise.
- Everyone should be encouraged and enabled to make his/her own decisions, or to participate as fully as possible in decision-making.
- Individuals have the right to make eccentric or unwise decisions.
- Proxy decisions should consider best interests, prioritizing what the patient would have wanted, and should be the ‘least restrictive of basic rights and freedoms’.

---

*Principles underlying the Mental Capacity Act 2005 (England and Wales), which applies to patients over the age of 16 years.*

Assessment of capacity is not a one-off judgement. Capacity can fluctuate and assessments of capacity should be regularly reviewed. Capacity should be understood as task-oriented. People may have capacity to make some choices but not others, and capacity is not automatically precluded by specific diagnoses or impairments. The way in which a doctor communicates can enhance or diminish a patient's capacity, as can pain, fatigue and the environment.

### Consent

Consent is integral to ethical and lawful practice. To act without, or in opposition to, a patient's expressed, valid consent is, in many jurisdictions, to commit an assault or battery. Obtaining informed consent fosters choice and gives meaning to autonomy. Valid consent is:

- given by a patient who has capacity to make a choice about his or her care
- voluntary, i.e. free from undue pressure, coercion or persuasion
- sufficiently informed
- continuing, i.e. patients should know that they can change their mind at any time.

### The basis of informed consent

Those seeking consent for a particular procedure must be competent in the knowledge of how the procedure is performed and its problems. Whilst it is common and good practice for written information to be provided to patients, the existence of written material and a consent form does not remove the responsibility to talk to the patient. The information given to a patient should be that which a ‘reasonable person’ would require whilst being alert to the particular priorities and concerns of individuals. Information shared should:

- cover risks and benefits
• explain possible consequences of treatment and non-treatment
• explain options
• disclose uncertainty; this should be as much part of the discussion as sharing what is well understood.

Patients should be encouraged to ask questions and express their concerns and preferences. Since it is the health and lives of patients that are potentially at risk, the moral focus of such disclosure should be on what is acceptable to patients rather than to the professionals.

Consent in educational settings
Much medical education and training takes place in the clinical environment. Future doctors have to learn new skills and apply their knowledge to real patients. However, patients must be given a choice as to whether they wish to participate in educational activities. The principles of seeking consent for education are identical to those applied to clinical situations.

Advance decisions
Advance decisions (sometimes colloquially described as ‘living wills’) enable people to express their wishes about future treatment or interventions. The decisions are made in anticipation of a time when a person ceases to have capacity. Different countries have differing approaches to advance decision-making and it is necessary to be aware of the relevant law in the area in which one is practising. Within the UK, advance decisions are governed by legislation; for example, the Mental Capacity Act 2005 applies in England and Wales. The criteria for a legally valid advanced decision are that it is:
• made by someone with capacity
• made voluntarily
• based on appropriate information
• specific and applicable to the situation in which it is being considered.

In practice, it is often the requirement of specificity that is most difficult for patients to fulfil because of the inevitable uncertainty surrounding future illness and potential treatments or interventions. There is one issue that, for many, goes to the heart of an ethical objection to advance decision-making: namely, the difficulty in anticipating the future and how one is likely to feel about that future.

Scope
An advance decision can be made to refuse treatment and to express preferences, but cannot be used to demand treatment. In general, no patient has the right to demand or request treatment that is not clinically indicated. Therefore it would be inconsistent to allow patients to include in their advance decisions requests for specific treatments, procedures or interventions. An advance decision cannot be used to refuse basic care, such as maintaining hygiene.

Format
Advance decisions are made orally or in writing. However, advance decisions on the withdrawal or withholding of life-sustaining treatment must be in written form and witnessed, and the decision should state explicitly that it is intended to apply even to life-saving situations. The more informal and non-specific the advance decision is, the more likely it is to be challenged or disregarded as being invalid. If working in a country where advance decisions are recognized, clinicians should make reasonable attempts to establish whether there is a valid advance decision in place; the presumption is to save life where there is ambiguity about either the existence or the content of an advance decision. Advance decisions should be periodically reviewed and amendments, revocations or additions are possible, provided that the person concerned still has capacity.

**Ethical and practical rationale**

The ethical rationale for the acceptance of advance decisions is usually said to be respect for patient autonomy and it represents the extension of the right to make choices about healthcare in the future. True respect for autonomy and the freedom to choose necessarily involves allowing people to make choices that others might consider misguided. Some suggest that giving patients the opportunity to express their concerns, preferences and reservations about the future management of their health fosters trust and effective relationships with clinicians. However, it could also be argued that none of us will ever have the capacity to make decisions about our future care because the person we become when ill is qualitatively different from the person we are when we are healthy.

**Lasting power of attorney**

Many countries allow for the appointment of a proxy, or for a third party, to make substituted judgements for people lacking capacity. In England and Wales, consent or refusal can be expressed by someone who has been granted a lasting power of attorney (LPA). Once a person's lack of capacity has been registered with the Public Guardian and the LPA granted, the person holding the power of attorney is charged with representing a patient's best interests. Therefore, it is imperative to establish whether there is a valid LPA in respect of an incapacitous patient and to adhere to the wishes of the person acting as attorney. The only circumstances in which clinicians need not follow the LPA is where the attorney appears not to be acting in the patient's best interests. In such situations, the case should be referred to the Court of Protection. Like advance decisions, the ethical rationale for the existence of LPAs is that prospective autonomy is desirable and facilitates informed care, rather than second-guessing patient preferences.

**Best interests of patients who lack capacity**

Where an adult lacks capacity to give consent, and there is no valid advance decision or power of attorney in place, clinicians are obliged to act in the patient's best interests. This encompasses more than an individual's best *medical* interests. In practice, the determination of best interests is likely to involve a number of people: for example, members of the healthcare
team, professionals with whom the patient had a longer-term relationship, and relatives and carers.

In England and Wales, an Independent Mental Capacity Advocacy Service provides advocates for patients who lack capacity and have no family or friends to represent their interests. ‘Third parties’ in such a situation, including Independent Mental Capacity Advocates, are not making decisions; rather, they are being asked to give an informed sense of the patient and his or her likely preferences. In some jurisdictions – for example, in North America – clinical ethicists play an advocacy role and seek to represent the patient's best interests.

**Provision or cessation of life-sustaining treatment**

A common situation requiring determination of a patient's best interests is the provision of life-sustaining treatment, often at the end of life, for a patient who lacks capacity and has neither an advance decision nor an advocate to speak for them. It is considered acceptable not to use medical means to prolong the lives of patients where:

• based on good evidence, the team believes that further treatment will not save life
• the patient is already imminently and irreversibly close to death
• the patient is so permanently or irreversibly brain-damaged that he or she will always be incapable of any future self-directed activity or intentional social interaction.

Moral and religious beliefs vary widely and, in general, decisions not to provide or continue life-sustaining treatment should always be made with as much consensus as possible amongst both the clinical team and those close to the patient. Where there is unresolvable conflict between those involved in decision-making, a court should be consulted. In emergencies in the UK, judges are always available in the relevant court.

Where clinicians decide not to prolong the lives of imminently dying and/or extremely brain-damaged patients, the legal rationale is that they are acting in the patient's best interests and seeking to minimize suffering rather than intending to kill, which would constitute murder. In ethical terms, the significance of intention, along with the moral status of acts and omissions, is integral to debates about assisted dying and euthanasia.

**Assisted dying**

Currently, in many countries, there is no provision for lawful assisted dying. For example, physician-assisted suicide, active euthanasia and suicide pacts are all illegal in the UK. In contrast, some jurisdictions, including the Netherlands, Switzerland, Belgium and certain states in the USA, permit assisted dying. However, even where assisted dying is not lawful, withholding and withdrawing treatment is usually acceptable in strictly defined circumstances, where the intention of the clinician is to minimize suffering, not to cause death. Similarly, the doctrine of double effect may apply. It enables clinicians to prescribe medication that has as its principal aim the reduction of suffering by providing analgesic relief but which is acknowledged to have side-effects such as the depression of respiratory effort (e.g. opiates). Such prescribing is justifiable on the basis that the intention is benign and the side-effects,
whilst foreseen, are not intended to be the primary aim of treatment. End-of-life care pathways, which provide for such approaches where necessary, are discussed in Chapter 3.

Although assisted dying is unlawful in the UK, the Director of Public Prosecutions (DPP) has issued guidance on how prosecution decisions are made in response to a request from the courts, following an action brought by Debbie Purdy. Thus, there are now guidelines that indicate what circumstances are likely to weigh either in favour of, or against, a prosecution. Nevertheless, the law itself is unchanged by the DPP's guidance; for a clinician to act to end a patient's life remains a criminal offence.

**Mental health and consent**

The vast majority of people being treated for psychiatric illness have capacity to make choices about healthcare. However, there are some circumstances in which mental illness compromises an individual's capacity to make his or her own decisions. In such circumstances, many countries have specific legislation that enables people to be treated without consent on the basis that they pose a risk to themselves and/or to others.

People who have, or are suspected of having, a mental disorder may be detained for assessment and treatment in England and Wales under the Mental Health Act 2007 (which amended the 1983 statute). There is one definition of a mental disorder for the purposes of the law. The Mental Health Act 2007 defines a mental disorder as ‘any disorder or disability of the mind’. Addiction to drugs and alcohol is excluded from the definition. Appropriate medical treatment should be available to those who are admitted under the Mental Health Act. In addition to assessment and treatment in hospital, the legislation provides for Supervised Community Treatment Orders, which consist of supervised community treatment after a period of detention in hospital. The law is tightly defined with multiple checks and limitations that are essential, given the ethical implications of detaining and treating someone against his or her will.

Even in situations in which it is lawful to give a detained patient psychiatric treatment compulsorily, efforts should be made to obtain consent if possible. For concurrent physical illness, capacity should be assessed in the usual way. If the patient does have capacity, consent should be obtained for treatment of the physical illness. If a patient lacks capacity because of the severity of a psychiatric illness, treatment for physical illness should be given on the basis of best interests or with reference to a proxy or advance decision, if applicable. If treatment can be postponed without seriously compromising the patient's interests, consent should be sought when the patient once more has capacity.

**Consent and children**

Where a child does not have the capacity to make decisions about his or her own medical care, treatment will usually depend upon obtaining proxy consent. In the UK, consent is sought on behalf of the child from someone with ‘parental responsibility’. In the absence of someone with parental responsibility – for example, in emergencies, where treatment is required urgently – clinicians proceed on the basis of the child's best interests.
Sometimes parents and doctors disagree about the care of a child who is too young to make his or her own decisions. Here, both national and European case law demonstrates that the courts are prepared to override parental beliefs if they are perceived to compromise the child's best interests. However, the courts have also emphasized that a child's best medical interests are not necessarily the same as a child's best overall interests. Whenever the presenting patient is a child, clinicians are dealing with a family unit. Sharing decisions, and paying attention to the needs of the child as a member of a family, are the most effective and ethical ways of practising.

As children grow up, the question of whether a child has capacity to make his or her own decisions is based on principles derived from a case called Gillick v. West Norfolk and Wisbech Area Health Authority, which determined that a child can make a choice about his or her health where:

• the patient, although under 16, can understand medical information sufficiently
• the doctor cannot persuade the patient to inform, or give permission for the doctor to inform, his or her parents
• a minor is seeking contraception, in cases where the patient is very likely to have sexual intercourse with or without adequate contraception
• the patient's mental or physical health (or both) is likely to suffer if treatment is not provided
• it is in the patient's best interests for the doctor to treat without parental consent.

The Gillick case recognized that children differ in their abilities to make decisions and established that function, not age, is the prime consideration when considering whether a child can give consent. Situations should be approached on a case-by-case basis, taking into account the individual child's level of understanding of a particular treatment. It is possible (and perhaps likely) that a child may be considered to have capacity to consent to one treatment but not another. Even where a child does not have capacity to make his or her own decision, clinicians should respect the child's dignity by discussing the proposed treatment, even if the consent of the parents also has to be obtained.

In the UK, once a child reaches the age of 16, the Mental Capacity Act 2005 states that he or she should be treated as an adult, except for the purposes of advance decision-making and appointing a lasting power of attorney.

Further reading

Confidentiality

Confidentiality is essential to therapeutic relationships. If clinicians violate the privacy of their patients, they risk causing harm, disrespect autonomy, undermine trust, and call the medical profession into disrepute. The diminution of trust is a significant ethical challenge, with potentially serious consequences for both the patient and the clinical team. Within the UK, confidentiality is protected by common and statutory law. Some jurisdictions make legal provision for privacy. Doctors who breach the confidentiality of patients may face severe professional and legal sanctions. For example, in some jurisdictions, breaching a patient's confidentiality is a statutory offence.

Respecting confidentiality in practice

Patients should understand that information about them will be shared with other clinicians and healthcare workers involved in their treatment. Usually, by giving consent for investigations or treatment, patients are deemed to give their implied consent for information to be shared within the clinical team. Very rarely, patients might object to information being shared, even within a team. In such situations, the advice is that the patient's wish should be respected, unless it compromises treatment. In almost all clinical circumstances, therefore, the confidentiality of patients must be respected. Unfortunately, confidentiality can be easily breached inadvertently. For example, clinical conversations take place in lifts, corridors and cafés. Even on wards, confidentiality is routinely compromised by the proximity of beds and the visibility of whiteboards containing medical information. Students and doctors should be alert to the incidental opportunities for breaches of confidentiality and seek to minimize their role in unwittingly revealing sensitive information.

When confidentiality must or may be breached

The duty of confidence is not absolute. Sometimes, the law requires that clinicians must reveal private information about patients to others, even if they wish it were otherwise (Box 1.5). There are also circumstances in which a doctor has the discretion to share confidential information within defined terms. Such circumstances highlight the ethical tension between the rights of individuals and the public interest.
Examples of circumstances in which a doctor is required to share confidential information

- Notifiable diseases, which, by virtue of public health legislation, must be notified to the relevant consultant in communicable disease control
- Court orders
- Road traffic accidents that lead to requests from the police
- Actual or suspected terrorist activity

Aside from legal obligations, there are three broad categories of qualifications that exist in respect of the duty of confidentiality, namely:

1. The patient has given consent.
2. It is in the patient's best interests to share the information but it is impracticable or unreasonable to seek consent.
3. It is in the public interest.

These three categories are useful as a framework within which to think about the extent of the duty of confidentiality and they also require considerable ethical discretion in practice, particularly in relation to situations where sharing confidential information might be considered to be in the ‘public interest’. In England and Wales, there is legal guidance on what constitutes sufficient ‘public interest’ to justify sharing confidential information, which is derived from the case of *W v. Egdell*. In that case, the Court of Appeal held that only the ‘most compelling circumstances’ could justify a doctor acting contrary to the patient's perceived interest in the absence of consent. The court stated that it would be in the public interest to share confidential information where:

- there is a real and serious risk of harm
- the risk is of physical harm
- there is a risk to an identifiable individual or individuals.

Consent should be sought wherever possible, and disclosure on the basis of the ‘public interest’ should be a last resort. Each case must be weighed on its own individual merits and a clinician who chooses to disclose confidential information on the ground of ‘public interest’ must be prepared to justify his or her decision. Even where disclosure is justified, confidential information must be shared only with those who need to know.

If there is a perceived risk to the public interest, does a doctor have a duty to warn? In some jurisdictions there is a duty to warn, but in England and Wales there is no professional duty to warn others of potential risk. The judgement of *W v. Egdell* provides a justification for breaches of confidence in the public interest but it does not impose an obligation on clinicians to warn third parties about potential risks posed by their patients.
Resource Allocation

Resources should be considered broadly to encompass all aspects of clinical care, i.e. they include time, knowledge, skills and space, as well as treatment. In circumstances of scarcity, waste and inefficiency of any resource are of ethical concern.

Access to healthcare is considered to be a fundamental right and has been captured in international law since it was included in the Universal Declaration of Human Rights. However, resources are scarce and the question of how to allocate limited resources is a perennial ethical question. Within the UK, the courts have made it clear that they will not force National Health Service (NHS) Trusts to provide treatments that are beyond their means. Nevertheless, the courts also demand that decisions about resources must be made on reasonable grounds.

Fairness

Both ethically and legally, prejudice or favouritism is unacceptable. Methods for allocating resources should be fair and just. In practice, this means that scarce resources should be allocated to patients on the basis of their comparative need and the time at which they sought treatment. It is respect on the part of clinicians for these principles of equality – equal need and equal chance – that fosters fairness and justice in the delivery of healthcare. For example, a well-run Accident and Emergency Department will draw on the principles of equality of need and chance to:

• decide who to treat first and how
• offer treatment that has been shown to deliver optimal results for minimal expense
• use triage to determine which patients are most in need and ensure that they are seen first, the queue (or waiting list) being based on need and time of presentation.

People should not be denied potentially beneficial treatments on the basis of their lifestyles. Such decisions are almost always prejudicial. For example, why single out smokers or the obese for blame, as opposed to those who engage in dangerous sports? Patients are not equal in their abilities to lead healthy lives and to make wise healthcare choices.

Education, information, economic worth, confidence and support are all variables that contribute to, and socially determine, health and wellbeing. As such, to regard all people as equal competitors and to reward those who, in many ways, are already better off is unjust and unfair.
Global perspectives

Increasingly, resource allocation is being considered from an international or global perspective. Beyond the boundaries of the NHS and the borders of the UK, moral questions about the availability of, and access to, effective healthcare are rightly attracting the attention of ethicists and clinicians. Anyone who is training for, or working in, medicine in the 21st century should consider fundamental moral questions about resource allocation, in particular those being raised by issues such as:

- the role and work of pharmaceutical companies
- the mobility of trained clinicians
- the preoccupation of funded and commercial biomedical research with diseases that are prevalent in developed countries
- notions of rights to health and life
- the status of those seeking asylum
- persistent inequalities in health.

Professional Competence and Mistakes

Doctors have a duty to work to an acceptable professional standard. There are essentially three sources that inform what it means to be a ‘competent’ doctor, namely:

1. the law
2. professional guidance from bodies such as the GMC
3. policy.

In practice, there is frequently overlap and interaction between the categories: for example, a doctor may be both a defendant in a negligence action and the subject of fitness to practise procedures. Professional bodies are established by, and work within, a legal framework and, in order to implement policy, legislation is required and interpretative case law will often follow.

Standards and the law

In most countries, the law provides the statutory framework within which the medical profession is regulated. For example, in the UK, it is the function of the GMC to maintain the register of medical practitioners, provide ethical guidance, guide and quality-assure medical education and training, and conduct fitness to practise procedures. Therefore it is the GMC that
defines standards of professional practice and has responsibility for investigation when a doctor's standard of practice is questioned.

Clinicians have a responsibility not only to reflect on their own practice, but also to be aware of and, if necessary, respond to the practice of colleagues, even in the absence of formal ‘line management’ responsibilities. In England and Wales, for example, the Public Interest Disclosure Act 1998 provides statutory protection for those who express formal concern about a colleague's performance, provided the expression of concern:
• constitutes a ‘qualifying disclosure’
• is expressed using appropriate procedures, and
• is made in good faith.

Clinical negligence

Negligence is a civil claim where damage or loss has arisen as a result of an alleged breach of professional duty, such that the standard of care was not, on the balance of probabilities, that which could be reasonably expected.

Of the components of negligence, duty is the simplest to establish: all doctors have a duty of care to their patients (although the extent of that duty in emergencies and social situations is uncertain and contested in relation to civil law). Whether a doctor has discharged his or her professional duty adequately is determined by expert opinion about the standards that might reasonably be expected and his or her conduct in relation to those standards. If doctors have acted in a way that is consistent with a reasonable body of their peers and their actions or omissions withstand logical analysis, they are likely to meet the expected standards of care. Lack of experience is not taken into account in legal determinations of negligence.

The most common reason for a negligence action to fail is causation, which is notoriously difficult to prove in clinical negligence claims. For example, the alleged harm may have occurred against the background of a complex medical condition or course of treatment, making it difficult to establish the actual cause.

Clinical negligence remains relatively rare and undue fear of litigation can lead to defensive and poor practice. All doctors make errors and these do not necessarily constitute negligence or indicate incompetence. Inherent in the definition of incompetence is time, i.e. on-going review of a doctor's practice to see whether there are patterns of error or repeated failure to learn from error. Regulatory bodies and medical defence organizations recommend that doctors should be honest and apologetic about their mistakes, remembering that to do so is not necessarily an admission of negligence (see p. 14). Such honesty and humility, aside from its inherent moral value, have been shown to reduce the prospect of patient complaints or litigation.

Professional bodies

Professional bodies have diverse but often overlapping roles in developing, defining and revising standards for doctors. The principal publications in which the GMC sets out standards
and obligations relating to competence and performance, are *Duties of a Doctor* and *Good Medical Practice*.

**Policy**

There have been an exponential number of policy reforms that have shaped the ways in which the medical competence and accountability agendas have evolved. One of the most notable is the increase in the number of organizations concerned broadly with ‘quality’ and performance. The increased scrutiny of doctors’ competence has found further policy translation in the development of appraisal schemes and the revalidation process. There have been other policy initiatives that adopt the rhetoric of ‘quality’, such as increased use of clinical and administrative targets, private finance initiatives, and the development of specialist screening facilities and treatment centres.

The issue of professional accountability in medicine is a hot topic. The law, professional guidance and policy documentation provide a starting point for clinicians. Complaints and possible litigation are often brought by patients who feel aggrieved for reasons that may be unconnected with the clinical care that they have received. When patients are asked about their decisions to complain or to sue doctors, it is common for poor communication, insensitivity, administrative errors and lack of responsiveness to be cited as motivation (see p. 14). There is less to fear than doctors sometimes believe. The courts and professional bodies are concerned neither with best practice, nor with unfeasibly high standards of care. What is expected is that doctors behave in a way that accords with the practice of a reasonable doctor – and the reasonable doctor is not perfect. As long as clinicians adhere to some basic principles, it is possible to practise *defensible* rather than *defensive* medicine. It should be reassuring that complaints and litigation are avoidable, simply by developing and maintaining good standards of communication, organization and administration – and good habits begin in medical school. In particular, effective communication is a potent weapon in preventing complaints and, ultimately, encounters with the legal and regulatory systems.

**Communication**

**Communication in Healthcare**

Good communication in healthcare is fundamental to achieving optimal patient care, safety and health outcomes. The aim of every healthcare professional is to provide evidence-based,
ethically sound and patient-centred care. This depends on a consulting style that fosters trust and demonstrates flexibility, openness, partnership, and collaboration with the patient.

Doctors work in multiprofessional teams and modern healthcare is more effective, more complex and more hazardous. Successful team communication is therefore vital.

**What is patient-centred communication?**

Patient-centred communication involves reaching a common ground about the illness, its treatment, and the roles that the clinician and the patient will assume *(Fig. 1.1)*. A good history is the key to diagnosis. Both the biomedical facts of the patient's illness and the patient's ideas, concerns, expectations and feelings are needed in order to discover what is the matter with the patient and what matters to the patient. This information is essential for accurate diagnosis and for gaining the patient's confidence, trust and involvement in appropriate management.

![Patient-centred clinical interview](Image)

The historical approach of ‘doctor knows best’ with patients' views not being considered is very outdated; this is not just societal but is driven by evidence about improved health outcome.

- Patients increasingly expect information and want their views taken into account in deciding treatment. This does not mean clinicians totally abdicate power. Patients want their doctors' expert opinions and may still prefer to leave matters to the clinician.
- Many health problems are long-term conditions and patients have to become expert to manage their conditions and reduce risks from lifestyle habits in a partnership approach to care.
- Patients expect humanity and empathy from their doctors, as well as competence. Clinicians can usually offer practical help with patients' concerns and expectations but, if not, they can always listen supportively.

Patient-centred communication requires a good balance between:
- clinicians asking all the questions needed to include or exclude diagnoses
- patients being asked to express their thoughts, ideas, concerns and expectations
• clinicians explaining and advising in ways patients can understand so that they can be involved in decisions about their care.

What are the effects of communication?

Enormous benefits accrue from good communication (Box 1.6). Patients' problems are identified more accurately and efficiently, expectations for care are agreed, and patients and clinicians experience greater satisfaction. Poor communication results in missed problems and concerns, strained relationships, complaints and litigation.

Box 1.6

Benefits of good communication

• Diagnostic accuracy
• Physical health outcomes (blood pressure, diabetes, asthma, pain)
• Emotional health and functioning
• Patient adherence
• Patient and clinician satisfaction
• Improved time management and costs
• Patient safety
• Reduced litigation

Diagnostic accuracy

Clinicians commonly interrupt patients after an average of 24 seconds, whether or not a patient has finished explaining the problem. A golden rule involves listening for 1 minute before interrupting. Clinicians are failing if a serious point is raised only as the patient is preparing to leave. One study found that, in 50% of visits, patients and doctors disagreed on the main presenting problem.

Health outcomes

Physical, emotional and functional health is improved by good communication. Conversely, the main predictive factor for patients developing depression on learning of the diagnosis of cancer is the way bad news is broken.

Adherence to treatment

Some 45% of patients are not following treatment advice properly. There is a 19% higher risk of non-adherence where physicians communicate poorly. Errors in use of medications are costly and risk patient safety. Patients may not understand or remember what they were told, while others actively decide not to follow advice and commonly do not tell their doctors. Research shows that clinicians rarely check patients' understanding or views, yet these affect
adherence (Box 1.7).

Box 1.7
Factors that improve adherence to clinical advice

Clinician
- Listens to and understands the patient
- Uses an appropriate tone of voice
- Elicits all of the patient's health concerns

Patient
- Is comfortable asking questions
- Feels sufficient time is spent with the clinician

Patient satisfaction and dissatisfaction
Satisfaction is largely a result of patients knowing they are:
- getting the best medical care
- being treated humanely as individuals and not as items on a conveyor belt.

Satisfaction affects psychological wellbeing and adherence to treatment, both of which have a knock-on effect on clinical outcomes. It also reduces patient complaints and litigation (Box 1.8). Some 70% of lawsuits are a result of poor communication rather than failures of biomedical practice.

Box 1.8
Behaviours influencing litigation

Patients are less likely to sue when clinicians:
- Orientate patients, e.g. ‘We are going to do this first and then go on to that’
- Use facilitative comments, e.g. ‘Uh huh, I see’
- Use active listening
- Check understanding
- Ask patients their opinions
- Use humour and laughter appropriately
- Conduct slightly longer visits (18 versus 15 min)
Clinician satisfaction
Healthcare professionals have a very high rate of occupational stress and burnout, which is costly both to them and to health services. Notwithstanding pressure from staffing shortages and inadequate resources, it is the quality of relationships with patients and colleagues that affects clinician satisfaction and happiness.

Improved time management and costs
Integrating patient-centred communication into all interviews actually saves time and reduces non-essential investigations and referrals, which waste resources. Hospital visits, admissions, length of stay and mortality rate are reduced where clinicians used a biopsychosocial approach to managing people with medically unexplained symptoms (25–50% of primary care visits are for medically inexplicable complaints). Patients given the latest evidence on treatment options commonly choose more conservative management with no adverse effects on health outcomes. This has potential for considerable savings in health budgets.

Barriers and difficulties in communication
Communication is not straightforward (Box 1.9). Time constraints can prevent both doctors and patients from feeling that they have each other's attention and that they fully understand the problem from each other's perspective. Under-estimation of the influence of psychosocial issues on illness and their costs to healthcare means clinicians may resort to avoidance strategies when they fear the discussion will unleash emotions that are too difficult to handle, upset the patient or take too much time (Box 1.10).

Box 1.9
Common barriers and difficulties in communication

Clinician factors
• Lack of knowledge of:
  – Role of psychosocial issues
  – Skills of communication
• Attitude:
  – Authoritarian manner and negative attitude to shared care
  – Unwillingness to examine own communication skills
• Skills:
  – Distancing to avoid difficult topics
  – Use of jargon
  – Lack of empathy
Shared factors

- Different first language
- Lack of privacy
- Lack of time
- Different cultural backgrounds
- Computers

Patient factors

- Anxiety
- Feeling powerless
- Reticence to disclose concerns
- Misconceptions
- Low health literacy
- Forgetfulness
- Hearing/visual and speech impairment

Box 1.10

Strategies that doctors use to distance themselves from patients' worries

Patient says: ‘I have this headache and I'm worried …’

- Selective attention to cues: ‘What is the pain like?’
- Normalizing: ‘It’s normal to worry. Where is the pain?’
- Premature reassurance: ‘Don’t worry. I'm sure you'll be fine'
- False reassurance: ‘Everything is OK’
- Switching topic: ‘Forget that. Tell me about …’
- Passing the buck: ‘Nurse will tell you about that’
- Jollying along: ‘Come on now, look on the bright side’
- Physical avoidance: Passing the bedside without stopping

(From Maguire P. Communication Skills for Doctors. London: Arnold; 2000, with permission.)

Patients, for their part, will not disclose concerns if they are anxious and embarrassed, or sense that the clinician is not interested or thinks that their complaints are trivial. Many patients have poor knowledge of how their body works and struggle to understand new information provided by doctors. Some concepts may be too unfamiliar to make sense of, even if described simply, and patients may be too embarrassed to say they do not understand. For example, when
explaining fasting blood sugar levels to newly diagnosed diabetics it was found that many did not realize that there is sugar in their blood.

Clinicians are human and are often rushed and stressed. They work against the clock and in fallible systems. However, as professionals, it is they, together with healthcare managers, who bear the responsibility for dealing with these difficulties and problems, not the patient.

**The Medical Interview**

**Structure and skills for effective interviewing**

Clinicians conduct some 200,000 medical interviews during their careers. Flexibility is key because each patient is different and a framework helps clinicians use time productively. The example below applies to a first consultation and may vary slightly in a follow-up appointment or emergency visit.

There are seven essential steps in the medical interview.

**1. Building a relationship**

Because patients are frequently anxious and may feel unwell, introductions and first impressions are critical to create rapport and trust. Without this, effective communication is impossible. Well-organized arrangements for appointments, reception and punctuality put patients at ease. Clinicians' non-verbal messages, body language, voice tone and unspoken attitudes have a huge impact on the emotional atmosphere of the interview. Seating arrangements, eye contact, facial expression and tone of voice should all convey friendliness, interest and respect.

**2. Opening the discussion**

The aim is to obtain all the patients' concerns, remembering that they commonly have at least three. Ask ‘What problems have brought you to see me today?’

Listen attentively without interrupting. Ask ‘And is there something else?’ to screen for other problems before exploring the history in detail.

Only when all concerns are identified can the agenda be prioritized, balancing the patients' main concerns with the clinician's medical priorities.

**3. Gathering information**

The components of a complete history are shown in *Box 1.11*. 
Components of a medical interview

- Nature of the key problems
- Date and time of onset
- Development over time
- Precipitating factors
- Help given to date
- Impact of the problem on the patient's life
- Availability of support
- Patient's ideas, concerns and expectations (ICE)
- Screening question

Listening skills

Attentive listening is essential. Ask patients to tell the story of the problem in their own words from when it first started up to the present. Patients will recognize that clinicians are listening if the clinicians look at them and not the notes or computer. Occasional nods encourage the patient to continue. Avoid interrupting before the patient has finished talking.

Questioning styles

The way a clinician asks questions determines whether the patient speaks freely or just gives one-word or brief answers (Box 1.12). Start with open questions (‘What problems have brought you in today?’) and move to screening (‘Is there anything else?’), focused (‘Can you tell me more about the pain?’) and closed questions (‘Where is the pain?’). Open methods allow clinicians to listen and to generate their problem-solving approach. Closed questions are necessary to check specific symptoms, but if used too early, they may lead to inaccuracies by missing patients' problems.

Box 1.12

Questioning style

Closed questioning style

Dr: ‘You say chest pain. Where is the pain?’ (closed Q)
Pt: ‘Just here.’ (pointing to sternum)
Dr: ‘And is it a sharp or dull pain?’ (closed Q)
Pt: ‘Quite sharp.’
Dr: ‘Does it go anywhere else?’ (closed Q)
Pt: ‘No, just there.’
Dr: ‘And you don’t smoke now, do you?’ (leading Q)
Pt: ‘Well … just the occasional one.’

**Open questioning style**

Dr: ‘Can you tell me about the pain you’ve been having?’ (open/focused Q)
Pt: ‘Well, it’s been getting worse over the past few weeks and waking me up at night. It’s just here (points to sternum), very sharp and I get a burning and bad acid taste in the back of my throat. I try to burp to clear it. I’ve taken antacids, which help a little, but I’m a bit worried about it. I’m losing sleep and I’ve got a busy workload, so that’s a worry too.’
Dr: ‘I see. So it’s bothering you quite a lot. Anything else you’ve noticed?’ (empathic statement, open screening Q)
Pt: ‘I get it more after I’ve had a few drinks. I have been drinking and smoking a bit more recently. Actually, I’ve been getting lots of headaches too, which I’ve just taken ibuprofen for.’
Dr: ‘You say you’re worried. Is there anything in particular that concerns you?’ (picks up on patient's cue and uses reflecting Q)
Pt: ‘I wondered if it might be an ulcer.’
Dr: ‘I see. So this sharp pain under your breastbone, with some acid reflux for several weeks, is worse at night and aggravated by drinking and smoking but not relieved by antacids. You’re busy at work, getting headaches, drinking and smoking a bit more and not sleeping well. You’re concerned this could be an ulcer.’ (summarizing)
Pt: ‘Yes, a friend had problems like this.’
Dr: ‘I can appreciate why you might be thinking that, then.’ (validation)
Pt: ‘Yes, and he had to have a “scope” so I wondered whether I would need one?’ (expectation)
Dr: ‘Well, let me explain first what I think this might be and then what I would recommend next … ’ (signposting)

Leading questions that imply the expected answer (‘You’ve given up drinking, haven't you?’) risk inaccurate responses, as patients may just say yes rather than disagree.

**4. Understanding the patient**

Finding out the patient's thoughts is an essential step towards holistic care and achieving common ground.

**Ideas, concerns and expectations (ICE)**

Patients seek help because of their own ideas or concerns about their condition. If these are not heard, they may think the clinician has not got things right and then not follow the advice. Moreover, any misconceptions will go uncorrected. A patient's views can emerge if the clinician listens carefully and picks up on cues. If these views are not forthcoming, it is
necessary to ask specific questions, for example:
- ‘What were you worried this might be?’
- ‘Are there any particular concerns you have about …?’
- ‘Was there anything you were hoping we might do about this?’

The example in Box 1.12 shows how, if the clinician listens, information that may be biomedically relevant emerges and the patient's views are revealed.

**Non-verbal communication**

In adult conversation, some 5% of meaning derives from words, 35% from tone of voice and 60% from body language and non-verbal communication. When there is a mismatch between words and tone, the non-verbal communication elements hold the truer meaning. Patients who are anxious, uneasy, puzzled or confused are more likely to communicate this through expression and/or restless activity – for example, of the feet and hands – than to tell the clinician outright. The observant clinician can pick up on this: ‘You seem uneasy about what I have said …’, thus inviting the patient to share their concerns. Doctors' non-verbal behaviour is also important. Voice tone, if harsh or uncaring, can even increase the risk of being sued.

**Empathizing**

Empathy has been described as ‘imagination for others’. It is different from sympathy (feeling sorry for the patient), which rarely helps. Empathy is a key skill in building the patient–clinician relationship and is highly therapeutic. The starting point is attentive listening and observing patients to try to understand their predicament. This understanding then needs to be conveyed back in a supportive way. Whilst empathy is about trying to understand, the phrase ‘I understand’ may be met with ‘how could you?’ It is usually more helpful to reflect back using some of the patient's own words and ideas. For example: ‘It sounds like …’ (patient heard); ‘I can see you are upset’ (patient seen); ‘I realize that this is a shock’ (acknowledgement); ‘Most people in your circumstances would feel angry’ (accepting the patient).

Empathy can be developed with practice but it has to be genuine and cannot be counterfeited by a repertoire of routine mannerisms.

**5. Sharing information**

Tailoring information to what patients want to know and the level of detail they prefer helps understanding. Most patients, irrespective of socioeconomic group, want to know ‘is this problem serious and how will it affect me; what can be done about it; and what is causing it?’ Research shows they cannot take in explanations about cause if they are still worrying about the first two concerns.

- Information must be not only related to the biomedical facts, but also tailored to patients' ideas and concerns.
- With adaptations for age, 70–80% of even the most unfamiliar, complex or alarming information can be understood and recalled if explained well (Box 1.13).
Giving information: the 3E model: explore, explain, explore

Explore

• **Ask**. Ask what the patient already knows or thinks is wrong. This allows you to confirm, correct or add new information.

Explain

• **Chunk and check**. Give information in chunks that are easy to assimilate, one thing at a time. Check after each chunk that the patient is understanding.

• **Signpost**. ‘I’ll explain first of all …’; ‘Can I move on now to explain treatment options …?’

• **Link**. Explain the cause and effect of the condition in the context of the patient's symptoms, e.g. ‘The reason you are experiencing … is because …’

• **Plain language**. Use clear, concise language; ‘translate’ any unavoidable medical terms and write them down.

• **Aid recall**. Make use of simple diagrams and leaflets; recommend websites and support organizations.

Explore

• **Teach back**. Use the universal precaution of always asking patients to recap to check you have explained it clearly enough.

6. Reaching agreement on management

Once the situation is understood, the clinician and patient need to agree on the best course for possible investigations and treatments.

**Negotiating – enlisting the patient's collaboration**

The clinician's opinion should be given and the patient's views sought. Check whether the patient wants to be involved or to leave decisions to the clinician. Partnership requires:

• a frank exchange of information

• the negotiation of options

• active involvement in decisions.

**Summarizing**

This allows information to be added and misunderstandings corrected. Summarizing is a feature of shared decision-making.
7. Providing closure

A final summary and an outline of next steps indicate the closing stage of the interview. Plans are confirmed for follow-up and for informing other healthcare professionals involved in the patient's care.

Some clinicians close the interview by asking whether the consultation has been useful, before saying goodbye.

Clinical records

All medical interviews should be well documented. Good records are the responsibility of everyone in the healthcare team (Box 1.14), as is maintenance of confidentiality. They are vital in providing best care, reducing error and ensuring patient safety.

Box 1.14

Essentials of record-keeping

What records should include

- Relevant clinical and psychosocial information – history and examination
- Relevant findings, both positive and negative
- Diagnosis, including uncertainties
- Investigations arranged
- Test results
- Correspondence, including e-mails and text messages
- Decisions made
- Information given to patients
- Consent
- Drugs or other treatments prescribed
- Follow-up and referrals

Criteria for good records

- Clear, accurate, legible and contemporaneous
- Dated and signed with printed name
- Written in pen (if not electronic)
- Written first hand
- Original – never altered (using a signed, dated additional note alongside any mistake)
- Kept secure
In many countries, patients have the right to see their records, which provide essential information when a complaint or claim for negligence is made. They are also valuable as part of audit to improve standards of healthcare.

Electronic patient records are increasingly replacing written ones. They include more information, overcome problems of legibility and reduce prescription error by 66% compared to handwritten ones. With adequate data protection, they offer immense potential for unifying record systems and allowing access across the healthcare team in primary, secondary and tertiary care sectors. Increasingly, patients will have access and even be contributors to their records.

The computer can, however, act as a considerable barrier to communication and guidelines exist for best practice when using one (Box 1.15).

**Further reading**

---

**Box 1.15**

‘ATTEND’: a mnemonic for patient–physician communication using the electronic medical record

**Acquaint yourself with the medical record**

- Acquaint yourself with the patient's record beforehand, allowing for less review ‘screen time’ while in the patient's presence

**Take a minute**

- Start the visit technology-free, giving the patient and his/her concerns your full attention

**Triangulate placement of computer, patient, clinician**

- Arrange the room so that it allows you to look at both the screen and the patient, and the patient to look at you and the screen
Engage, explain, educate

• Engage the patient in your use of the computer as a tool during the visit
• Explain what you are doing in both entering data and looking for information on the computer (signposting)
• Educate the patient by letting him/her see what you are seeing on the screen, especially graphs, images

No more screen

• When discussing sensitive issues, completely disengage from the screen (look at the patient, turn away from the screen, take your hands off the keys)

Describe the discharge/Don’t forget to log out

• Be explicit about what orders you are entering in the computer at the end of the visit and what the patient should expect (e.g. scheduling, tests)

(Rosenbaum M, Jansen KL, Shen W, Skelly K, Wilbur J. University of Iowa Carver College of Medicine, 2014. Personal communication.)

Team Communication

Modern healthcare is complex and patients are looked after by multiple healthcare professionals working in shifts. Effective team communication is absolutely essential and this is never more vital than when people are busy or a patient is critically ill. Contexts for team communication include ward handovers, requests for help, acceptance of referrals and communication in the operating theatre. Prior to an operation, all clinical staff take a ‘time out’ and go through a final checklist. This consists of staff introductions, check of the patients’ details, site and side of surgery, and a rundown of the drugs being used. Lessons from industries such as aviation show how to reduce errors caused by poor communication.

Problems arise when information is not transmitted, is misunderstood or is not recorded. Communication styles vary. Some people are indirect and more elaborate in their speech, whilst others come straight to the point, leaving out detail and their own rationale. Each type can feel irritated, offended or puzzled by the other and most complaints in teams relate to communication. Handover between teams is helped when everyone adopts a clear system.

Frameworks such as **SBAR** (**Situation–Background–Assessment–Recommendation**) use standardized prompt questions in four sections to ensure team members share concise and focused information at the correct level of detail (*Box 1.16*). This increases patient safety.

**Box 1.16**

**SBAR: a structure for team communication**
S – Situation
• My name is …
• I am the junior doctor on ward …
• I am calling about Mr …, under consultant …
• The reason I am calling is …

B – Background
• The patient was admitted on … for …
• The significant medical history …
• Brief summary: medications, laboratory results, diagnostic tests, procedures

A – Assessment
• Summarize relevant information gathered on examination of the patient, charts and results
• Vital signs: heart rate, respiratory rate, oxygen saturation, blood pressure, temperature; assessment of alertness, voice, pain, unresponsiveness (AVPU)
• Early warning or similar score
• What has changed
• Interpretation of this

R – Recommendation (examples)
• I think the patient may need …
• I need your advice on how to proceed …
• I think the patient needs urgent review in the next (timeframe) …

Hierarchies make it harder for people to speak up. This can be dangerous if, for example, a nurse or junior doctor feels unable to point out an error, offer information or ask a question. Hinting and hoping is not good communication. Team leaders who ‘flatten’ the hierarchy by knowing and using people’s names, routinely have briefings and debriefings, do not let their own self-image override doing the right thing, and positively encourage colleagues to speak up, reduce the number of adverse events. Teamwork requires collaboration, open sharing of ideas and a readiness to discuss weaknesses and errors.

Communication on discharge is just as essential and primary care physicians need sufficient information, including details of medication, to continue care safely.

Breaking Bad News

Bad news is any information that is likely to alter a patient's view of the future drastically. The way news is broken has an immediate and long-term effect. When it is skilfully performed, the patient and family are enabled to understand, cope and make the best of even very bad circumstances. These interviews are difficult because biomedical measures may be of little or no help, and patients are upset and can react unpredictably. The clinician may also feel upset, more so if there is an element of medical mishap. The two most difficult things that clinicians report are how to be honest with the patient whilst not destroying hope, and how to deal with the patient's emotions.

Withholding information from patients or telling only the family is a thing of the past and becoming so even in parts of the world where traditionally disclosure did not occur. Although truth can hurt, deceit hurts more. It erodes trust and deprives patients of the information they need to make choices. Most people now express the wish to be told the truth and the evidence is that patients:

• usually know more than anyone realizes and may imagine things worse than they are
• appreciate clear information about even the worst news and want the opportunity to talk openly and ask questions, rather than join in a charade of deception
• differ in how much they can take in at a time.

Having a framework helps clinicians to present bad news in a factual, unhurried, balanced and empathic fashion whilst responding to each patient. Prepare the key points you want the patient to understand about the diagnosis, implications and prognosis, what can be done and the next steps.

S – Setting

• See the patient as soon as the current information has been gathered.
• Ask not to be disturbed and hand bleeps to colleagues.
• If possible, patients should have someone with them.
• Choose a quiet place; seat and introduce everyone.
• Indicate your status, the extent of your responsibility towards the patient and the time available.

P – Perception

Ask before telling. Find out what has happened since the last appointment and what has been
explained or construed so far. This stage helps gauge the patient's perception but should not be too drawn out.

I – Invitation
• Indicate you have the results and ask if the patient wants you to explain.
• Assess how much the patient would like to know.
• If patients do not want details, offer to answer any questions they may have later or to talk to a relative or friend.

K – Knowledge
If the patient wishes to know:
• Give a warning to help the patient prepare: ‘I'm afraid it looks more serious than we hoped.'
• Then give the details.
• At this point, WAIT: allow the patient to think, and only continue when the patient gives some lead to follow. This pause may be long – commonly, a matter of minutes – but it helps patients take in the situation. They may shut down and be unable to hear anything further until their thoughts settle down.
• Give direct information, in small chunks. Avoid technical terms. Check understanding frequently – ‘Is this making sense so far?’ – before moving on. Watch for signs the patient can take no more.
• Invite questions.
• Emphasize which things – for example, pain and other symptoms – are fixable and which others are not.
• Be prepared for the question: ‘How long have I got?’ Avoid providing a figure to an individual, which is bound to be inaccurate. Common faults are to be overly optimistic. Some patients wish to know survival rates for their condition. Tell them as much as is appropriate. Stress the importance of ensuring that their quality of life is made as good as possible from day to day.
• Provide some positive information and hope, tempered with realism.

E – Empathy
Responding to the patient's emotions is about the human side of medical care and also helps patients to take in and adjust to difficult information. A range of emotions are experienced in seriously and terminally ill patients (Box 1.17).
• Be prepared for the patient to have disorderly emotional responses of some kind. Acknowledge them and wait for them to settle before continuing.
• Crying can be a release for some patients. Allow time rather than rushing in to stop the crying.
• Learn to judge which patients wish to be touched and which do not. You can always reach out
and touch their chair.

- Keep pausing to allow patients to think and frame their questions.
- Watch for shutdown; stop the interview if necessary and arrange to resume later.

**S – Strategy and summary**

Patients who have a clear plan for the next and future steps are likely to feel less anxious and uncertain. The clinician must ensure that:

- the patient has understood what has been discussed because, at times of emotion, misconceptions can take root

- crucial information is written down to take away

- the patient knows how to contact the appropriate team member and thus has a safety net in place, and when the next appointment is (preferably soon), who it is with and its purpose

- family members are invited to meet clinicians as the patient wishes and further sources of information are provided

- everyone is bid goodbye, starting with the patient.

**Follow-up**

Bad news is a process and not a one-off. Patients may well not remember everything from the last visit and recapping is necessary. Always start by asking what they have understood so far. It is extremely distressing for patients to hear conflicting things from different clinicians. Keep colleagues informed and document accurately what was said to a patient and what the patient's wishes are.

The move from active treatment to palliative care is particularly difficult. Patients will want to know what happens next: for example, ‘Will I be in pain?’ ‘Can I stay at home?’ and ‘How long do I have?’ Give clear answers with acknowledgement of any uncertainty. The priorities in patient care now are relief of symptoms, quality of life and enabling the patient to settle family matters or unfinished business.

The clinician's role is to mediate between the patient, other medical staff and the patient's
relatives whilst continuing to be an empathic and caring doctor.

---

**When Things Go Wrong**

When things go wrong, as inevitably they do at some time, even in the best of medical care, it is distressing for all concerned. Doctors need to communicate honestly and clearly to minimize distress and act immediately to put matters right, if that is possible. The consultation that occurs after an adverse experience is crucial in influencing any decision to sue.

Being open is recognized as good practice internationally. Doctors should offer an apology and explain fully and promptly what has happened, and the likely short-term and long-term effects of any harm. Reluctance to say ‘sorry’ comes from a fear that it is an admission of fault, which later implies liability, but guidelines from official bodies emphasize that this is not so. As well as being morally right, an honest approach decreases the trauma felt by patients and relatives following an adverse event and is more likely to lead to forgiveness. Examples of an open approach in the USA, Australia and Singapore have actually reduced the costs of complaints.

Having a clear framework also helps to reduce clinicians' stress and develop their professional reputation for handling difficult situations properly.

**Complaints**

Much of the enormous increase in complaints and medical lawsuits is related to failures in communication. Whilst avoidance and defensiveness are common human responses, professionals must deal with dissatisfaction and complaints as soon as they happen, to save problems escalating and becoming major traumas for all concerned.

The majority of complaints come from the exasperation of patients who:

- feel deserted and devalued by their clinician
- have not been able to obtain clear information
- feel that they are owed an apology
- are concerned that other patients will go through what they have.
Many complaints are resolved satisfactorily once these points are dealt with promptly and appropriately \((\text{Box 1.18})\).

\textbf{Box 1.18}

\textbf{Responding to complaints}

- Remember the complainant is still a patient, to whom there is a duty of care
- Listen and express regret for distress
- Acknowledge when things have gone wrong – be objective, not resentful or defensive
- Apologize for actual or perceived shortcomings
- Provide easily understood information or explanations
- Offer appropriate redress
- Explain how things will improve
- Leave medical records strictly unaltered

These interactions are very difficult for everyone and training is recommended to help all healthcare professionals. Clinicians should work in a professional culture that regards complaints as a valuable source of feedback, which deserves to be noted, collected and used constructively to improve services.

\textbf{Lawsuits}

Lawsuits, the extreme form of complaint, are commonly rooted in poor communication or miscommunication, aggravated by a sense of grievance. Clinicians with authoritarian paternalistic styles are more likely to be sued. Some 17% of patients affected by medical injury in the UK want financial compensation or disciplinary action. Any clinician faced with a lawsuit must seek specialist advice.

\textbf{Culture and Communication}

Whilst doctors strive to treat all patients equally, those from minority cultures receive poorer healthcare irrespective of socioeconomic status and even when they speak the same language as the clinician. They experience fewer expressions of empathy, shorter consultations and less inclusion in shared decision-making. They also tend to say less in consultations.

Clinicians commonly express anxiety and uncertainty about how to respond to cultural diversity, how to use advocates (interpreters) and how to avoid causing offence.

\textbf{Beliefs}

We all take our culture for granted but it can profoundly affect ideas about symptoms, causes of illness, and appropriate behaviour and treatment.
Beliefs influence when a patient seeks medical assistance, what patients and doctors expect of the consultation, and how they communicate. In some cultures, for example, it is very difficult for a woman to see a male doctor. Sometimes, family members may think it is their duty to talk for the patient whilst the doctor will expect to talk directly with the patient. Sensitive topics may be more difficult but avoidance could jeopardize care. It helps to apologize if offence is inadvertently caused and explain why such questions are required. Clinicians vary too. Those from traditional cultures may have a more paternalistic style than some patients want.

Language

Patients sometimes bring a family member or friend to interpret. The latter may not understand medical questions and may be censoring sensitive matters or expressing their own views rather than the patient's. Confidentiality cannot be guaranteed and patients may feel restricted in what they can say. On the other hand, patients may want a trusted family member to translate. Children should not be used to interpret.

Ideally, a trained interpreter should be used. Ask for the correct pronunciation of a patient's name and about any cultural differences in body language. Arrange seating to see both the patient and the advocate but always look and speak directly to the patient. Speak in short phrases, avoid jargon and find out the patient's ideas, concerns and expectations. Watch for non-verbal communication and check that the patient understands.

Clinicians sometimes worry that interpreters are editing, when long exchanges are followed by only a short summary back to them. It helps to ask interpreters to translate exactly what has been said. The interpreter can stand outside the curtain during examination. Always thank the interpreter at the end. If professional interpreters are not available, use telephone language lines. Advocates are people from the patient's culture who not only translate but also can explain beliefs and concerns that are relevant in the patient's culture. They also help patients to understand the workings of the healthcare system.

Non-verbal communication

Awareness of cultural taboos – for example, handshaking, eye contact, personal space and sensitive subjects – can help in maintaining dignity and respect.

Paraverbal communication varies across cultures. We infer things from tone of voice, stress on words and phrases, silence, pace, and politeness conventions that are used. Some cultures are more open, direct and assertive than others. Some languages do not differentiate gender in common nouns and pronouns, so ‘he’ and ‘she’ may be used interchangeably. It is hardly surprising that misunderstandings occur and it can be much harder to create a rapport. It is worth remembering that smiling is a universal expression of kindness and warmth.

Patients may be more or less traditional, so check out assumptions.

Patients WHO Have Impaired Faculties for
Communication

All healthcare professionals need patience, ingenuity and willingness to learn to be able to communicate effectively with patients who have impaired communication faculties.

Impaired hearing

Some 55% of people over 60 are deaf or hard of hearing. Patients may be accompanied by a signer but less than 1% of hearing-impaired people sign. Many hard of hearing people lip-read and some common-sense tips are listed in **Box 1.19**. Clinicians who mumble, speak fast or have strong accents have a responsibility to make particular efforts to be understood.

**Box 1.19**

**Communicating with people who are deaf or hard of hearing**

- Ask if they need to lip-read when you are speaking
- Position yourself on the better hearing side
- Smile and use eye contact
- Face the light
- Do not cover your face or mouth
- Use plain language
- Speak clearly but not too slowly
- Do not shout
- If stuck, write it down
- Check for understanding
- Never say ‘Forget it’!

(RNID: [http://www.rnid.org.uk/information_resources/factsheets](http://www.rnid.org.uk/information_resources/factsheets))

Conversation aids may be available or patients may be asked how best to communicate with them.

Impaired vision

Patients who have visual impairment can miss non-verbal cues in communication. It may sound obvious, but it helps to make more conscious efforts to use the patients' names so they know they are being spoken to. Clinicians should avoid sudden touch, explain what they are about to do, and say what they are doing as they go along. Large-print information sheets should be available, with audio recordings, Braille and Moon versions for blind people ([http://www.rnib.org.uk](http://www.rnib.org.uk)).
Patients WHO Have Limited Understanding or Speech

Aphasia is a communication disorder following strokes. Even though hearing and thought processes are unaffected, patients find it hard to understand, or they know what they want to say but cannot find the words; they are literally ‘lost for words’. This also affects their ability to write, gesture, draw or mime their thoughts.

Patients may have a strength in one area – for example, understanding – with a weakness in another other area – for example, expression – or vice versa.

It helps to find a quiet place without distractions, to make eye contact and attract the person's attention. Speak slowly and clearly, use simple phrases and leave plenty of time between sentences to allow for extra processing time. Make it obvious when changing the subject.

Closed questions requiring ‘yes’ or ‘no’ answers are easier. Write down key words or headings to which both the patient and the clinician can refer. This helps because the auditory memory needed to ‘hold on to’ the spoken word taxes the patient's language system. Use pictures and have pen and paper to hand if the patient can use them.

Much can be learnt from carers or watching speech and language therapists. Visit: http://www.ukconnect.org.

Influences on Communication

The internet

The internet has revolutionized ready access to information, and in 2010 some 65% of the UK population surfed the net with medical queries. Research on its impact on the doctor–patient relationship is emerging. People report feeling more able to ask informed questions and having less fear of the unknown. Most doctors support internet use in enhancing consultations and especially post diagnosis, when it helps patients understand and manage their illness.

Directing patients to trustworthy, reputable internet sites is helpful.
Decision aids

Weighing up treatment benefits and risks where both may be substantial but not guaranteed is very hard for patients. Decision aids that are evidence-based, are written in non-technical language and often include visual representations help people digest complex statistical information. They are reliable and from independent sources. Formats include web applications, DVDs, computer programs, leaflets and structured counselling. They are growing in number and are listed on the Cochrane register (see ‘Significant websites’).

Studies show these resources do not increase patients' anxiety and their use results in a 21–44% reduction in choice of invasive surgical options over more conservative treatments without adverse effects on health.

Training in Communication Skills

This chapter has covered principles and practical advice on communication in healthcare. There is clear evidence that communication ability is not just innate; it is a professional skill that can be improved and used in everyday practice. The need for clinicians to update their skills continually is recognized as working patterns in healthcare, societal expectations and technological advances change. However, skills cannot be learned entirely from books; the opportunity to practise and receive constructive feedback on performance is essential.

Reliable internet information for patients
Clinical pharmacology

Introduction

Prescribing is a key skill required by all doctors, at least at some stage in their careers. This chapter provides an introduction to the principles of rational therapeutics. The 1984 ‘Nairobi Declaration’ emphasized that prescribing should be to the right patient with the right drug at the right dose, and at an affordable cost. Thus, the prescription of a medicine needs to take into account the potential benefits and harms of that medicine, and ensure that every step is taken to maximize the benefit : harm ratio. The key principles of prescribing are described in
Box 2.1

Key principles of prescribing

• **Be clear about the reasons for prescribing.** Obtain an accurate diagnosis and have clear aims of what the benefits will be from prescribing the drug.

• **Obtain an accurate drug history.** Patients should be asked about their current medications, over-the-counter herbal medicines, and illicit drug usage. A past history of intolerances, including true allergic reactions, is also required.

• **Obtain an accurate history of other factors that might affect the benefit : harm ratio of drugs.** Take note of liver and renal impairment, age, whether patient is pregnant or breast-feeding, and co-morbidities.

• **Establish what the patient expects from the drug, and deal with any concerns.** Provide good information for the patient and answer any questions clearly.

• **Select the most clinically effective, cost-effective and safe medicine for the patient, based on an assessment of the individual.** Optimize the benefit : harm balance by choosing the right dose and frequency, and the right drug, in the the best formulation, route of administration and duration of treatment. Prescribe within the licence of the medicine, except when no alternative is available.

• **Adhere to guidelines and local and national formularies.** Based on the needs of the individual patient, use the most reliable information to identify the medicine most suited to the patient.

• **Write prescriptions legibly using the correct documents, or prescribe electronically, depending on availability.** Take care to avoid medication errors.

• **Monitor the patient for both efficacy and safety after starting the drug.** This is essential to optimize dose, identify adverse reactions, and determine when to stop the medicine. Report adverse reactions using spontaneous reporting schemes, if appropriate.

• **Communicate clearly with other healthcare professionals and patients about the reasons for prescribing decisions.** Communication is essential to optimize the benefit : harm ratio of drugs, particularly when there are multiple prescribers for a single patient.

• **Prescribe within your competencies.** Prescribing should be within the limits of your knowledge and experience. Do not be afraid to ask for advice, and ensure that complex prescriptions are checked (e.g. when calculating doses).

(Adapted from British Pharmacological Society; http://www.bps.ac.uk/SpringboardWebApp/userfiles/bps/file/Clinical/BPSPrescribingStatement03Feb2010.pdf.)
There are many reasons for prescribing drugs to patients. These are as follows:

**Disease treatment**
A reliable diagnosis is crucial before starting treatment, which may either cure or, more often, control a disease process. An accurate diagnosis ensures that a patient is not exposed, unnecessarily, to the hazards or costs of a particular intervention. However, a prior diagnosis may not be possible in every circumstance; for example, in infection, the initiation of ‘blind’ antimicrobial therapy is justified when delay would expose a patient to hazard or discomfort.

The choice of the drug often depends on clinical factors (such as age, concomitant disease and concurrent therapy), pharmaceutical factors (the availability of other medicines and relative cost-effectiveness) and, increasingly, individual (host) factors. For instance, trastuzumab is only of value in women with breast cancer whose malignant cells express the HER2 epidermal growth factor receptor. Tailoring or targeting treatment, dependent on the use of biomarkers (e.g. genetic polymorphisms or gene expression pattern), is increasingly being used. This promising approach has become known as ‘personalized medicine’.

**Symptom relief**
Drugs are frequently used in the relief of symptoms: for example, in the treatment of severe pain, constipation or pruritus. The issue here is to monitor the patient so that the effectiveness of symptom relief can be judged and, if it is inadequate, either the dose or drug can be altered. Ensure that the drug is stopped when no longer indicated. Doctors are good at starting drugs but very bad at stopping them!

**Prevention**
Medicines are also given to otherwise healthy individuals. In such circumstances, there must be a very clear imperative to ensure that the benefits to the individual outweigh the harm. Examples include:

- immunization against serious microbial infections (e.g. influenza vaccination)
- the reduction of individual risk factors to prevent later disease (e.g. the use of antihypertensive or lipid-lowering agents to reduce the chances of ischaemic heart disease and stroke)
- oral contraceptives in sexually active women wishing to avoid pregnancy.

**The Choice of Drug**
Selecting the right drug involves three elements:

- the drug's clinical efficacy for the proposed use
- the balance between the drug's efficacy and safety
- patient preference.

The most common approach to assessing a drug's efficacy is the randomized controlled trial
(RCT), although other approaches (see p. 28) can be informative. The demonstration of absolute efficacy (against placebo) may, itself, be insufficient. Where there is more than one treatment for the same indication, these should be compared with one another, taking account of the magnitude of their benefits, their individual adverse reaction profiles, and their costs. There are also ethical concerns to the use of placebos; these should only be used when there are no other effective treatments, when withholding drugs poses no serious risk of harm, and when there are methodological reasons (but where there is no risk of harm from withholding treatment).

Direct comparisons of one treatment versus another are particularly useful but are often unavailable. In such cases, indirect techniques can be used. For example, none of the novel oral anticoagulants (dabigatran, rivaroxaban, apixaban and edoxaban) has been tested against the others, but comparative effectiveness can be modelled using indirect comparison of the individual RCTs in which each drug was compared with warfarin.

Patients’ own preferences should be discussed to enable them to be equal partners in decision-making about whether, and how, they wish to be treated. Moreover, a full understanding of the reasons for considering treatment, the likely benefits and the possible adverse reactions has repeatedly been shown to improve ‘concordance’ with treatment regimens.

**Further reading**

**The Dose**

The dose administered to the patient is crucial in determining both efficacy and safety of medicines. Appropriate drug dosages will usually have been determined from the results of so-called ‘dose-ranging’ studies during the original development programme.

In some cases, drug doses are **fixed**, with all patients being given the same dose: for example, levonorgestrel for emergency contraception. However, these situations are unusual. For example, although the majority of patients are given 75 mg per day of aspirin, doses of up to 300 mg per day have been used for the secondary prevention of myocardial infarction.

More commonly, doses are **titrated**. For many drugs, there are wide inter-individual variations in response. As a consequence, whilst a particular dose may, in one person, lack any therapeutic effect, the same dose in another may cause serious toxicity. Prescribers should start at a low dose and titrate to the most effective dose, which should, in all cases, determine the lowest effective dose. This is necessary because of the inter-individual variability in the dose–response curve, whereby there is an increase in response with an increase in dose, until a
plateau effect is reached \textit{(Fig. 2.1)}. 

The reasons for this \textbf{variability in response} can be divided into two broad areas:

\begin{itemize}
  \item \textbf{Pharmacokinetic} factors, where the dose administered does not necessarily equate with systemic or tissue drug concentrations: that is, exposure. This may be due to differences in the rates of drug absorption, metabolism and/or excretion.
  \item \textbf{Pharmacodynamic} factors, where there are differences in the sensitivity of the drug target that generally fall into the categories of receptors, enzymes, ion channels, transporters, DNA or transcription factors.
\end{itemize}

\textbf{Pharmacokinetics}

Pharmacokinetics is the study of \textit{what the body does to a drug}. This can be divided into four different processes: absorption, distribution, metabolism and excretion.

\textbf{Absorption}

Drugs can be administered by various different routes \textit{(Box 2.2)} but oral administration is the most common. The main determinants of a drug's plasma concentration after oral administration are its bioavailability \textit{(Box 2.3)} and its rate of systemic clearance (by hepatic metabolism or renal excretion). A drug's oral bioavailability depends on the extent to which it is:

\begin{itemize}
  \item \textit{Destroyed in the gastrointestinal tract}, especially by gastric acid.
  \item \textit{Unable to cross the gastrointestinal epithelium}. Drugs can cross either by passive diffusion or by active uptake by transporters that are abundant in the gut epithelial barrier. Such transporters can be either influx transporters (pumping drugs from the gut lumen into the cell, such as the PEPT1 transporter for the absorption of penicillins) or efflux transporters
\end{itemize}
(pumping drugs from cells back into the gut lumen, such as the P-glycoprotein that can limit the absorption of many drugs).

• **Metabolized by the liver** before reaching the systemic circulation (so-called pre-systemic or ‘first-pass’ metabolism). First-pass metabolism can be avoided by the intravascular, intramuscular or sublingual routes.

### Box 2.2

**Routes of drug administration**

<table>
<thead>
<tr>
<th>Route</th>
<th>Description</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>Buccal</td>
<td>Rapid absorption, avoids first-pass metabolism</td>
<td>Midazolam for status epilepticus</td>
</tr>
<tr>
<td>Epidural</td>
<td>Used for analgesia</td>
<td>Epidural anaesthetic for pain relief during labour</td>
</tr>
<tr>
<td>Inhaled</td>
<td>Achieves high concentrations at site of disease with limited systemic absorption</td>
<td>Salbutamol for acute asthma relief</td>
</tr>
<tr>
<td>Intramuscular</td>
<td>Easier than intravenous route but absorption is less predictable</td>

GTN, glyceryl trinitrate; MRSA, meticillin-resistant *Staphylococcus aureus*

### Box 2.3

**Key pharmacokinetic parameters**

• **Area under the curve**: A plasma concentration time curve and a measure of the actual body exposure to a drug after administration of a dose of the drug; expressed in mg/L x h.

• **Bioavailability**: The fraction or proportion of a drug that enters the systemic circulation. Thus, while intravenous formulations have 100% bioavailability, administration via other routes will have <100% bioavailability.

• **Clearance**: Volume of plasma cleared of the drug per unit time.

• $C_{max}$: Peak plasma concentration after drug administration.
• **Concentration**: Amount of drug in a given volume. Even when the dose is similar, concentrations (and thus exposure) will vary between individuals.

• **Dose**: Amount of drug administered. This may be micrograms, milligrams or grams. Occasionally, drugs are administered per body weight or body surface area.

• **Elimination half-life**: The time required for the drug concentration to reach half its original value.

• **$T_{\text{max}}$**: Time to reach $C_{\text{max}}$.

• **$V_d$**: Volume of distribution – the apparent volume in which a drug is distributed. Drugs with low $V_d$ are predominantly in the circulation, while drugs with a high $V_d$ have diffused into the peripheral tissue compartment.

---

**Distribution**

This is the process by which drugs are distributed from the bloodstream to organs and cells. Most drugs will circulate in the bloodstream bound to plasma proteins, most commonly albumin. Free drug, which is the active drug, is usually in dynamic equilibrium with protein-bound drug, with the latter being released as the free drug concentration decreases.

**Metabolism**

Metabolism takes place in many different organs, the liver being the most common site. The function of metabolism is to convert lipid-soluble drugs to water-soluble drugs that can then be excreted by the kidneys. Metabolism usually inactivates a drug, but in some cases, it can convert a prodrug into an active drug (e.g. enalapril to enalaprilat), or lead to the formation of toxic metabolites (e.g. the formation of N-acetyl-para-benzoquinoneimine in paracetamol overdose). Drug metabolism occurs in two stages:

• **Phase I** is the modification of a drug, by oxidation, reduction or hydrolysis. Of these, oxidation is the most frequent route and is largely undertaken by a family of isoenzymes known as the cytochrome P450 system. Inhibition or induction of cytochrome P450 isoenzymes is a major cause of drug interactions (see p. 24).

• **Phase II** involves conjugation with glucuronate, sulphate, acetate or other substances to render the drug more water-soluble and therefore able to be excreted in the urine.

**Excretion**

Excretion of drugs and their metabolites occurs most commonly via the kidneys, although faeces, breath and sweat represent other routes of excretion. In the kidney, free drug is filtered through the glomerulus and excreted in the urine as long as it is water-soluble. Lipid-soluble drugs are usually reabsorbed in the renal tubules. Some drugs, such as benzylpenicillin, are actively excreted by cells in the proximal convoluted tubule. Renal impairment reduces the elimination of water-soluble drugs, and thus reduction of the maintenance dose must be undertaken to avoid toxicity.
Pharmacodynamics

Pharmacodynamics is the study of what the drug does to the body. Pharmacodynamic sources of variation in drug action can be due to changes in the expression of the drug target, their affinity or their selectivity. This can be caused by genetic factors (see p. 25) and also by disease. For example, in renal impairment, pharmacodynamic factors determine the sensitivity to a drug.

Pharmacodynamic tests can be used in clinical practice to target therapy or to avoid undue sensitivity. Examples include the following:

• Expression of oestrogen and HER2 receptors in women with breast cancer are used as markers of responsiveness to anti-oestrogens and trastuzumab (respectively).

• The V600E BRAF somatic gene mutation in patients with malignant melanoma is used to determine whether vemurafenib will be effective (see p. 25).

• Pseudocholinesterase (also known as butyrylcholinesterase) inactivates the neuromuscular blocking agent suxamethonium. Patients with mutations in the pseudocholinesterase gene can develop prolonged paralysis after the administration of suxamethonium.

Pharmacodynamic sources of variation in drug response have not been as well studied as pharmacokinetic factors. The prospect for ‘personalized prescribing’ will be enhanced when the interplay between pharmacokinetics and pharmacodynamics is better understood, which will then permit drug selection and dosing to become much more precise.

Affordability and Cost-Effectiveness

All healthcare systems try to provide their populations with the highest standards of care within the resources they have at their disposal. The money countries spend on healthcare, however, varies widely (Fig. 2.2). The differences between countries' expenditure on healthcare are almost entirely determined by their wealth, as reflected in per capita gross domestic product (GDP), with richer countries spending more on healthcare than poorer ones. Consequently, an intervention that might be affordable in the USA, Norway or Sweden is not necessarily affordable in China, India or Indonesia. Increasing use is therefore being made of formal analyses of costs and benefits, by both developed and, to a lesser extent, lower- to middle-income countries, to help decide on healthcare priorities.
There are a number of different approaches to the economic evaluation of healthcare interventions but the main one is known as ‘cost–utility analysis’. The main features are as follows:

• The costs are reflected in the price of the product, together with additional sums associated with its administration (including extra costs of any associated hospital care, and additional investigations, for the care of patients with adverse drug reactions). Any savings that may accrue from the use of an intervention are also included in the calculation.

• The benefits are assessed from the increase in quality of life (sometimes known as the gain in health utility) as a result of using an intervention, in comparison with alternative forms of treatment (which, in the absence of an active comparator, may be ‘best supportive care’). The utility gain is expressed on a scale of 0 (dead) to 1 (perfect health). This utility gain is then multiplied by the number of years for which it is ‘enjoyed’, to provide the quality-adjusted life years (QALY) gained.

• The incremental cost-effectiveness ratio (ICER) is estimated by dividing the total net costs (which includes any savings) by the QALY gained. In England, ICERs of an intervention costing less than £20 000 per QALY gained are likely to be regarded as cost-effective; as the ICER rises, so does the likelihood of the intervention being rejected for use in the National Health Service on grounds of cost-ineffectiveness.

The virtue of cost–utility analysis, in the evaluation of both new and established products, is that it allows comparisons to be made between differing treatments for differing conditions. Examples of the ICERs of some of the interventions examined by the National Institute for Health and Care Excellence (NICE) are shown in Box 2.4.

Prescribing in Special Populations

**Neonates, infants, children and adolescents**

The use of drugs in young people poses special problems. Extrapolating from adult dosage regimens, merely adjusting for weight, leads to excessive (and potentially toxic) doses because:

- the rates of hepatic metabolism and renal excretion of drugs are reduced in neonates and infants
- premature babies have approximately 1% of their body weight as fat (compared with 20% in adults), leading to a marked increase in plasma drug levels of fat-soluble drugs.

There are other difficulties in prescribing for children:

- Many treatments have never been subject to formal trials in either children or adolescents and their benefits and risks have not, therefore, been appropriately assessed in these age groups. In order to redress this, regulatory agencies, such as the European Medicines Agency, now require manufacturers to provide Paediatric Investigation Plans if a new drug is licensed for adults only.
- For many drugs, there are no paediatric preparations or formulations. Instead, adult products are used.
- Precise oral dosing is often impossible in babies, who spit out unpleasant-tasting products!
- Adverse effect profiles of medicines may be different in children compared with adults (e.g. Reye syndrome in children given aspirin, suicidal ideas in depressed adolescents treated with
selective serotonin reuptake inhibitors).

The elderly

The demography of our population is changing with the numbers of elderly people increasing. It is therefore essential to be aware of the potential issues that arise in prescribing for the elderly:

• Renal function declines with age at the rate of approximately 1 mL/min after the age of 40 years. Extrapolation of drug dosages, from those appropriate in younger adults, may therefore lead to toxic plasma levels in older patients.

• Changes in drug distribution due to changes in body composition, and the preferential distribution of the cardiac output to the brain, may also predispose to toxicity.

• Co-morbidity, often associated with polypharmacy, leads to increased opportunities for disease–drug and drug–drug interactions.

• Concordance with treatment regimens diminishes as the number of prescribed drugs increases, and is especially poor in the face of cognitive impairment.

• Exaggerated pharmacodynamic effects of drugs acting on the central nervous, cardiovascular and gastrointestinal systems are common.

Examples of common problems encountered in the use of drugs amongst older people are shown in Box 2.5.

**Pregnant women**

Clinicians should be extremely cautious about prescribing drugs to pregnant women and only essential treatments should be given. When a known teratogen is needed during pregnancy (e.g. an anticonvulsant drug or lithium), the potential adverse effects should be discussed with the parents, preferably before conception. Teratogens are best known for causing structural malformations: for example, congenital heart disease. However, teratogens can also lead to neurodevelopmental problems without any obvious structural damage. For example, exposure to sodium valproate *in utero* can lead to developmental neurotoxicity, which is manifested as cognitive and behavioural problems. Some known human teratogens are shown in *Box 2.6.*

### Box 2.6

| Misoprostol | Moebius syndrome (rare neurological condition) |
| Thalidomide (and possibly lenalidomide) | Phocomelia |

*Note:* All drugs should be avoided in pregnancy unless benefit clearly outweighs the risk.

**Breast-feeding women**

Although most drugs can be detected in breast milk, the quantity is generally small. This is because, for most drugs, the concentration in milk is in equilibrium with plasma water (i.e. the non-protein-bound fraction). A few drugs (e.g. aspirin, carbimazole, methotrexate) may, however, cause harm to the infant if ingested in breast milk. The relevant drug literature should be consulted when prescribing for nursing mothers.

**Monitoring Drug Therapy**

The combination of pharmacokinetic and pharmacodynamic causes of variability makes
monitoring of the effects of treatment essential. Three approaches are used.

**Pre-treatment dose selection**

In patients who have known, or suspected, impaired renal function, it is usually possible to predict dose requirements from their estimated glomerular filtration rate (eGFR), usually based on serum creatinine levels. If treatment needs to be started before the eGFR is available, in patients who have very advanced renal impairment or if renal function is fluctuating, then treatment can be started with conventional doses but the prescriber should be prepared to make dose adjustments within 24 hours.

**Measuring plasma drug concentrations**

For a few drugs, dosages can be effectively monitored by reference to their plasma concentrations *(Box 2.7)*. This technique is only useful, however, if both of the following criteria are fulfilled:

* There is a reliable and available drug assay.
* Plasma concentrations correlate well with both therapeutic efficacy and toxicity.

**Box 2.7**

**Measuring drug effects**

For many drugs, dosage adjustments are made in line with patients' responses. Monitoring can involve dose titration against a therapeutic end-point or a toxic effect. Objective measures (such as monitoring antihypertensive therapy by measuring blood pressure, or cytotoxic therapy with serial white blood cell counts) are most helpful, but subjective ones are necessary in many instances (as with antipsychotic therapy in people with schizophrenia).
Adverse Drug Reactions

Adverse drug reactions (ADRs), defined as ‘the unwanted effects of drugs occurring under normal conditions of use’, are a significant cause of morbidity and mortality. The burden of ADRs on hospitals is huge in both adults and children (Box 2.8). ADRs also account for about 2.5% of emergency room visits, and about 1 in 4 patients in primary care will have an adverse reaction, but fortunately these are mild in most cases. Unwanted effects of drugs are 5–6 times more likely in the elderly than in young adults, and the risk of an ADR rises sharply with the number of drugs administered. ADRs are also more common in women than in men.

**Classification**

Two types of ADR are recognized.

**Type A (augmented) reactions (Box 2.9)**

These:

- are qualitatively normal, but quantitatively abnormal, manifestations of a drug’s pharmacological or toxicological properties
- are predictable from its known pharmacological or toxicological actions
- generally show a clear dose–response relationship
- are usually common
- are only occasionally serious.
### Box 2.9

</tbody>
</table>

*In children and adolescents.

ACE, angiotensin-converting enzyme; SSRIs, selective serotonin reuptake inhibitors.

Whilst some reactions, such as hypotension with angiotensin-converting enzyme (ACE) inhibitors, may occur after a single dose, others may develop only after months (pulmonary fibrosis with amiodarone) or years (second malignancies with anticancer drugs).

**Type B (idiosyncratic) reactions (see Box 2.9)**

These have no resemblance to the recognized pharmacological or toxicological effects of the
drug. They:
• are qualitatively abnormal responses to the drug
• are unpredictable from its known pharmacological or toxicological actions
• show a dose–response relationship that is complex and not easily discernible
• are usually rare
• are often serious.

**Diagnosis**

All ADRs mimic some naturally occurring disease, and the distinction between an iatrogenic aetiology and an event unrelated to the drug is often difficult. The patient should be asked not only about prescription drugs but also about over-the-counter medicines, herbal medicines and illicit drugs. Although some effects are obviously iatrogenic (e.g. acute anaphylaxis occurring a few minutes after intravenous penicillin), many are less so.

Causality assessment of a suspected ADR can be difficult, particularly in patients on multiple drugs. The following simple rules (remembered by the mnemonic TREND) can help in assessing causality:

• **Temporal relationship.** The time interval between the administration of a drug and the suspected adverse reaction should be appropriate. Acute anaphylaxis usually occurs within a few minutes of administration, whilst aplastic anaemia will only become apparent after a few weeks (because of the lifespan of erythrocytes). Drug-induced malignancy, however, will take years to develop.

• **Rechallenge.** Re-institution of the suspected drug, to see if the event recurs, is often regarded as an absolute diagnostic test. This is, in many instances, correct but there are two caveats. First, it is rarely justifiable to subject a patient to further hazard. Second, some ADRs develop because of particular circumstances, which may not necessarily be replicated on rechallenge (e.g. hypoglycaemia with an antidiabetic agent).

• **Exclusion of other causes.** An ADR is a diagnosis of exclusion, and other causes should be excluded by taking a careful clinical history and undertaking relevant investigations. For example, in drug-induced liver injury, it may be necessary to exclude viral, autoimmune and metabolic causes by blood tests, and cholelithiasis by ultrasound. In a few instances, the diagnosis of an adverse reaction can be inferred from the plasma concentration (see Box 2.7).

• **Nature and novelty of the reaction.** Many ADRs have been reported before, which can help in assessing causality. Some conditions (e.g. angio-oedema or toxic epidermal necrolysis) are so typically iatrogenic that an ADR is very likely. Where an event is a manifestation of the known pharmacological property of the drug, it can be recognized as a type A ADR (e.g. hypotension with an antihypertensive agent, or hypoglycaemia with an antidiabetic drug).

• **Dechallenge.** Failure of remission when the drug is withdrawn (i.e. ‘dechallenge’) is unlikely to be an ADR. The diagnostic reliability of dechallenge is not, however, absolute; if
the ADR has caused irreversible organ damage (e.g. malignancy), then dechallenge will result in a false-negative response.

Management

As a general rule, type A reactions can usually be managed by a reduction in dosage, whilst type B reactions almost invariably require the drug to be withdrawn (and never re-instituted). Most ADRs resolve spontaneously when the drug is withdrawn, but specific therapy is sometimes required for ADRs such as bleeding with warfarin (vitamin K), acute dystonias (benztropine) or acute anaphylaxis (see Emergency Box 8.24). Desensitization is sometimes carried out for immune-mediated reactions but this should be done by a specialist with appropriate resuscitation facilities.

When a patient suffers an ADR, this should be reported to the regulatory agency: for example, through the UK’s yellow card reporting scheme to the Medicines Healthcare Products Regulatory Agency. The criteria for reporting vary across the world but, in general, all ADRs to new drugs should be reported, while only the serious ADRs to established drugs (i.e. those that have been on the market for more than 2 years) should be reported.

Further reading

Drug Interactions

Drugs can interact with each other (drug–drug interactions; DDIs), with food (drug–food interactions) and with herbal medicines (drug–herbal interactions) (Box 2.10). These interactions, in general, can be either pharmacokinetic (affecting the processes of absorption, distribution, metabolism and excretion), pharmacodynamic (synergistic or antagonistic) or mixed. Approximately 1% of all ADRs that lead to hospital admission are due to DDIs. A major risk factor for DDIs is polypharmacy, which is becoming more common because of the co-morbidities associated with an ageing population. About 57% of patients above the age of 65 years are on more than five drugs, with 12% being on more than ten drugs. The use of multiple drugs in a patient is necessary in some cases, but regular review of medicines is essential in order to optimize doses and stop those drugs that are no longer required. Prescribing additional drugs in a patient already on medicines should only be done after a careful history, if it is clinically indicated, and with adjustment of dose through regular monitoring (clinical and/or laboratory, as appropriate).

Box 2.10

Some examples of drug interactions
Food–drug interactions are also becoming increasingly recognized. A common example is grapefruit juice and drugs metabolized by CYP3A4 (e.g. simvastatin – see Box 2.10, verapamil and tacrolimus, to name a few). Grapefruit juice inhibits CYP3A4 in the intestinal wall, increasing the bioavailability of these drugs and resulting in higher exposure, and toxicity.

Herbal medicines are taken by almost 20% of the population but rarely asked about when a patient's clinical history is taken. Many different herbal–drug interactions have been described, the best recognized of which is with St John's Wort (SJW), which is an inducer of P450 enzymes and drug transporters such as P-glycoprotein. SJW can lead to increased drug metabolism, reduction in drug concentration, and failure of therapeutic effect. An example is interaction with immunosuppressants such as prednisolone and ciclosporin, where the use of SJW has led to allograft rejection.

Inter-Individual Variability in Drug Response

Patients vary in the way they respond to drugs, in terms of both efficacy and safety. In some circumstances, this may be due to clinical and environmental factors. Age, body weight, renal and hepatic function, concomitant drugs, co-morbidities, diet, smoking and alcohol are all known to affect the pharmacokinetics and sometimes the pharmacodynamics of drugs. Genetic factors affecting both the pharmacokinetics and pharmacodynamics of drugs also play a role in determining how individuals respond to drugs.

Genetic causes of altered pharmacokinetics

Both pre-systemic hepatic metabolism and the rate of systemic hepatic clearance may vary markedly between healthy individuals. Variability in the genes that encode drug-metabolizing enzymes (Box 2.11) is a major determinant of the inter-individual differences in the therapeutic and adverse responses to drug treatment. Genetic polymorphisms can affect both phase I and phase II drug-metabolizing enzymes.

Approximately 25% of all medicines currently in use are substrates for CYP2D6. The frequencies of the variant alleles show racial variation and a small proportion of individuals may have three or more copies of the active gene. The phenotypic consequences of the defective CYP2D6 include the increased risk of toxicity with those antidepressants or antipsychotics that undergo metabolism by this pathway. Additionally, reduced conversion of a
prodrug to the active metabolite may also compromise efficacy in some patients; for example, poor metabolizers of CYP2D6 may be at increased risk of breast cancer relapse with tamoxifen. Conversely, in individuals with multiple copies of the active gene (ultra-rapid metabolizers), there are extremely rapid rates of metabolism and therapeutic failure at conventional doses. Ultra-rapid metabolizers may also be at increased risk of toxicity with the conversion of prodrugs to active metabolites; this has been shown with codeine, which is metabolized to morphine and has caused respiratory depression, particularly in children.

Warfarin is predominantly metabolized by CYP2C9. In most populations, between 2% and 10% are homozygous for an allele that results in low enzyme activity. Such individuals will therefore metabolize warfarin more slowly, leading to higher plasma levels, a greater risk of bleeding, and a requirement for lower doses if the international normalized ratio (INR) is to be maintained within the therapeutic range. When combined with the genetic polymorphisms in the vitamin K epoxide reductase complex (VKORC1) genes (a pharmacodynamic variation), and age and body mass index (BMI), over 50% of the variation in individual daily dose requirement can be predicted. Pre-prescription genotyping for CYP2C9 and VKORC1 has been shown to improve anticoagulation control.

Individual differences in the activity of thiopurine methyltransferase (TPMT), a phase II enzyme, are used to determine the appropriate doses of mercaptopurine and azathioprine. Testing for TMPT activity is therefore undertaken routinely in children undergoing treatment for acute lymphatic leukaemia and people with Crohn's disease. Slow acetylators (deficient in N-acetyltransferase type 2) have an increased risk of hepatotoxicity with isoniazid, while individuals with deficient UGT1A1 activity are at increased risk of toxicity from irinotecan.

**Genetic causes of altered pharmacodynamics**

Genetic variation also affects pharmacodynamic targets, which can, in turn, lead to variation in both the efficacy and the safety of drugs. For example, variation in the β2-adrenoceptor gene can affect response to salbutamol (albuterol). Glucose-6-phosphate dehydrogenase deficiency, the most common enzyme deficiency in the world, can predispose patients to acute red cell haemolysis with certain drugs such as primaquine, dapsone, sulphonamides and rasburicase. The biggest clinical advances in this area have occurred in two therapeutic areas:

- **Cancer.** Sequencing of the cancer genome has identified novel driver mutations. This has led to the development of targeted therapies, which have been remarkably successful in the treatment of some malignancies, even when they are at an advanced stage (e.g. melanoma, see p. 20).

- **Drug safety.** Some immune-mediated reactions involving the skin and liver can now be predicted by genotyping for certain human leucocyte antigen (HLA) polymorphisms. For example, pre-prescription genotyping for HLA-B*57:01 has been shown to be clinically effective and cost-effective in preventing hypersensitivity to the anti-human immunodeficiency virus (HIV) drug abacavir. Similarly, HLA-B*15:02 predisposed patients from South-east Asia to Stevens–Johnson syndrome with carbamazepine.
**Future perspective**

As we learn more about the human genome, and the fact that many drugs undergo metabolism via many pathways and act on a number of targets, most of which show polymorphic expression, it may be possible in the future to utilize this information to personalize drug therapy to improve both efficacy and safety of drugs. This represents one component of the drive towards personalized medicine.

**Further reading**

**Evidence-Based Medicine**

Clinical practice should, as far as possible, be based on formal evidence of benefit rather than theoretical speculation, anecdote or authoritative pronouncements.

One of the main applications of evidence-based medicine has been in therapeutics. Treatments should only be introduced into routine clinical care if they have been demonstrated to be effective in appropriate studies. Three approaches are used:

1. randomized controlled trials
2. controlled observational trials
3. uncontrolled observational studies.

**Randomized controlled trials (RCTs)**

In this type of study, patients with a particular condition are allocated – at random – to one of two (and sometimes more) treatments. At the end of the study, the outcomes in the groups are compared. The purpose of the RCT is to minimize bias and confounding. In order to minimize patient bias, the participants themselves are generally unaware of their treatment allocations (a ‘single-blind’ trial); and in order to reduce doctor bias, treatment allocations are also withheld from the investigators (a ‘double-blind’ trial). To recruit sufficient numbers of patients, and to examine the effects of treatment in different settings, it is often necessary to conduct the trial at several locations (a ‘multicentre’ trial).

RCTs may be designed to assess whether one treatment is better than another (a ‘superiority’ trial), or whether one treatment is similar to another (an ‘equivalence’ trial). There are a number of other variants, including crossover trials, cluster randomized controlled trials, inferiority trials and futility trials (see ‘Further reading’).
Assessing randomized controlled trials

In assessing the relevance and reliability of an RCT, a number of features in its design and analysis need to be taken into account.

**Randomization**

The method of randomization should be robust and, in particular, the investigator should be unaware of which treatment a patient entering a trial will receive. This avoids selection bias.

**Maintaining blindness**

Ideally, in RCTs, neither the investigator nor the patient should be aware of the treatment allocations until the end of the study. This, though, is not always possible. Adverse drug reactions, for example, may make it obvious which treatment a patient has been given. Nevertheless, maintaining ‘blindness’ is necessary where the outcome is subjective (e.g. relief of pain, alleviation of depression) if bias is to be avoided.

**Were the treatment groups comparable?**

The key questions to ask are:

- Were the patients in each group similar in their ‘baseline’ characteristics?
- Were they, for example, of similar age, with similar severity and duration of illness?
- If not, are the differences likely to influence the results?
- Has the statistical analysis (using analysis of co-variance or Cox's proportional hazards model – see below) tried to adjust for them?

**Box 2.12** shows some of the baseline characteristics of a trial comparing prednisolone with placebo in the treatment of Bell’s palsy.

---

**Box 2.12**

Summary of a multicentre randomized placebo-controlled trial of prednisolone (25 mg twice daily, for 10 days) in the treatment of Bell's palsy

---
**Outcomes**

There are two ways to analyse the outcomes of an RCT:

- **Per protocol analysis:** this includes only those who completed the study.
- **Intention-to-treat analysis:** this includes all patients from the time of randomization.

Ideally, there should be no difference in the results of these two types of analysis but, in reality, the results of a per protocol analysis are usually more advantageous to a treatment than an intention-to-treat analysis. The reason is that the intention-to-treat analysis will take account of patients who have withdrawn from the trial because of adverse reactions. It is therefore a much more robust approach. The results of the intention-to-treat analysis, in the trial of prednisolone in Bell's palsy, are shown in **Box 2.12**. The trial results indicate, with a high probability, that treatment of Bell's palsy with prednisolone will increase the chances of a full recovery of facial nerve function.

**Are the results generalizable?**

Were the patients enrolled into the study a reasonable reflection of those likely to be treated in routine clinical practice? Or were they a selected population that excluded significant patient...
groups (such as the elderly)? If the latter is true, view the results with caution.

**Analysis of a superiority trial**

The analysis of a superiority trial is based on the premise – the ‘null hypothesis’ – that there is no difference between the treatments. The null hypothesis is rejected if the probability of the observed result occurring by chance, the p value, is less than 1 in 20 (i.e. p <0.05). There are three caveats, though:

- Any difference may still be due to chance; and it is often better to await the results of at least two independent studies before adopting a new treatment.
- A trial may show no ‘statistically significant’ difference, when one in fact exists, because too few patients have been included. In other words, the trial lacked sufficient ‘power’. The ‘power’ of a study (the number of patients needed in each treatment group to detect a pre-defined difference) should have been defined at the outset. If the study was under-powered, the results of the study should be interpreted with extreme care.
- A statistically significant difference may not necessarily be clinically relevant. Scrutiny of the magnitude of the effect, and its 95% confidence intervals (CI), is a far better guide than the p value.

**Effect size.**

The results of the well-designed trial in *Box 2.12* show, very convincingly, that the treatment of Bell’s palsy with prednisolone increases the chances of complete recovery of facial nerve function, at 12 months, from 81.6% to 94.4%. This is a far more convincing description of the benefits of treatment than the p value.

**Number needed to treat (NNT).**

Another expression of the benefit of a treatment can be derived from the NNT. This is an estimate of the numbers of patients who need to be treated with a drug to achieve one positive result. In the study shown in *Box 2.12*, the NNT to enable one patient with Bell's palsy to regain normal facial nerve function, after prednisolone treatment, is 8.

**Analysis of an equivalence trial**

The aim of an equivalence trial is to determine whether two (or possibly more) treatments produce similar benefits. During the design of such trials, it is necessary to decide what difference is unimportant from a clinical perspective and then to calculate the number of patients needed in order to have an 80% or 90% chance of showing this. In equivalence trials, such power calculations show that the number of patients required is invariably greater than those needed for superiority trials. In equivalence studies, the comparator itself must, of course, already have been shown to be effective.

**Meta-analysis**
It is possible to summate the results of all the controlled trials that have been performed in the treatment of a particular condition so as to refine the estimate of effectiveness. This technique minimizes random error in the assessment of the effect size of a treatment because more patients are included than could be accommodated in any single trial. A meta-analysis should be performed (and interpreted) because of the heterogeneity of the individual studies used in it. Meta-analyses are most often based on the results of the summary statistics reported in the original reports. Occasionally (but more often in the past few years), meta-analyses use the data from the individual patients involved in the original studies. This technique is time-consuming and requires the original triallists to agree to providing the necessary data.

**Controlled observational trials**

Three types of observational study have been used to test the clinical effectiveness of therapeutic interventions:

- historical controlled trials
- case–control studies
- before-and-after studies.

**Historical controlled trials**

Despite the value of the prospective RCT, there are many treatments that have never been subjected to this technique; their efficacy, however, is unquestioned. Examples include insulin in the treatment of diabetic ketoacidosis, thyroxine for hypothyroidism, vitamin B<sub>12</sub> in pernicious anaemia and defibrillation for ventricular fibrillation. In a historical controlled trial, the outcome in patients treated with the study drug is compared to that of previously untreated people with the same disease. Treatments can be accepted into routine use on the basis of favourable comparisons with historical controls when the following criteria are met:

- There should be a biologically plausible basis for the observed benefits.
- There should be no appropriate treatment that could be reasonably used as a control.
- The condition should have a known and predictable natural history.
- The treatment should not be expected to have adverse effects that would compromise its potential benefits.
- There should be a reasonable expectation that the magnitude of the therapeutic effects of treatment will be large enough to make the interpretation of its benefits unambiguous.

**Case–control studies**

This type of study design compares people with a particular condition (the ‘cases’) with those without (the ‘controls’). The approach has been used predominantly to identify epidemiological ‘risk factors’ for specific conditions such as lung cancer (smoking) or sudden infant death syndrome (lying prone), as well as in the evaluation of potential ADRs (such as deep venous thrombosis with oral contraceptives).
A case–control design allows an estimation of the odds ratio (OR), which is the ratio of the probability of an event occurring to the probability of the event not occurring (Box 2.13). An OR that is significantly greater than unity indicates a statistical association that may be causal. The ORs for deep venous thrombosis and the current use of oral contraceptives varies from 2 to 4 (depending on the preparation); this indicates that the risk of developing a deep venous thrombosis on oral contraceptives is between 2 and 4 times greater than the background rate.

<table>

<td>a</td>
</tr>
<tr>
<td>Risk factor absent</td>
<td>b</td>
</tr>
<tr>
<td>The odds ratio (OR) = (a ÷ b) / (c ÷ d)</td>
<td></td>
</tr>
</tbody>
</table>

In some studies, the OR for a particular observation has been found to be significantly less than unity, suggesting ‘protection’ from the condition under study. Some studies of women with myocardial infarction indicated protection in those using hormone-replacement therapies but it has subsequently been shown that the result was due to bias. On the other hand, case–control studies have consistently shown that aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs) are associated with a reduced risk of colon cancer. This seems to be a causal effect.

Case–control studies claiming to demonstrate the efficacy of a drug need to be interpreted with great care; the possibility of bias and confounding is substantial, as in the studies of hormone-replacement therapy and myocardial infarction. Confirmation from one or more RCT is usually essential.

Before-and-after studies
It has sometimes been inferred that observed improvements seen in patients before, and after, the use of a particular treatment is evidence of efficacy. Such an approach is fraught with difficulties; the combination of a placebo effect, as well as regression to the mean, is likely to negate most studies using this type of design. Nevertheless, there are some circumstances where genuine efficacy can be confidently concluded with such designs: the benefits of hip replacement and cataract surgery are good examples. Such instances can be regarded as special examples of the use of implicit historical controls.

Uncontrolled observational studies
Uncontrolled case series cannot provide primary evidence for efficacy, unless they are undertaken in circumstances that are virtually those of historical controlled trials. Case series can, however, sometimes be of value in demonstrating the generalizability of the results of
RCTs.

**Evaluation of new drugs**

New drugs are subjected to a vigorous programme of pre-clinical and clinical testing before they are licensed for general use *(Box 2.14)*. At the time new products are licensed there can be confidence in their efficacy for their agreed indications. Conclusions about their safety must, at this point, be provisional, which is why emphasis is placed on post-marketing.

---

**Box 2.14**

**Evaluation of new drugs**

**Phase I: Healthy human subjects (usually men)**
- First use in humans
- Evaluation of safety and toxicity
- Pharmacokinetic assessment
- Sometimes pharmacodynamic assessment
- Approximately 100 subjects

**Phase II: First assessment in patients**
- Safety and toxicity evaluated
- Dose range identified
- Pharmacokinetic and pharmacodynamic monitoring
- Approximately 500 subjects

**Phase III: Use in wider patient population**
- Efficacy main objective
- Safety and toxicity also carefully monitored
- Often multicentre trials
- Approximately 2000 patients involved

**Phase IV: Post-marketing surveillance**
- All patients prescribed drug monitored
- Efficacy, safety and toxicity measured
- Quantification of unusual drug adverse effects
- Yellow Card and spontaneous reports of adverse reactions
- Often very large numbers of patients observed
Statistical Analyses

The relevance of statistics is not confined to those who undertake research but extends to anyone who wants to understand the relevance of research studies to their clinical practice.

The average

Clinical studies may describe, quantitatively, the value of a particular variable (e.g. height, weight, blood pressure, haemoglobin) in a sample from a defined population. The ‘average’ value (or ‘central tendency’, in statistical language) can be expressed as the mean, median or mode, depending on the circumstances (Fig. 2.3).

• The **mean** is the average of a distribution of values that are grouped symmetrically around the central tendency.

• The **median** is the middle value of a sample. It is used, particularly, where the values in a sample are asymmetrically distributed around the central tendency.

• The **mode** is the interval in a frequency distribution of values that contains more values than any other.
In a symmetrically distributed population, the mean, median and mode are the same. The average value of a sample, on its own, is of only modest interest. Of equal (and often greater) relevance is the confidence we can place on the sample average as truly reflecting the average value of the population from which it has been drawn. This is most often expressed as a confidence interval, which describes the probability of a sample mean being a certain distance from the population mean. If, for example, the mean systolic blood pressure of 100 undergraduates is 124 mmHg, with a 95% confidence interval of ± 15 mmHg, we can be confident that if we replicated the study 100 times, the value of the mean would be within the
range 109–139 mmHg on 95 occasions. It is intuitively obvious that the larger the sample, the smaller will be the size of the confidence interval.

**Correlation**

In clinical studies, two or more independent variables may be measured in the same individuals in a sample population (e.g. weight and blood pressure). The degree of correlation between the two can be investigated by calculating the correlation coefficient (often abbreviated to ‘r’).

The **correlation coefficient** measures the degree of association between the two variables and may range from 1 to −1:

- If \( r = 1 \), there is complete and direct concordance between the two variables.
- If \( r = -1 \), there is complete but inverse concordance.
- If \( r = 0 \), there is no concordance.

Statistical tables are available to inform investigators as to the probability that \( r \) is due to chance. As in other areas of statistics, if the probability is less than 1 in 20 (\( p < 0.05 \)), then by custom and practice it is regarded as statistically significant. There are, however, two caveats:

- The 1 in 20 rule is a convention and does not exclude the possibility that a presumed association is due to chance.
- The fact that there is an association between two variables does not necessarily mean that it is causal. For example, a correlation between blood pressure and weight, with \( r = 0.75 \) and \( p < 0.05 \), does not mean that weight has a direct effect on blood pressure (or vice versa).

Correlation analyses can become complicated. The simplest (least squares regression analysis) presumes a straight-line relationship between the two variables. More complicated techniques can be used to estimate \( r \) where a non-linear relationship is presumed (or assumed); where the distributions deviate from normal; where the scales of one or both variables are intervals or ranks; or where a correlation between three or more variables is sought.

**Survival analyses**

In studies where individuals are observed over a long(ish) period of time, and in which it is unreasonable (or erroneous) to assume that event rates are constant, the technique of survival analysis is used. This is most commonly reported as the **hazard ratio (HR)** with its 95% confidence interval. The HR is the probability that, if an event in question has not already occurred, it will happen in the next (short) time interval.

**Continuous outcomes**

Studies such as that in **Box 2.12** may report outcomes using one or more continuous scales. In this study of the effects of prednisolone in the treatment of Bell’s palsy, the House–Brackmann measure of facial nerve function was used as the outcome measure. Conventional tests of statistical significance using Student’s t-test, for example, can be calculated to assess whether the null hypothesis can be rejected.
**Number needed to treat (NNT)**

As discussed earlier, the NNT is an estimate of the number of patients that need to be treated for one to benefit compared to no treatment. If the probabilities of the end-points with the active drug and no treatment (i.e. placebo) are respectively \( p_{\text{active}} \) and \( p_{\text{no treatment}} \), then the NNT can be calculated thus:

\[
\text{NNT} = \frac{1}{p_{\text{active}} - p_{\text{no treatment}}}
\]

An analogous measure – the **number needed to harm (NNH)** – is the number of patients that need to be treated with a drug to cause one patient to be subject to a specific harm.

**Other statistical techniques**

Statisticians have developed a range of sophisticated methods to handle a wide variety of biomedical problems. Unless an investigator is supremely (and usually unwisely) confident, it is sensible to seek professional advice in analysing numerical data that look complicated. In doing so, it is invariably wiser to do so at the time the study is being designed rather than after the results have been generated!

**Further reading**

**Information Sources**

Pharmacotherapy moves at a very rapid pace and it is impossible for anyone to keep up with contemporary advances. Reliable prescribing advice can be found in:

- The *Summary of Product Characteristics (SmPCs)* produced by manufacturers and vetted by drug regulatory authorities (for the UK, these are the Medicines and Healthcare Products Regulatory Agency and the European Medicines Agency).

- The relevant national formulary. Many countries have their own formularies: for example, the UK has the *British National Formulary* (BNF), produced jointly by the British Medical Association and the Royal Pharmaceutical Society.

- Guidance produced by national health technology agencies such as the UK’s National Institute for Health and Care Excellence (NICE).
Advice on the management of individual conditions, available in the form of clinical guidelines (systematically developed statements to assist practitioner and patient decisions about appropriate healthcare for specific clinical circumstances). Some of these are published by national medical societies. In the UK, NICE is the main developer of clinical guidelines.

Patient information leaflets are supplied with all prescribed medication.

# Palliative medicine and symptom control

*Miriam J Johnson, Gail E Eva, Sara Booth*

## Introduction and general aspects

Palliative care is the active total care of patients who have advanced, progressive, life-shortening disease. It should be based on needs and not diagnosis, and is required in non-malignant diseases as well as in cancer *(Box 3.1)*.

### Box 3.1

**Key components of a modern palliative care service**

- Management based on *needs*, not diagnosis: the symptom burden of non-malignant disease often equals that of cancer
- Care that is independent of the patient's location and that helps patients to remain at home

## Symptom control

## Extending palliative care to people with non-malignant disease

- Heart failure | 37 |
- Chronic respiratory disease | 37 |
- Renal disease | 38 |
- Neurological disease | 38 |

## Palliative care of the frail elderly | 39 |

## Care of the dying | 41 |
if possible, avoiding unwanted admissions to hospital
• Rehabilitation for people with advanced disease
• Support for carers
• Bereavement care for people with pathological grief problems
• Telephone advice for other clinicians; dissemination of palliative care knowledge
• Teaching for clinicians, from undergraduate level to postgraduate life-long learning

The goal of palliative care is to achieve the best possible quality of life for patients and their carers by:
• managing physical, psychological, social and spiritual problems so as to provide excellent symptom control
• enabling patients to be cared for and to die in the place of their choice
• enabling the acceptance of death as a normal process when life-prolonging treatments no longer improve or maintain quality of life
• providing the opportunity to say goodbye and bring closure.

Who provides palliative care?
A hallmark of palliative care is the multiprofessional team, as single professionals cannot provide the breadth of necessary expertise. The emotional demands of working in this area require team support to enable balanced, compassionate and professional care.

All healthcare providers should have basic palliative care skills and access to a specialist palliative care (SPC) team. They should be aware of the services that the local SPC teams can offer and recognize when referral is appropriate. A problem-based approach to disease management will ensure that patients and carers obtain access to appropriate support services, including SPC, and will avoid an either/or approach (‘either curative treatment or palliative care’).

Good communication between members of the healthcare team, and between patient and carer, underpins the successful management of advanced disease and end-of-life care. Effective liaison between the hospital, primary care and hospice is also essential.

When should palliative care needs be assessed – problems rather than prognosis?
Early assessment of needs, with SPC referral if required, is crucial to achieving the best outcome for rehabilitation and for maintaining or improving quality of life for both patient and carer. Palliative care is most effective when it is included as part of routine care as soon as possible after diagnosis, alongside disease-specific therapy, such as radio/chemotherapy for cancer or cardiac medication for heart failure. Early referral links palliative care with quality-of-life improvements; positive associations increase the likelihood that patients and families continue to use palliative care services when they need them over the course of the illness. In
cancer, there is good evidence that integrating palliative care and anti-tumour treatment soon after diagnosis reduces long-term distress and increases survival in selected cases.

If palliative care is seen only as relevant to the end-of-life phase, patients who have non-malignant disease are denied expert help for complex symptoms. Timely management of physical and psychosocial issues earlier in the course of disease prevents intractable problems later (Box 3.2).

### Box 3.2

**Problems arising when specialist palliative care (SPC) is delayed until the end of life**

- There is insufficient time to achieve good symptom control by combining non-pharmacological and pharmacological components
- SPC services are deemed less acceptable by patient and family, being associated with ‘dying’ or ‘giving up’ or ‘giving in’ to illness
- Psychological distress and physical symptoms become intractable and contribute to complex grief
- It becomes too late to adopt a rehabilitative approach or teach/use non-pharmacological interventions that need a degree of training and patient motivation (e.g. cognitive behavioural approaches, mindfulness meditation, attendance at day therapy)

**What are the patient's needs and what is the patient's understanding?**

The causes of a patient's symptoms are often multifactorial, and a holistic assessment is central for optimum management. Assessment of the patient's understanding of the disease, understanding their future wishes and acknowledging their concerns, will help the team plan and implement effective support. Patients will have differing needs for information, and will deal with ‘bad news’ in different ways. A sensitive approach, respecting individual requirements, is crucial.

**How can patients use palliative care services?**

Changes in the provision of SPC services have been forced by the increase in the number of patients who survive malignant disease, as well as recognition of the needs of patients who have non-malignant disease. Many patients will use SPC services for a limited period (weeks to months) for complex problems to be addressed, and then are discharged. They have the opportunity for re-referral if help is required later.

**Further reading**

Symptom Control

Good palliative care integrates the control of symptoms with appropriate non-pharmacological approaches, such as anxiety management and rehabilitation (see p. 36).

Pain

Pain (see also pp. 818–820) is a feared symptom in cancer. At least two-thirds of people with cancer suffer significant pain. Pain has a number of causes, and not all pains respond equally well to opioid analgesics (Fig. 3.1). The pain is related to the tumour either directly (e.g. pressure on a nerve) or indirectly (e.g. due to weight loss or pressure ulcers). It may result from a co-morbidity such as arthritis. Emotional and spiritual distress may be expressed as physical pain (termed ‘opioid irrelevant pain’) or will exacerbate physical pain.
The term ‘total pain’ encompasses a variety of influences that contribute to pain:

- **Biological**: the cancer itself, cancer therapy (drugs, surgery, radiotherapy).
- **Social**: family distress, loss of independence, financial problems from job loss.
- **Psychological**: fear of dying, of pain, or of being in hospital; anger at dying or at the process of diagnosis and delays. Depression can stem from all of the above.
- **Spiritual**: fear of death, questions about life’s meaning, guilt.

A visual analogue scale for pain can be used (*Fig. 3.2*).
The WHO analgesic ladder

Most cancer pain can be managed with oral or commonly used transdermal preparations. The World Health Organization (WHO) cancer pain relief ladder guides the choice of analgesic according to pain severity (Fig. 3.3, Box 3.3).
FIGURE 3.3  WHO analgesic ladder for cancer and other chronic pain. Step 2 can be omitted, going to morphine immediately. Adjuvant drugs are listed in Box 3.3. *Opioids include all drugs with an action similar to that of morphine, i.e. binding to endogenous opioid receptors. † Continue non-steroidal anti-inflammatory drug (NSAID)/paracetamol regularly when opioid started.
**Box 3.3**

**Commonly used adjuvant analgesics**

<table>

</tr>
</tbody>
</table>

If *regular* use of optimum dosing (e.g. paracetamol 1 g × 4 daily for step 1) does not control the pain, then an analgesic from the next step of the ladder is prescribed. As pain has different physical aetiologies, an adjuvant analgesic may be needed in addition: for example, the tricyclic antidepressant amitriptyline for neuropathic pain (see Box 3.3).

**Strong opioid drugs**

**Dose titration and route**

*Morphine* is the drug of choice and, in most circumstances, should be given regularly by mouth. The dose should be tailored to the individual's needs by allowing ‘as required’ doses; morphine does not have a ‘ceiling’ effect. If a patient has needed further doses in addition to the regular daily dose, then the amount in the additional doses can be added to the following day's regular dose until the daily requirement becomes stable: a process called ‘titration’. When the stable daily dose requirement has been established, the morphine can be changed to a sustained-release preparation. For example:

- 20 mg morphine elixir 4-hourly
- = 120 mg morphine per day
- = 60 mg twice daily of a 12-hour preparation or
- = 120 mg daily of a 24-hour preparation.

The starting dose of morphine is usually 5–10 mg every 4 hours, depending on patient size, renal function and whether a weak opioid is already being given.

If there is significant renal dysfunction, morphine should be used in low doses and should not be given in continuous dose regimens (e.g. by subcutaneous infusions) because of the risk of metabolite accumulation (it is renally excreted). In renal impairment, an alternative opioid (e.g. fentanyl) can be given transdermally (e.g. 72-hour self-adhesive patches) or by subcutaneous infusion.

N.B. A word of caution about opioid transdermal patches: serum levels do not change quickly with transdermal patches, and they are also cumbersome to titrate in patients with
escalating or unstable pain. They should be kept at a stable dose, and a more dose-responsive preparation used to gain pain control.

If a patient is unable to take oral medication due to weakness, swallowing difficulties, or nausea and vomiting, the opioid should be given parenterally. For cancer patients who are likely to need continuous analgesia, continuous subcutaneous infusion is the preferred route.

Both doctors and patients may have erroneous beliefs, such as the fear of addiction, which mean that adequate doses of opioids are not prescribed or taken. However, iatrogenic addiction is very rare, with the risk being <0.01%; the adverse effects and morbidity from uncontrolled pain are much higher.

**Side-effects**
The most common side-effects are:

- **Nausea and vomiting.** These can usually be managed or prevented with antiemetics (such as metoclopramide). Some antiemetic solutions for injection can be combined with an opioid for continuous subcutaneous infusion, e.g. haloperidol or metoclopramide; always check compatibility data.

- **Constipation.** This is common and should be anticipated with administration of a combination of stool softener (e.g. macrogols) and stimulants, either separately or in one preparation. Naltrexone is a peripherally acting opioid receptor antagonist that is used if response to other laxatives is poor.

    If side-effects are intractable, a change of opioid is often helpful.

**Toxicity**
Confusion, persistent and undue drowsiness, myoclonus, nightmares and hallucinations indicate opioid toxicity. This may follow rapid dose escalation and responds to dose reduction and slower retitration. It may indicate pain that is poorly responsive to opioids and the need for adjuvant analgesics.

Antipsychotics such as haloperidol may help settle the patient's distress whilst waiting for resolution of toxicity. Some patients will tolerate an alternative opioid such as oxycodone better, or an alternative route such as subcutaneous injection.

**Adjuvant analgesics**
The most commonly used adjuvant analgesics are described in *Box 3.3*. Other treatments, such as radio/chemotherapy, anaesthetic or neurosurgical interventions, acupuncture and transcutaneous electrical nerve stimulation (TENS), may be useful in selected patients.

Regular review is necessary to achieve optimal pain control, including regular assessment to distinguish pain severity from pain distress.

**Further reading**
Quigley C. Opioids in people with cancer-related pain. *Clin Evid (Online)* 2008;
Gastrointestinal symptoms

Anorexia, weight loss, malaise and weakness

These result from the cancer-cachexia syndrome of advanced disease and carry a poor prognosis. Although attention to nutrition is necessary, the syndrome is mediated through chronic stimulation of the acute phase response, and tumour-secreted substances (e.g. lipid mobilizing factor and proteolysis-inducing factor). Thus, calorie–protein support alone gives limited benefit; parenteral feeding has been shown to make no difference to patient survival or quality of life.

Management is supportive unless the patient is fit enough for and responds to anti-tumour drugs. Specific therapies such as eicosapentaenoic acid (EPA), fish oil, cyclo-oxygenase (COX) inhibition with non-steroidal anti-inflammatory drugs (NSAIDs) and antioxidant treatments are used.

Advice from a dietician is helpful. Some patients benefit from a trial of a food supplement that contains EPA and antioxidants. Megestrol may help appetite but weight gain is usually caused by fluid or fat. The drug is also thrombogenic and is of little benefit and should therefore not be used.

Corticosteroids were recommended as appetite stimulants and are still commonly used. However, the weight gained is usually caused by fluid, and muscle catabolism is accelerated leading to a proximal myopathy. Any benefit in appetite stimulation tends to be short-lived. Thus, corticosteroids should be limited to short-term use only.

Nausea and vomiting

Nausea and vomiting are common, and often due to use of opioids without antiemetics such as haloperidol 1.5 mg × 1–2 daily or metoclopramide 10–20 mg × 3 daily.

When nausea and vomiting are associated with:

• **Chemotherapy.** Patients should have an antiemetic, starting with metoclopramide or domperidone, but if the risk of nausea and vomiting is high, give a specific 5-hydroxytryptamine₃ (5-HT₃) antagonist, e.g. ondansetron 8 mg orally or by slow i.v. injection.

• **Chemical causes** e.g. hypercalcaemia. Haloperidol 1.5–3 mg daily is the first choice. Metoclopramide is also a prokinetic and therefore useful for emesis due to gastric stasis or constipation. Cyclizine 50 mg × 3 daily is also used.

• **Any cause of vomiting.** It may be necessary to start antiemetic therapy parenterally by continuous subcutaneous infusion to gain control. If the patient has gastrointestinal obstruction, this route may need to be continued.
**Gastric distension**

Gastric distension due to pressure on the stomach by the tumour (squashed stomach syndrome) is treated with a prokinetic: for example, domperidone 10 mg × 3 daily.

**Bowel obstruction**

*Metoclopramide* is helpful but to be avoided in complete bowel obstruction, where an antispasmodic such as hyoscine butylbromide is preferred. A dose of 60–120 mg/24 hours s.c. is usually recommended, but much higher doses (300–480 mg) may be needed as parenteral hyoscine butylbromide can be rapidly inactivated in humans.

*Octreotide* (a somatostatin analogue) is commonly used in bowel obstruction to try to reduce gut secretions and the volume of vomitus, but a recent randomized controlled trial failed to show any benefit over placebo. *Ranitidine* may have a role in reducing gastric secretions.

**Physical measures**, such as a defunctioning colostomy or a venting gastrostomy, may be helpful. Occasionally, a lower bowel obstruction is resolved with insertion of a stent, or transrectal resection of tumour in selected individuals. Steroids shorten the length of episodes of obstruction, if resolution is possible.

In *advanced disease*, patients should be encouraged to drink and take small amounts of soft diet as they wish. With good mouth care, the sensation of thirst is often avoidable, thus sometimes preventing the need for parenteral fluids unless otherwise indicated.

---

**Respiratory symptoms**

**Breathlessness**

Breathlessness remains one of the most distressing and common symptoms in palliative care, causing the patient serious discomfort. It is highly distressing for carers to witness. Full assessment and active treatment of all reversible conditions, such as drainage of pleural
effusions, or optimization of treatment of heart failure or chronic pulmonary disease is mandatory. In advanced cancer, breathlessness is often multifactorial in origin and many of the contributory factors are irreversible (e.g. cachexia), so a ‘complex intervention’ combining a number of different treatment strategies has the greatest impact. Aspects of breathlessness management are summarized in Box 3.4. Intractable severe breathlessness in a patient who is dying may require sedation in order to provide comfort but more invasive interventions are usually avoided. Non-invasive ventilation (NIV) has been shown to alleviate distressing dyspnoea and is also associated with a reduced opioid requirement; this may be helpful in selected patients.

**Box 3.4**

**Key points for successful management of breathlessness**

- **Start treatment early.** Patients who are likely to develop breathlessness should learn non-pharmacological approaches early in the disease course, before breathlessness has become severe.

- **Involve the carer in the treatment strategy.** Watching breathlessness episodes and being unable to help is a terrifying experience (and promotes the panic–anxiety cycle); if patients and carers develop a joint ritual for crises, chronic anxiety can be reduced.

- **Ensure management is rehabilitative** (see p. 36). This increases physical fitness, hope and self-efficacy, and may enable patient and carer to achieve goals that once seemed impossible.

- **Integrate psychological, physical and social interventions.** These are important, as with all palliative care.

**Breathlessness with panic and anxiety**

Patients often experience a panic–breathlessness cycle and fear dying during an acute episode of breathlessness. This is unlikely in chronic disease, unless there is an acute complication, and reassurance will help. The perception of breathlessness is mediated by the central nervous system and can be modulated by thoughts and feelings about the sensation. Education about breathlessness and exploration of psychological precipitators or maintainers can reduce its impact.

**Measures to alleviate breathlessness**

Non-pharmacological approaches, such as using a hand-held fan, pacing or prioritizing activities to maximize activity within limitations, breathing training and anxiety management, are helpful, along with a tailored exercise programme (*Box 3.5*). There is no evidence to suggest that oxygen therapy reduces the sensation of breathlessness in advanced disease more than just cool airflow. A hand-held fan should be used before oxygen, unless the latter is indicated by significant hypoxaemia or disease management. Opioids, used orally or
parenterally, can palliate breathlessness. If panic/anxiety is significant, a quick-acting benzodiazepine such as lorazepam (used sublingually for rapid absorption) is useful.

### Box 3.5

**Key non-pharmacological interventions for breathlessness**

<table>
<thead>
<tr>
<th>Intervention</th>
<th>Putative mechanism of action</th>
<th>Most useful</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Hand-held fan</strong></td>
<td>Cools area served by second and third branches of trigeminal nerve</td>
<td>For reducing length of episodes of SOB on exertion or at rest</td>

<td>Increases muscle bulk, simulating effect of exercise</td>
<td>In patients who: live alone are unable to attend a rehabilitation group have a short prognosis have co-morbidities that prevent exercise</td>
</tr>
</tbody>
</table>

CBT, cognitive behavioural therapy; SOB, shortness of breath (breathlessness).

**Cough**

Persistent unproductive cough can be helped by the antitussive effect of opioids (e.g. morphine). Excessive respiratory secretions can be treated with hyoscine hydrobromide 400–600 µg every 4–8 hours but does give a dry mouth. Glycopyrronium is also useful by subcutaneous infusion of 0.6–1.2 mg in 24 hours.

**Further reading**

Nava S, Ferrer M, Esquinas A et al. Palliative use of non-invasive ventilation in end-of-life
Other physical symptoms

People with cancer may develop other physical symptoms caused by the tumour directly (e.g. hemiplegia due to brain secondaries) or indirectly (e.g. bleeding or venous thromboembolism due to disturbances in coagulation). Symptoms may also result from treatment, such as lymphoedema following treatment for breast or vulval cancer, or heart failure secondary to anthracycline or trastuzumab therapy. The principles of holistic assessment, reversal of reversible factors and appropriate involvement of the multiprofessional team should be applied.

Lymphoedema

The pain and disabling swelling associated with lymphoedema can be alleviated through complete decongestive therapy (CDT), a treatment that employs a massage-like technique and comprises manual lymphatic drainage, compression bandaging and gentle exercise. Diuretics should not be used. Referral to a specialist lymphoedema therapist or nurse is useful.

Fatigue

Fatigue is a significant and debilitating problem for palliative patients. It has physical, cognitive and affective components; unlike normal tiredness, it is not relieved by usual sleep or rest. An assessment for reversible contributory factors, such as anaemia, hypokalaemia or over-sedation due to poorly optimized medication, should be undertaken. Management strategies are:

- **non-pharmacological**: relaxation, sleep hygiene, resting ‘pro-actively’ rather than collapsing when exhausted, and planning, pacing and prioritizing daily activities

- **pharmacological**: low-dose methylphenidate (central nervous system stimulant), or short-term corticosteroids used in conjunction with the SPC team, may help.

Loss of function, disability and rehabilitation

Some of the most pressing concerns include increasing physical frailty, loss of independence, and perceived burden on others. Evidence suggests that functional problems are not routinely assessed, and not as well managed as pain and other symptoms. Rehabilitation can:

- contribute to patients' quality of life by providing strategies for managing declining physical function and fatigue, and by offering resources that might make life easier for patients and carers (e.g. equipment or a wheelchair)
• support patients' adaptation to disability, helping them to increase social participation and find fulfilment in everyday living
• minimize carer stress and distress.

A referral to physiotherapy or occupational therapy is helpful for patients whose ability to carry out daily activities is compromised by illness or its treatment. However, it must be remembered that effective rehabilitation is a team effort and is not solely the domain of nursing and allied health professionals. Doctors also have a major role to play in attending to functional problems and fatigue; they should not see these as inevitable, unavoidable and insoluble.

There is a need to take into account changing performance status as well as changes in goals and priorities. It can be helpful to identify short-term, achievable goals and focus on these. Most patients wish to remain at home for as long as possible and to die at home, given adequate support. Patients’ community rehabilitation needs should not be neglected.

**Psychosocial issues**

Depression is a common feature of life-limiting and disabling illness, and is often missed or dismissed as ‘understandable’. However, it may well respond to the usual antidepressant drugs and/or to non-pharmacological measures such as cognitive behavioural therapy, increased social support (e.g. day therapy) and support for family relationships. Such interventions can make a big difference to the patient's quality of life and ability to cope with the situation.

**Further reading**

**Extending Palliative Care to People with Non-Malignant Disease**

The principles of palliative care can be applied throughout medical practice so that all patients, irrespective of care setting (home, hospital or hospice), receive appropriate care from the staff looking after them and have access to SPC services for complex issues. Some principles are outlined in *Box 3.6*. Patients who have chronic non-malignant disease, such as organ failures (heart, lung and kidney), degenerative neurological disease and human immuno-deficiency virus (HIV) infection:

• have a similar or greater symptom burden than people with cancer
• may live longer with these difficulties
• benefit from a palliative care approach with access to SPC for complex problems.
**Box 3.6**

**Key points in palliative care**

- Patients should always be involved in decisions about their care.
- Quality of life is increased when treatment goals are clearly understood by everyone, including patient and carer.
- The multidisciplinary team provide a high standard of care but there must be realism and honesty about what can be achieved.
- End-of-life care is often delivered in hospices or the home.
- Care at home should be encouraged for as long as possible, even if the patient's preferred place of death is elsewhere.
- Discussions about end-of-life care planning are best held outside times of crisis, with clinicians with whom the patient has a good relationship. Discussions must be recorded and made known to everyone involved in the patient's care.

There may be a less clear end-stage of disease but the principles of symptom control are the same: holistic assessment, reversal of reversible factors and multiprofessional support.

Patients who have non-malignant disease may have very close relationships with their usual team, and an integrated approach is essential to allow optimization of disease-directed medication as well as palliation. People with non-malignant disease may live for years with a difficult illness and so their palliative care needs to differ in some respects from that of cancer patients *(Box 3.7)*. However, symptom management is largely transferable, with some exceptions and extra complexities as outlined below.

**Box 3.7**

**Differences between palliative care for people with malignant and non-malignant diseases**
<table>
<thead>
<tr>
<th>Cancer</th>
<th>Non-malignant disease</th>
</tr>
</thead>
<tbody>
<tr>
<td>Standard treatment regimens, even in advanced disease</td>
<td>Advanced disease often needs bespoke pharmacological interventions, which may interact with palliative drugs. Close teamwork is essential to avoid adversely affecting outcomes, e.g. in use of opioids and many other drugs</td>
</tr>
<tr>
<td>Relatively new diagnosis (weeks to months)</td>
<td>Usually many years of illness with loss of social networks, employment and practical support</td>
</tr>
<tr>
<td>Sudden death is rare (although it can happen, e.g. pulmonary embolus, neutropenic sepsis)</td>
<td>Sudden death is relatively frequent as a result of cardiovascular/diabetic complications (e.g. in chronic kidney disease)</td>
</tr>
<tr>
<td>Cancer and associated problems are the main morbidities</td>
<td>Co-morbidities due to disease or treatment often cause most problems and shape end-of-life care</td>
</tr>
<tr>
<td>Prognosis is usually predictable</td>
<td>Prognosis difficult to determine: patients with many ‘near-death experiences’ and admissions can recover</td>
</tr>
<tr>
<td>Support from SPC services is often started early in the disease course</td>
<td>Main support may be from a medical unit, e.g. dialysis unit</td>
</tr>
<tr>
<td>Standard hospice services (e.g. day therapy) often suit treatment patterns well</td>
<td>Standard hospice service may not be offered (clinician ignorance) or may not be feasible (e.g. for dialysis patient attending hospital 3 days a week)</td>
</tr>
</tbody>
</table>

Throughout the course of the illness, careful open discussion of possible future options is essential. Early discussion of difficult choices is as helpful for patients who have non-malignant disease as it is for those with cancer, and these discussions are ideally held when the patient is relatively well and outside an acute episode. Discussions delayed until the crisis of acute admission may lead to acceptance of an invasive treatment that is later regretted by the patient.

### Heart failure

There are special considerations with respect to cardiac medication in advanced disease:

- **Drugs** that are commonly used in palliative care but usually contraindicated in heart failure, such as amitriptyline and NSAIDs, may be appropriate when the patient is dying.

- **Sudden death** is more common than in patients who have malignancy and a patient may have an implanted defibrillator in place. If present, these devices should be reprogrammed to pacemaker mode in advanced disease because they have not been shown to improve survival in severe heart failure and it will be distressing for patient, carer and staff if the defibrillator discharges as the patient is dying.

- **Peripheral oedema** can become a major problem and more resistant to diuretic therapy; careful balancing of medication regimens is therefore required. Ultimately, symptom relief is prioritized over renal function.

- **Medications** should be rationalized to reduce polypharmacy, e.g. ceasing drugs prescribed to reduce long-term secondary risk (e.g. statins) and continuing drugs that help symptom control (including angiotensin-converting enzyme inhibitors, which benefit symptoms as well as survival). Beta-blockers may have to be stopped if the patient can no longer maintain non-
symptomatic hypotension.

Regarding statins, a recent randomized trial of withdrawal versus continuation of statin in those thought to be in the last year of life showed no detrimental effect on quality of life with withdrawal.

**Chronic respiratory disease**

**Chronic obstructive pulmonary disease (COPD)**

COPD is the most common chronic respiratory disease. Patients may live increasingly restricted lives for years, rather than the months or weeks that are common once someone with cancer becomes breathless. Patients usually reach late middle age or old age before becoming very disabled, and an elderly spouse often has to carry significant physical burdens.

Because of the risk of dependency, falls and memory problems, non-pharmacological approaches to anxiety are more appropriate than benzodiazepines (see Box 3.5). Short-acting benzodiazepines should be reserved for severe panic episodes.

Palliative care breathlessness services can be very helpful for those unable to comply with pulmonary rehabilitation. Emergency admissions to hospital for non-medical reasons are often due to anxiety and the support offered by community palliative care services working with respiratory teams can help prevent these.

**Other chronic respiratory diseases**

Other chronic respiratory illnesses that often require palliative care include:

- **Idiopathic pulmonary fibrosis.** This has a trajectory similar to that of cancer, with rapidly developing breathlessness and cough. The breathlessness of idiopathic pulmonary fibrosis is particularly frightening but may respond well to opioids; early access to hospice services is particularly relevant to help with symptom control and anxiety.

- **Cystic fibrosis.** Patients are teenagers or young adults who usually have known their respiratory team all their lives. An integrated team involving SPC clinicians ensures good symptom control and provides useful support when difficult decisions have to be made about treatments (e.g. lung transplant), as well as offering psychosocial care to the family.

- **Primary pulmonary hypertension.** Patients are often young and treated far from home in specialist centres. They require symptom control in close consultation with the medical team, and it is essential for any dependent children to receive the care they need.

**Ventilatory support (see pp. 1163–1167)**

For many patients who have respiratory failure, non-invasive ventilation (NIV) has superseded the use of intermittent positive pressure ventilation (IPPV) on intensive therapy units. However, there are patients who are likely to need IPPV during admission for an acute exacerbation. For some of this group, life has become burdensome, rendering the net benefit for this procedure less or negligible. These patients should be put in contact with hospice
services when they are relatively stable (not during acute exacerbations), anticipating an alternative place of admission in the event of subsequent deteriorating health.

**Opioid titration in non-malignant respiratory disease**

In non-malignant respiratory disease, opioid titration may need to follow a different pattern from that used in malignant disease, in which many patients are already on opioids for pain control before they develop breathlessness. Some clinicians recommend a cautious approach for these chronically breathless patients who have non-malignant disease, but the evidence indicates that those with adequate renal function may safely be started on 5–10 mg modified release morphine, given appropriate monitoring. Constipation can be a problem (see p. 34) but recently naloxegol (a pegylated derivative of the μ-opioid receptor antagonist naloxone) has been shown to be helpful without reducing the analgesic effect of opioids.

**Further reading**

**Renal disease**

All care for patients who have end-stage chronic kidney disease (CKD) is directed towards maintenance or improvement of renal function. Prescribing is complicated, particularly if patients are receiving dialysis. Care must be taken not to cause renal damage inadvertently with potentially renotoxic medication, and close liaison with the renal team is mandatory.

In patients who have CKD, co-morbidities such as cardiovascular disease, diabetes or osteoporosis may cause greater problems than the renal disease. Those with a fluctuant course of symptoms, such as the 25–33% who have coexisting cardiac disease, bear disproportionately greater physical and psychological burdens.

**Patients who are on dialysis**

Patients attend three times per week (and receive social support from this). Thus additional attendance at a hospice day therapy service may be too tiring. If further support from SPC services is needed, then outpatient clinics, community support (for patient and/or carer) or even admission may be more suitable.

**Withdrawal of dialysis**

Withdrawal of dialysis is necessary if the effort of attendance becomes too great when there is little improvement in quality of life and the impact of other co-morbidities becomes intrusive.

If there is no residual renal function, survival after withdrawal of dialysis is likely to be a few days at most. In contrast, patients who have some residual function (usually those who
have had dialysis for only a few weeks or months) may live for months or even a year after withdrawal. Patients and carers need to understand these differences in order to make informed choices.

**Patients who are not on dialysis**

Maximizing and preserving remaining renal function are critical considerations in deciding which medications can or should be prescribed:

- Medication that accelerates loss of renal function may markedly reduce survival in patients who can live on very little remaining renal function.
- The renal impact of both dose and drug choice must be taken into account. For example, morphine and diamorphine metabolites accumulate in end-stage renal dysfunction; thus strong opioids such as alfentanil or fentanyl should be used instead.

Close liaison with the medical team is essential for drug prescribing.

**Further reading**

**Neurological disease**

People who suffer from chronic degenerative neurological diseases have a considerable burden of palliative care needs, including:

- difficulties in swallowing (e.g. in motor neurone disease)
- loss of mental capacity – the ability to understand, weigh up, come to a decision and communicate that decision.

Ideally, discussions regarding the patient's wishes should take place in advance, if the patient is able to do this, so that these can be supported.

**Motor neurone disease**

Motor neurone disease is usually rapidly progressive, often requiring hospice support. Percutaneous endoscopic gastrostomy (see p. 213) feeding may be required. In addition, if ventilatory failure develops, nocturnal NIV may be offered. Patients and their carers need to understand:

- why this treatment has been offered (to prevent hypercarbia and morning headache and confusion)
- when this treatment will be withdrawn (when it is no longer helping to maintain or improve quality of life in the face of advancing disease).

Patients need to be given a clear understanding of what alternative symptom control will be offered at withdrawal.
**Multiple sclerosis**

Pain is often prominent in multiple sclerosis because of muscle spasm; patients may become too disabled to attend outpatient clinics and then receive very little surveillance. Hospice day therapy service, rehabilitation and support for the family can make a huge impact on quality of life.

**Dementia**

Dementia-related palliative care needs arise in the context of neurological conditions that:

- tend to occur in older people (Alzheimer's disease and multi-infarct dementia)
- also affect younger people (e.g. Parkinson's disease, multiple sclerosis, Huntington's disease).

It is often difficult to ascertain whether these patients are in pain. An assessment tool that assesses behavioural response to pain, such as the Abbey and Doloplus, which uses vocalization (e.g. groaning), facial expression (e.g. frowning), change in body language (fidgeting, rocking), behaviour change (e.g. confusion, refusing to eat) and physical changes, can be useful.

Dementia poses special problems with respect to inpatient palliative care. For example, in the UK, many hospice inpatient units will not accept mobile patients who have dementia because the patient's safety cannot be guaranteed. However, they will care for those at the end of life with other SPC needs – for example, a distressed young family – or pain, and will often support other services by providing advice on symptom control.

**Further reading**

**Palliative Care of the Frail Elderly**

People worldwide are living longer as diseases, both communicable and non-communicable, are better managed. However, the palliative care needs of older patients often go unrecognized and are therefore under-treated. The physiological effects of ageing itself are compounded by co-morbidity, polypharmacy and unhealthy lifestyles. These factors lead to a higher mortality than expected, a heavy symptom burden and shortened life expectancy, compared to those who remain in good health at the same advanced age. Recognition of and attention to the care of these patients can improve outcomes by encouraging carers to produce individual care plans for the elderly frail.

Frailty is an emerging syndrome in the elderly. It has many definitions but can be thought of as a state of extreme vulnerability with ‘a progressive physiological decline in multiple organ systems’. This leads to a marked loss of function, loss of physiological reserve and an increased vulnerability to disease and death. There are a number of physiological changes that
are associated with normal ageing (Box 3.8), as well as the cumulative impact of chosen or imposed ‘unhealthy’ ways of life and chronic pre-existing diseases. The proportion of detrimental changes that can be prevented or ameliorated by different behaviour earlier in life, or by supporting people to maintain healthy habits into older age, is debatable. Box 3.9 shows the ‘five ways to wellbeing’, which, if practised with other public health teaching on moderate alcohol intake, maintenance of a healthy weight and rejection of smoking, would help to preserve health and activity as life advances.

Box 3.8

HPA axis, hypothalamic–pituitary–adrenal axis.

Box 3.9

Five ways to wellbeing (New Economics Foundation)

Connect with people

- Help the older person to find ways to be in contact with other people to avoid social
isolation and loneliness. *Evidence shows that we need both depth and breadth in our relationships for optimum health at any age.*

**Be active**
- Encourage physical activity that is enjoyable. Incorporate exercise into daily routines as much as possible. A slow walk to the toilet is better than a commode by the bedside. *Exercise facilitates the achievement of the other ways to wellbeing and increases the likelihood of successful self-care, as well as being of key importance for maintaining and improving the health of cardiovascular and musculoskeletal systems.*

**Take notice**
- Facilitate the older person's interest in current affairs and local news, as well as their immediate surroundings. *Meditation and/or relaxation techniques to manage anxiety are of value at any age and help people to live in the present moment rather than being disabled by past fears and worries or anxiety about the future. They can be taught in hospital by occupational therapists/physiotherapists, psychologists and some specialist nurses and physicians, and education can be maintained on discharge by community resources.*

**Keep learning**
- Encourage the older person to try something new. *There is accumulating evidence that continuing to learn new skills or maintain learning in established interests is good for mental health, possibly slows cognitive decline and helps with symptom control (distraction).*

**Give**
- Doing things for others is rewarding. Encourage the older person to see themselves as worthwhile, valuable contributors in their own communities, however small that might be. *Evidence shows that altruism is good for mental health and the palliative care literature demonstrates that even the very ill welcome opportunities to be involved in work that helps others.*

Frailty, however, implies vulnerability to a loss of function in many areas. There are a number of scoring indices for frailty. The Fried Frailty Score assesses:
- *slowness in walking*
- *exhaustion*
- *weakness* (decreased hand grip strength)
- *physical inactivity* (low energy expenditure)
- *weight loss* (body mass index <18.5 or >5% weight loss in the last year).
A score of 3 or more defines frailty, although slow walking, low physical activity and weight loss, as well as cognitive impairment, were independently associated with disability and a poorer prognosis.

**Assessment of the frail elderly person presenting in a medical setting**

The frail elderly person may present acutely to medical services in a number of different ways. It is essential for there to be an individual focus on improving and/or maintaining the current quality of life. As there is a high mortality in this group, all care of the frail elderly person can be considered ‘palliative’. A central tenet of palliative care is to assess the presence and severity of symptoms and to elicit the patient's priorities for future management. This will identify frail adults. Thus acute hospital admissions provide an opportunity to begin discussions with patients and their families about their preferences for future care. Treatment should be offered on the basis of individual need and potential for benefit for that individual, rather than chronological age. The aims of assessment and management are to:

- identify and treat reversible causes of decline
- detect and control troublesome symptoms and form individualized treatment plans
- screen for weight loss, pain, dyspnoea, falls, depression and insomnia
- assess severity of frailty and identify those with worse prognostic indicators (see above)
- communicate to the patient and the family the prognostic implications of frailty, its likely course, and available support.

**Context of the consultation**

Care with regard to the setting and conduct of the consultation is necessary to enable individuals to tell their story and make their wishes clear. Assessment may need to be phased to obtain all the necessary information and should involve the multidisciplinary team, as medical and social care needs can often not be differentiated; one is only possible when the other is implemented effectively.

The following are questions to ask:

- **Is the individual frail elderly person being treated in a dignified way?** Are they being called by their title and surname, and not a diminutive? Are people shouting at them or belittling them? Are they dressed, covered up, sitting comfortably and/or adequately supported if in bed?
- **Does the patient have problems with hearing or sight?** Do they have particular communication needs, e.g. a quiet side room to avoid background noise, help with their hearing aid (is it in? is it working?), assistance finding their glasses.
- **Do they need help with information to support their use of drug treatment or understanding of their illness?**
- **Have they come from home or somewhere else?** Does this setting suit them or is it now part of the problem (see *Box 3.8*)?
A full assessment of mental capacity is necessary. In those who are unable to provide their own full history, details should be sought from other sources of information such as:

- those looking after them in their nursing or residential home
- their primary care team
- their relatives who support them to live independently/with whom they live.

Ensure that you know whom to contact for advice if you have any doubts about the individual's ability to make informed decisions for themselves. Always take advice from a senior clinician if you have doubts.

**Management of the frail elderly person**

Following the comprehensive assessment, an early priority is to reverse what is reversible; rehabilitation should be provided, again tailored to the individual’s potential for improvement or adaptation.

- **Treat symptoms.** Investigation and treatment of known medical problems should be appropriate for the individual (*Box 3.10*). Investigation and management of any new disease will follow the general principles as for other age groups but remembering that the frail elderly will have a high mortality in the year after admission.

---

**Box 3.10**

**Care of the frail elderly person: an example**

Mrs Jones is found to have a urinary tract infection, which responds well to oral antibiotics. An assessment demonstrates that her hearing aid needs changing and that her sight might be improved by anti-vascular epithelial growth factor injections for her macular degeneration. She no longer requires metformin and her statin is stopped, as it is no longer providing her with benefit. Rehabilitation with more mobility aids is enabling her to transfer from bed to chair and so get up during the day. She is found to have an abdominal mass but declines investigation of it beyond the CT scan. However, she does report that the mass is painful and she is referred to the hospital palliative care team. Her pain is easily controlled on a small regular dose of oral opioid and a community palliative care nurse specialist follows her up with primary care in her nursing home, where she dies 3 months later, without further admission.

- **Discuss the future sensitively.** Discussions about wishes for future care are complex with anyone who has life-threatening disease. They may not see themselves that way and assumptions should not be made about what frail elderly individuals want or how they view their health status. They may not feel that they are particularly ill or even that they have a poor prognosis, despite having reached a great age. General medical management needs to be integrated with symptom control. The SPC team should be contacted for advice or involved
with management when there are difficulties with this or with complex discussions with the individual or their family.

**Review the drug chart.** One feature of frailty is that patients are often taking large numbers of drugs, some of which may be causing disabling adverse effects without any immediate benefit for that individual's quality of life. Reviewing every drug with the patient may be very helpful in lessening symptom burden and may help reduce confusion and sedation.

In summary, palliative care should be available to everyone on the basis of need. It is frequently not offered to the frail elderly and symptoms are known to be both under-detected and under-treated in this group. Ensure this does not happen when you are caring for a frail elderly person. Contact the palliative care team for advice, even if referral for transfer of care is not necessary.

### Care of the Dying

Most people express a wish to die in their own homes, provided their symptoms are controlled and their carers are supported. However, patients die in any setting and so all healthcare professionals should be proficient in end-of-life care.

Reports of inadequate hospital care have led to the development of integrated pathways of care for the dying. Pathways act as prompts of care, including psychological, social, spiritual and carer concerns in those who are diagnosed as dying. The latter is a decision reached by a multiprofessional team through careful assessment of the patient and exclusion of reversible causes of deterioration.

**Do not attempt resuscitation (DNAR) orders**

- The resuscitation status of every patient should be discussed by senior doctors at the time of admission and the decision documented in the notes.

- Many hospitals have specific DNAR forms. Deciding a person's resuscitation status is a careful balance of risk versus benefit. The patient's co-morbidities and pre-morbid quality of
life should be taken into account.

- The patient and family should be involved in this discussion, and the medical reasoning behind the decision explained. If the patient requests that cardiopulmonary resuscitation is not performed in the event of cardiopulmonary arrest, those wishes should be respected.

  Remember that a decision not to resuscitate a patient is not the same as the decision to withhold other treatment. A patient who is not for resuscitation may still be eligible for antibiotics, fluids, endoscopy and even surgery. Management should remain positive, allowing the patient to die free of distress and with dignity.

**Care of the dying tools**

The Liverpool Care Pathway (LCP; **Box 3.11**) has come in for a great deal of criticism. It is a four-stage end-of-life tool designed to transfer the standard of hospice care of the dying into the hospital (see **Box 3.10**). Now adapted for any setting, it was the most commonly used pathway for care of the dying in the UK and is still in use in several other countries.

<table>
<thead>
<tr>
<th>Box 3.11</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Stages in the Liverpool Care Pathway— an end-of-life tool</strong></td>
</tr>
<tr>
<td>• Recognition of the dying phase</td>

</tr>
<tr>
<td>• Ongoing assessment and monitoring</td>
</tr>
<tr>
<td>• Care of the carers after the patient's death</td>
</tr>
</tbody>
</table>

The LCP has provision for departures from the ‘prompts of care’—for example, discontinuation of intravenous antibiotics or parenteral fluids—if a clinical need can be demonstrated. The patient is reviewed regularly (at least daily). Occasionally, the patient improves whilst on the pathway and can be returned to usual care if this is deemed more appropriate by the clinical team. For those who do not improve, the LCP prompts advanced prescription of medication to ease the symptoms most likely to arise in the dying phase (pain, breathlessness, nausea, agitation and excess respiratory secretions) to allow timely action.

Engagement with family and carers is vital, and it should not be assumed that they will recognize or understand the signs of imminent death. The LCP has supportive information leaflets that carers should find useful.

UK national hospital audits have assessed and monitored the level of care documented against the standards set in the LCP. However, following some well-publicized errors of implementation of the tool in the UK in 2013–2014, and in the face of a lack of randomized controlled trial evidence to support its use, the LCP was withdrawn and replaced by individual care plans outlined by the Leadership Alliance for the Care of Dying People. Since then, a
A cluster randomized trial of the LCP in cancer patients has reported no significant difference in overall quality of care, but did show improvements in coordination of care, treatment with dignity, family self-efficacy, and respect and information and decision-making.

Global health

Babulal Sethia, Parveen Kumar

Introduction

The discipline of ‘global health’ evolved from ‘international health’, which focused historically on the study and management of infectious tropical diseases. There is no universally agreed definition of ‘global health’ (GH). It is ‘an area of study, research and practice that places a priority on improving health and achieving equity in health for all people worldwide’. It recognizes that health is determined by problems, issues and concerns that transcend national boundaries, and looks at the healthcare needs of people across the world as well as in individual nations. Such needs are seen in high-, as well as low- and
middle-income countries (LMICs), but may be particularly acute, for example, during or after conflicts of war, with the consequences of population displacement or of direct trauma, including rape. Effective delivery of GH needs inevitably requires multidisciplinary collaboration between healthcare workers, politicians, economists and scientists in pursuit of both individual wellbeing and population-based prevention and care. Examples of successful interventions include campaigns for the provision of vaccines by the Global Alliance for Vaccines and Immunization (GAVI), and initiatives to reduce the economic exploitation of child labour. On the infection front, the African Programme for Onchocerciasis control has used the safe drug, ivermectin, which, as a single dose given annually, has transformed the lives of millions. Another example is the use of praziquantel for the eradication of schistosomiasis (bilharzia), one of the most common but neglected tropical diseases, initiated by the Schistosomiasis Control Programme and funded by many organizations.

The scale of the problem worldwide

Data published by the World Health Organization (WHO) in 2012 show that although life expectancy had increased by 6 years since 1990 (mean 70 years in males, range 62–79 years), several unacceptable facts remain true:

• Around 6.6 million children under the age of 5 years die each year.
• Preterm birth (before 37 weeks' gestation) accounts for >1 million deaths per year.
• Each day, 800 women die due to complications of pregnancy and childbirth.
• Cardiovascular diseases are the leading cause of death globally.
• Some 70% of deaths from the human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) occur in sub-Saharan Africa.
• Mental health disorders, such as depression, are amongst the 20 leading causes of disability worldwide.
• Tobacco kills nearly 6 million people each year (and is predicted to kill 8 million per year by 2030).
• Almost 1 in 10 people has diabetes.
• Nearly 1.24 million people die from road traffic accidents every year.

Millennium Development Goals

At the Millennium Summit in September 2000, world leaders from 189 countries adopted a
series of time-bound goals, to be achieved by 2015. Twenty-one targets were enshrined within the eight Millennium Development Goals (MDGs). These goals are listed in Figure 4.1.

![Millennium development goals](image)

The goals provided a focus for a major increase in GH investment from all countries, particularly for disease-specific entities (MDG 6: HIV/AIDS, malaria). However, critics have noted that much of the early financial investment for these commitments was used to defray existing debt in low- and middle-income countries (LMICs), whilst progress in the achievement of the targets by 2015 was very uneven. Furthermore, it has been suggested that failures in achievement of MDG targets was inevitably promoted by a lack of local participation in their original development (MDGs 1, 2 and 7). A significant deficiency in the MDGs was a failure to mention agriculture specifically, an essential component of the challenge to eradicate extreme hunger and poverty posed in MDG 1.

Notwithstanding a variety of criticisms, much progress in achieving parts of the MDGs was reported by 2014, as noted in the update issued by the WHO in 2014 (Box 4.1).

### Box 4.1

**Achievement of millennium development goals (MDGs)**

**key facts**

- Globally, the number of deaths of children under 5 years of age fell from 12.6 million in 1990 to 6.6 million in 2012
- In developing countries, the percentage of underweight children under 5 years old dropped from 25% in 1990 to 15% in 2012
- Births attended by a skilled health worker have increased globally, but still fewer than 50% of births are attended in the WHO African region
- Globally, new HIV infections declined by 33% between 2001 and 2012
- Existing cases of tuberculosis are declining, along with deaths among HIV-negative
The new set of goals, targets and indicators issued by the UN states are called **Sustainable Development Goals (SDGs)**, to be achieved by 2030. These demonstrate a wide-ranging and more integrated approach between the agreed goals, especially with regard to those that succeed MDGs 1, 2 and 7. There are 17 proposed goals incorporating 169 targets. They are worthy aims but may turn out to be unrealistic, as they cover a vast area for improvement (**Box 4.2**). Health is only explicitly mentioned in one target (Goal 3) and this emphasizes the fact that the concept of health is inextricably linked to the other major players like politics, economics and agriculture. Goal 3 has been expanded to be more explicit and includes nine targets and four additional targets that were missing from the MDGs. They now include non-communicable diseases, mental ill health, road accident injuries and universal health coverage (**Box 4.3**). The UN Secretary General, Ban Ki-moon, has offered conceptual guidance, suggesting six essential overarching SDG elements: ‘dignity, prosperity, justice, partnership, planet, people’.

**Box 4.2**

**Sustainable Development Goals: the 17 proposed aims**

1. End poverty in all its forms everywhere
2. End hunger, achieve food security and improved nutrition, and promote sustainable agriculture
3. Ensure healthy lives and promote wellbeing for all at all ages
4. Ensure inclusive and equitable quality education and promote life-long learning opportunities for all
5. Achieve gender equality and empower all women and girls. A target example: eliminating violence against women
6. Ensure availability and sustainable management of water and sanitation for all
7. Ensure access to affordable, reliable, sustainable and modern energy for all
8. Promote sustained, inclusive and sustainable economic growth, full and productive employment, and decent work for all
9. Build resilient infrastructure, promote inclusive and sustainable industrialization, and foster innovation
10. Reduce inequality within and amongst countries
11. Make cities and human settlements inclusive, safe, resilient and sustainable
12. Ensure sustainable consumption and production patterns
13. Take urgent action to combat climate change and its impacts
14. Conserve and sustainably use the oceans, seas and marine resources for sustainable development
15. Protect, restore and promote sustainable use of terrestrial ecosystems, sustainably manage forests, combat desertification and halt and reverse land degradation, and halt biodiversity loss
16. Promote peaceful and inclusive societies for sustainable development, provide access to justice for all and build effective, accountable and inclusive institutions at all levels
17. Strengthen the means of implementation and revitalize the global partnership for sustainable development

For the 169 targets enshrined within the goals, see http://www.un.org/sustainabledevelopment/.

Box 4.3

The nine main targets and four additional targets (3.a–d) of the Sustainable Development Goal for health (GOAL 3)

3.1. By 2030, reduce the global maternal mortality ratio to less than 70 per 100 000 live births
3.2. By 2030, end preventable deaths of newborns and children under 5 years of age, with all countries aiming to reduce neonatal mortality to at least as low as 12 per 1000 live births and under-5 mortality to at least as low as 25 per 1000 live births
3.3. By 2030, end the epidemics of AIDS, tuberculosis, malaria and neglected tropical diseases, and combat hepatitis, water-borne diseases and other communicable diseases
3.4. By 2030, reduce by a third premature mortality from non-communicable diseases through prevention and treatment, and promote mental health and wellbeing
3.5. Strengthen the prevention and treatment of substance abuse, including narcotic drug abuse and harmful use of alcohol
3.6. By 2020, halve the number of global deaths and injuries from road traffic accidents
3.7. By 2030, ensure universal access to sexual and reproductive healthcare services, including family planning, information, and education, and the integration of reproductive health into national strategies and programmes
3.8. Achieve universal health coverage, including financial risk protection, access to quality essential healthcare services, and access to safe, effective, quality and affordable essential medicines and vaccines for all
3.9. By 2030, substantially reduce the number of deaths and illnesses from hazardous chemicals and air, water, and soil pollution and contamination
3.a. Strengthen the implementation of the WHO Framework Convention on Tobacco Control in all countries, as appropriate
3.b. Support the research and development of vaccines and medicines for the communicable and non-communicable diseases that primarily affect developing countries, provide access to affordable essential medicines and vaccines in accordance with the Doha Declaration on the TRIPS Agreement and Public Health, which affirms the right of developing countries to use to the full the provisions in the TRIPS Agreement regarding flexibilities to protect public health, and, in particular, provide access to medicines for all.

3.c. Substantially increase health financing and the recruitment, development, training and retention of the health workforce in developing countries, especially in the least developed countries and small island developing states.

3.d. Strengthen the capacity of all countries, in particular developing countries, for early warning, risk reduction and management of national and global health risks.

---

**Global Burden of Disease**

In 2006, 90% of GH funds were spent in high-income countries that carried only 10% of the disease burden (*Fig. 4.2*). Clearly, the world faces many health challenges that are difficult to prioritize.

The Global Burden of Disease (GBD) Study 2010 provides critical data for guiding prevention and other interventions. This study is a worldwide collaboration across 302 institutions and has retrospectively reassessed the data from 1990, 2005 and 2010 using the same methodology, thus enabling accurate comparisons of health trends. This gives an understanding of the present and future health priorities for the global community and for individual countries. It was made possible by the introduction of a new metric in 2010, which gave a single measure to quantify the burden of diseases, injuries and risk factors. This disability-adjusted life year (DALY) metric allowed the comparison of burden across diseases, both untreated and treated, mortality, morbidity, disability, injuries and risk factors. DALYs measure health gaps, as opposed to health expectancies. They are derived from the calculation of the years of life lost due to early death (YLL) and years lived with disability (YLD).

\[
\text{DALY} = \text{YLL} + \text{YLD}
\]

Unfortunately, this GBD equation has some deficiencies and limitations. It does not, for example, address rapid transitions in GH, such as demographic changes, changes in causes of death, and changes in causes of disability. DALYs do not identify the transitional demographic changes of increases in population number, and of population age. A change in DALYs, whilst a potentially useful indicator of health outcomes, must therefore be interpreted with care. Both a decrease and an increase in DALYs may reflect improved outcomes. A decrease in DALYs for maternal and neonatal deaths can be accounted for by better education, nutrition or obstetric facilities. However, an increase in DALYs is seen when an ageing population requires treatment for chronic ill health, despite a reduction in mortality.

**Further reading**

**Poverty**

More than 3 billion people, nearly half of the world population, live in poverty (defined as living on less than US$2.50 per day), and more than 1.3 billion individuals receive less than US$1.25 per day (extreme poverty). Some 1 billion children worldwide live in poverty.

In ‘The Future We Want’, the outcome document of the 2012 Rio + 20 Conference on the Sustainable Development Agenda, the need to accord the highest priority to poverty eradication was agreed. The 2016 SDGs (see Box 4.2) include five goals (SDGs 1, 2, 12, 13 and 15) relating to this ambition.

**Poverty, hunger, agriculture and climate change**

These issues are inextricably interdependent. Food production is compromised when
Agricultural land is directed towards alternative uses, such as industrial development. On the other hand, 25% of food is wasted in LMICs by crop deterioration due to deficiencies in transport and storage. The UK and US together waste approximately US$81 billion of food each year.

In 2009, the UCL–Lancet Commission on ‘Managing the Health Effects of Climate Change’ called climate change ‘the biggest global health threat of the 21st century’. Changes in climate pose major threats to human health, either directly (heatwaves, floods, droughts), or indirectly (agricultural losses, mass migration). For example, a 1° rise in mean temperature in India would result in the loss of 7 million tons of wheat (Fig. 4.3). By limiting the use of fossil fuels and reducing carbon emissions, it is possible to avoid a potentially catastrophic rise in global temperature (Fig. 4.4). Urgent action is essential if the gains in GH and development of the last 50 years are to be maintained.
Pain and suffering, especially in LMICs, is often caused by the catastrophic expenditure associated with chronic illness and disease. Every year, as many as 150 million people face financial catastrophe as a result of having to pay for health care.

**Further reading**

[http://www.grida.no/publications/ The Environmental Food Crisis.](http://www.grida.no/publications/)

**Water and Sanitation**

Poor water, sanitation and hygiene are major causes of early mortality, particularly in children. In 2010, 11% of the world population lacked access to clean water supplies. WHO/UNICEF defined an improved water supply as ‘one that, by nature of its construction or through active intervention, is protected from outside contamination, in particular from contamination with faecal matter’. The statement also stipulated that each person should have access to at least 20 L of water per day from a source within 1 km of the user's dwelling.

The target to halve the proportion of people without sustainable access to safe drinking water and basic sanitation by 2015 (MDG 7) was not met. One in five people still defecates in the open, and 13% live where water is collected from unprotected sources. Some of the other consequences of inadequate sanitation are listed in **Box 4.4**. It is clear that most of the mortality resulting from poor sanitation and unsafe drinking water is preventable.
Box 4.4

Sanitation

- 2.5 billion people lack adequate sanitation
- Open defecation results in the death of >750,000 children under 5 years of age annually
- 80% of diseases in LMICs are caused by poor sanitation/unsafe water
- More than 7 out of 10 people without improved sanitation were rural inhabitants (2006)
- Every $1 spent on sanitation brings a $5.5 return by keeping people healthy and productive
- Improvement in sanitation could save 1.5 million children each year.

LMICs, low- and middle-income countries.

Water is usually collected by women, often from distant sources; this can be a hazardous journey, as the women are unprotected and open to abuse. A secondary effect of improved access to water is that the time saved in collecting water can now be spent on income generation, food production, education and activities that can lead to social and health benefits.

Organizations and the Global Health Agenda

International support for GH initiatives may be directed at disease-specific projects (vertical care models) or allied to national health system development. Some of the vast number of organizations active in these areas are listed in Box 4.5. The contributions of these bodies overlap considerably but cover the key areas for health development and infrastructural support, including the response to emergency situations (war and natural disasters). The areas encompass service delivery, patient care, education and training, research, equipment, medicines and human resources. Investment in healthcare systems promotes public health benefit by the provision of vaccination, hygiene and sanitation, as well as major infrastructural projects including technology and communications, such as building roads.

Box 4.5

Some organizations involved in global aid

International organizations

- World Health Organization (WHO)
- Global Fund to fight AIDS, Tuberculosis and Malaria
Empowering the local population to help themselves by delivering local appropriate education is of paramount importance. Global Health through Education Training and Service
(GHETS) is an American non-governmental, non-profit organization that works with a network of medical and nursing schools to increase the number of locally trained, primary healthcare workers. These schools build community-based clinics in rural and urban areas.

---

**Education**

Education has a major impact on the health of a nation. There is evidence to suggest that the more years spent in schooling, the better the health outcomes. Literacy and, in particular, health literacy can have a major impact on nutrition and the control of disease: for example, by the simple process of hand washing. Education helps to promote healthier lifestyles, both by improving nutrition and development, and by reducing the risks associated with infectious diseases. As a result, unemployment falls whilst family and community wellbeing is improved.

Women have a crucial role in the welfare of their families and the development of a country's good health. Traditionally, women have a lower social status in societies where they are suppressed. Nevertheless, it is they who have the dominant impact on the health of the family and the wellbeing of children. They shoulder all the demands of child care, and of care of the elderly and the sick, as well as all household responsibilities.

Approximately 25% of girls in ‘developing countries’ become mothers before the age of 18. These pregnancies have a high rate of deaths from complications of pregnancy and childbirth. The cost to a country's economy of adolescent pregnancy, as a share of gross domestic product, can be as high as 30%. The education and welfare of women should be major issues in any developing society, as they reduce poverty and aid a country's development.

**Further reading**

---

**Maternal Health and Child Health**

Maternal health (see also Ch. 29)
Women remain disadvantaged in many parts of the world. Every second, 380 women become pregnant, 190 women face unplanned or unwanted pregnancy (e.g. from rape), 110 women experience a pregnancy-related complication, 40 women have an unsafe abortion, and 1 woman dies from a pregnancy-related complication. These stark data support the arguments for women to control their own health and fertility.

Of major concern, 303,000 women die in childbirth every year and 80% of these deaths are avoidable (WHO). Maternal mortality figures are more than 100 times greater in low-income countries (LICs) compared to higher-income countries (HICs). The risk of dying in pregnancy varies from 1 : 8 in Mali, compared to 1 : 17,400 in Sweden. The major medical causes of death are haemorrhage, hypertensive disease of pregnancy and infections. Haemorrhage can be intra- or pre-partum, when the most common cause is placental abruption, or postpartum, when the uterus fails to contract, causing fatal haemorrhage. Hypertensive disease can be complicated by pre-eclampsia (see p. 1303). Infections can be caused, for example, by bacteria, HIV, malaria and syphilis. Obstructed labour is another potentially fatal complication and can be due to the fibrosis caused by female genital mutilation (FGM), traditionally practised in some countries. As most maternal and neonatal deaths occur around delivery, the need for basic and emergency care around the time of labour and delivery is paramount. The presence of a skilled birth attendant has been shown to reduce both maternal and neonatal mortality in many LMICs.

**Child health**

Globally, the under 5 years mortality rate has fallen mainly due to the prevention of pneumonia, diarrhoea and malaria by organizations and governments working together. Nevertheless, over 50% of these deaths could have been prevented by access to simple and affordable interventions. Most of these deaths are caused by pre-term complications, birth asphyxia, diarrhoea, pneumonia and malaria. Almost half are linked to malnutrition. These children die from common, otherwise non-fatal, childhood ailments. Deaths in children under 5 years of age are mainly concentrated in Southern Asia and in sub-Saharan Africa, where children are 15 times more likely to die compared with children in developed regions. In the rest of the world, mortality figures dropped from 32% (1990) to 18% (2013; WHO).

**Vaccination**

The World Health Assembly produced a framework to prevent millions of deaths by more equitable access to vaccines, and adopted a ‘Decade of Vaccines Global Vaccine Action Plan 2011–2020’. GAVI plays a critical role in this area by financing and facilitating delivery of vaccine platforms. By 2013, it had immunized 440 million additional children and prevented 6 million future deaths.

**Child labour**

The global number of children engaged in child labour declined by one-third between 2000 and 2012 (246 million dropping to 168 million). More than half (85 million) are engaged in
hazardous work. Agriculture remains the most important sector utilizing child labour (98 million).

**Child nutrition**

Improving child nutrition remains a global imperative. According to data from UNICEF (2013), stunting affects 165 million children under 5 years of age. This problem can be mitigated by interventions during maternal pregnancy and before the child is 2 years old.

**Further reading**

**Mental Health**

Mental health (including psychological and neurological problems) constitutes 13% of the Global Burden of Disease (GBD). This exceeds the figures for cardiovascular disease and cancer.

Depression represents a major clinical challenge with 350 million patients worldwide. It is the third commonest contributor to GBD. Alcohol and illicit drug misuse account for >5% of the global mental health burden. Additionally, it is estimated that suicide will account for 1.5 million deaths each year by 2020, with a further 15–30 million people attempting suicide.

Globally, the incidence of dementia is accelerating and 7.7 million new cases occur each year. This increased burden disproportionately affects low- and middle-income countries, where resources are few. All of this represents a major worldwide financial burden.

**Further reading**

Accidents and Trauma

We are currently in the midst of a global trauma epidemic. It is estimated that 5.8 million people die each year as a result of injury and trauma. At least 2 million of these deaths are potentially avoidable.

Injuries are a significant and increasing cause of mortality and morbidity; more than 90% of injury-related deaths occur in LMICs.

Around 5 billion people do not have access to safe, affordable surgical and anaesthesia care when needed, particularly in LMICs. Many of those who do access care risk personal financial ruin. The WHO estimates that, by 2030, trauma from road traffic accidents will be the third most common cause worldwide of both mortality and disability (as measured in DALYs).

The Guidelines for Essential Trauma Care (WHO 2004) have established a core list of 11 essential trauma care services (Box 4.6). The implementation of these recommendations has been hampered by deficiencies in planning and infrastructure that need to be addressed by national governments.

Further reading

Box 4.6

International guidelines for essential trauma care (‘rights of the injured’)

- Obstructed airways cleared and maintained
- Impaired breathing supported until the injured person is self-ventilating
- Pneumothorax and haemothorax promptly relieved
- Bleeding stopped promptly
- Shock recognized and treated with intravenous fluid replacement
- Traumatic brain injury treated with timely decompression of space-occupying lesions
- Intestinal and other abdominal injuries promptly addressed
- Disabling extremity injuries corrected
- Unstable spinal cord injuries managed appropriately with early immobilization
- Appropriate rehabilitative services available
- Medications for the above and for pain control readily available

Conflict and Catastrophe

Recent years have seen a number of natural disasters; examples include earthquakes in Haiti (2010) and Nepal (2015), the Sri Lanka tsunami (2004), and typhoon Haiyan in the Philippines (2013). Conflicts also persist in Syria, South Sudan, the Ukraine and numerous other parts of the world. Effective global action following these unexpected events is frequently compromised by deficiencies in the disaster response, including the provision of inappropriate resources and inexperienced personnel. Many such deficiencies can be rectified by appropriate training in disaster response. Other elements of an effective international response must address long-term restructuring issues. Following conflict, regulation of the trade in armaments is critical.

Conflicts and catastrophes severely disrupt healthcare provision, especially for women and children. The use of rape as a weapon of war magnifies this tragedy. Furthermore, disruption to education, together with the physical sequelae of conflict, leads to increased long-term societal healthcare burdens, especially in the field of mental health.

Economics and Politics in Global Health

Funding for initiatives in the GH development of LMICs (also known as Development Assistance for Health, DAH) has, historically, originated from multiple sources (see Box 4.5). Whilst these initiatives may have been beneficial for some specific diseases like malaria (see pp. 297–301), tuberculosis (pp. 1106–1113) and HIV/AIDS (pp. 331–355), health systems development has frequently lagged behind such high-profile schemes. The consequences of this were seen in the slow response of the WHO and others to the 2014 outbreak of Ebola in Africa.

Improvements in healthcare result in economic growth. For example, a 10% reduction of malaria in endemic areas is associated with a 0.3% increase in GDP. Treatment of HIV-positive patients with anti-retroviral drugs results in net economic benefit through increased productivity and a reduction in medical care treatment costs. A failure to invest in health and health systems is a threat to future global prosperity, particularly in poor countries. As an example, surgery is currently a neglected component of health systems and it is estimated that 5 billion people currently lack access to safe, affordable surgical and anaesthesia care when needed. The cumulative loss of economic productivity between 2015 and 2030, in the absence of a significant scaling up of global surgical services, is estimated at US$12.3 trillion.

Political decisions regarding investment in healthcare and health systems also need to focus on infrastructure, including food and agriculture, the environment and human rights issues, especially the rights of women. In essence, the pursuit of ‘pro-poor’ policies that place the poor at the centre of development policy is essential for future global prosperity.

Further reading
Social Determinants of Health

The drivers of health inequities reside in the social, economic and political environments. The WHO (2008) defined the social determinants of health as ‘the conditions in which people are born, grow, live, work, and age. These circumstances are shaped by the distribution of money, power and resources at global, national and local levels.’ The social gradient of health follows the socioeconomic pattern from the top to the bottom. In general, the lower the individual is within their socioeconomic position, the worse their health; this is seen globally in HICs, as well as LMICs. The socioeconomic status of a person is their social position in society and this is determined by their education, income and occupation.

There is now clear evidence to justify national policies that aim to reduce health inequity and the health divide across all countries. It has also been suggested that reduction in health inequities should become one of the main criteria used to assess the effectiveness of health systems and governments as a whole.

Human Rights and the Value of Engagement in Global Health

The Universal Declaration of Human Rights (1948), whilst not legally binding, serves as a ‘common standard for all peoples and all nations’. It has given rise to two new legally binding covenants: the International Covenant on Civil and Political Rights and the International Covenant on Economic, Social and Cultural Rights.

The WHO is a specialized agency of the United Nations with a remit for international public health. Its constitution enshrines ‘the highest attainable standard of health’ as a fundamental right of every human being. The right to health contains four elements: availability (of programmes of public health), accessibility (of health facilities and services in a non-discriminating fashion), acceptability (ethical and cultural requirements), and good-quality care.
There is a worldwide shortage of healthcare workers from all disciplines (Fig. 4.5). Engagement in GH challenges helps to promote patterns of behaviour that benefit healthcare workers, as well as the recipients of their endeavours. Altruistic behaviours, team-working and appreciation of cultural diversity are but a few benefits of participation in GH challenges.

**Medical electives**

Both medical students and doctors may undertake periods of time visiting and working in unfamiliar environments, often in other countries. This is mutually beneficial to all participants, provided that a culture of shared learning is embraced. All such visits should have clear objectives and measurable educational outcomes. Pre-departure preparation should include consideration of culture, ethical challenges and security issues. All visitors must work within their approved competencies and comply with national guidance on good medical practice. It is essential for the appropriate processes for bipartite support and supervision to be secure.

Maximum benefit is achieved when there is a mutual commitment to long-term partnership. This type of experience promotes personal altruistic behaviours.

Disease and the Environment

The incidence and prevalence of disease and causes of death within a community are a reflection of interrelated factors:

- Genetic predisposition.

- **Nutrition, poverty and affluence** (see p. 183), some countries having a grossly uneven distribution between rich and poor. This leads to chronic disease such as diabetes and obesity mainly in the cities, with malnutrition and infectious disease in the rural areas.

- Purity of water sources and sanitation facilities (see p. 47).

- Atmospheric pollution.

- Environmental disasters and accidents.

- Background ionizing radiation and man-made radiation exposure, deliberate or accidental.

- Environmental temperature.

- Patterns of infective disease (see p. 222).

- Political forces determining levels of healthcare, preventative strategies and effects of war on civilian populations (see p. 49).

Some of these environmental effects have been clearly documented within the last decade: for example, the massive civilian mortality and morbidity during the Afghan war, previous Iraq wars and current military action in the Middle East. Loss of life and disease prevalence following the 2006 tsunami, the earthquakes in Szechuan (2008) and Haiti (2010), and cyclone Nargis in the Irawaddy delta have been huge. Aspects related to global health are discussed in more detail in Chapter 4.

Flooding caused by El Niño in East Africa resulted not only in an increase in breeding sites for mosquito vectors but also in a major outbreak of Rift Valley fever due to the enforced close proximity of cattle and humans.

Tobacco use (active and passive), obesity (see pp. 206–212) and excess alcohol consumption also play a significant role in disease. Physical inactivity has an effect on mortality that is equivalent to tobacco use or obesity. Worldwide health programmes have been established in most countries to reduce these effects.

**Further reading**

Environmental Temperature

Climate change is an unquestionable phenomenon due mainly to increased carbon dioxide production and changes in our habitat.

The effect of environmental temperature ($T_{Env}$) is paramount in infective diseases; increases
as small as 1°C cause major changes in disease vectors. Patterns of infective disease are likely to change radically within the next 20 years. Climate effects are already becoming apparent, such as:

- changes in the patterns of malaria in South-east Asia
- the occurrence of dengue fever in southern Italy
- outbreaks of cholera, and seasonal variation in diarrhoea and vomiting.

Research into the effect of climate change on the changing patterns of infective diseases will point to potential ways in which national and international efforts can be targeted.

**Heat Injury**

Body core temperature (T\text{Core}) is maintained at 37°C by the thermoregulator centre in the hypothalamus, which integrates information from skin temperature sensors with core temperatures from receptors in the brain and in the walls of large blood vessels.

Heat is produced by cellular metabolism and is dissipated through the skin by both vasodilatation and sweating, and in expired air via the alveoli. When the environmental temperature (T\text{Env}) is >32.5°C, profuse sweating occurs.

*Sweat evaporation* is the principal mechanism for controlling T\text{Core} following exercise or in response to an increase in T\text{Env}.

*Heat acclimatization* takes place over several weeks. The sweat volume increases and the sweat salt content falls. Increased evaporation of sweat reduces T\text{Core}.

---

**Heat cramps**

Painful muscle cramps, usually in the legs, often occur in fit people when they exercise excessively, especially in hot weather. Cramps are probably due to low extracellular sodium caused by excess intake of water over salt. They can be prevented by increasing dietary salt. They respond to combined salt and water replacement, and in the acute stage to stretching and muscle massage. T\text{Core} remains normal.

---

**Heat exhaustion**

At any environmental temperature (especially with T\text{Env} of >25°C), and with a high humidity, strenuous exercise in clothing that inhibits sweating, such as a wetsuit or military uniform, can cause an elevation in T\text{Core} in less than 15 minutes. Weakness/exhaustion, cramps, dizziness and syncope, with T\text{Core} >37°C, define heat exhaustion. Elevation of T\text{Core} is more critical than water and sodium loss. Heat exhaustion may progress to heat stroke, a serious emergency (see below).
**Management**

Reduce ($T_{\text{Env}}$) if possible and cool the patient with sponging and fans. Give $O_2$ by mask. Other causes of high $T_{\text{Core}}$, such as malaria, should be ruled out if appropriate.

Oral rehydration with both salt and water (25 g of salt per 5 L of water/day) is given in the first instance, with adequate replacement thereafter. In severe heat exhaustion, intravenous fluids are needed; 0.9% saline is given. Monitor serum sodium and correct secondary potassium loss.

**Heat stroke**

Heat stroke is an acute life-threatening situation in which $T_{\text{Core}}$ rises $>41^\circ$C. There is headache, nausea, vomiting and weakness, progressing to confusion, coma and death. The skin *feels* intensely hot to the touch. Sweating is often absent but not invariably so.

Heat stroke can develop in unacclimatized people in hot, humid, windless conditions, even without exercise. Sweating may be limited by prickly heat (plugging or rupture of the sweat ducts, leading to a pruritic, papular, erythematous rash).

Excessive exercise in inappropriate clothing, such as exercising on land in a wetsuit, can lead to heat injury in temperate climates. Diabetes, alcohol and drugs, such as antimuscarinics, diuretics and phenothiazines, can contribute. Heat stroke can lead to a fall in cardiac output, lactic acidosis and intravascular coagulation.

**Prevention**

Acclimatization, fluids, avoidance of inappropriate clothing and common sense are required.

**Management**

- Apply standard life support measures (ABCDE).
- Reduce $T_{\text{Env}}$ if possible.
- Arrange cold water immersion if facilities are available. Otherwise, cool the patient with sponging, icepacks or fanning.
- Give $O_2$ by mask.
- Move the patient to a medical facility. Manage in intensive care: monitor cardiac output and respiration; measure biochemistry, clotting and muscle enzymes.
- Give fluids intravenously so the intravascular volume remains normal.

Prompt treatment is essential and can be curative, even with a $T_{\text{Core}}$ of $>41^\circ$C. Morbidity and mortality are directly related to the duration of the high $T_{\text{Core}}$.

Complications are hypovolaemia, intravascular coagulation, cerebral oedema, rhabdomyolysis, and renal and hepatic failure.
Cold Injury

Cold injury may be divided into hypothermia, which is whole-body cooling, and peripheral cold injury (Box 5.1).

Box 5.1

Cold injury

- Hypothermia is defined as a core temperature of <32°C
- Peripheral cold injury includes:
  - Frostbite: the local cold injury that follows freezing of tissue
  - Non-freezing cold injury: the damage – usually to feet – following prolonged exposure to a $T_{Env}$ between 0° and 5°C, usually in damp conditions

Hypothermia

Hypothermia occurs in many settings.

At home. Hypothermia can occur when $T_{Env}$ is <8°C, if there is poor heating, inadequate clothing and poor nutrition. Depressant drugs, such as hypnotics, as well as alcohol, hypothyroidism or intercurrent illness also contribute. Hypothermia is commonly seen in the poor, frail and elderly. The elderly have a diminished ability to sense cold and also have little insulating fat.

Neonates and infants become hypothermic rapidly because of a relatively large surface area in proportion to subcutaneous fat.

Outdoors on land. Hypothermia is a prominent cause of death in climbers, skiers and polar travellers, and in wartime. Wet, cold conditions with wind chill, physical exhaustion, injuries and inadequate clothing are contributory. Babies and children are at risk because they cannot take action to warm themselves.

Cold water immersion. Dangerous hypothermia can develop following immersion for more than 30 min to 1 hour in water temperatures of 15–20°C. In $T_{Water}$ <12°C, limbs rapidly become numb and weak. Recovery takes place gradually, over several hours following rescue.
**Clinical features**

Mild hypothermia \( T_{Core} < 32^\circ C \) causes shivering and initially intense discomfort. However, the hypothermic subject, though alert, may not act appropriately to rewarming: for example, by huddling, wearing extra clothing or exercising. As the \( T_{Core} \) falls below 32°C, severe hypothermia causes impaired judgement – including lack of awareness of cold – and drowsiness and coma. Death follows, usually from ventricular fibrillation.

**Diagnosis**

Diagnosis is straightforward, if a low-reading thermometer is available. If not, rapid clinical assessment is reliable. Someone who *feels* icy to the touch – abdomen, groin, axillae – is probably substantially hypothermic. If the person is clammy, uncooperative or sleepy, \( T_{Core} \) is almost certainly <32°C.

**Sequelae**

Pulse rate and systemic blood pressure fall. Cardiac output and cerebral blood flow are low in hypothermia and can fall further if the upright position is maintained or the thorax restrained by a harness, or by hauling during evacuation. This is why helicopter and lifeboat winch rescues are often carried out with a stretcher rather than a chest harness.

Respiration becomes shallow and slow. Muscle stiffness develops; tendon reflexes become sluggish, then absent. As coma ensues, pupillary and other brainstem reflexes are lost; pupils are fixed and may be dilated in severe hypothermia. Metabolic changes are variable, with either metabolic acidosis or alkalosis. Arterial \( PO_2 \) may appear normal: that is, falsely high.

There is shift of the oxygen dissociation curve (see p. 90) to the left because of the reduction in temperature of haemoglobin. Thus, if an arterial blood sample from a hypothermic patient is analysed at 37°C, the \( PO_2 \) will be falsely high. Within the range 37–33°C, this factor is around 7% per degree centigrade. Many blood gas machines also calculate the arterial saturation; this too will be falsely high. When a patient is monitored using a pulse oximeter, the level of arterial oxygen saturation \( (S_aO_2) \) will, however, be correct, but if \( S_aO_2 \) is then converted by calculation to \( P_aO_2 \), a downward correction must be applied – simply due to hypothermia.

Bradycardia with ‘J’ waves (above the isoelectric line at the junction of the QRS complex and ST segment; *Fig. 5.1*) are pathognomonic of hypothermia. Prolongation of PR and QT intervals and the QRS complex also occurs. Ventricular dysrhythmia (tachycardia/fibrillation) or asystole is the usual cause of death.
Management

- Maintain the patient horizontal or slightly head-down.
- Rewarm gradually.
- Correct metabolic abnormalities.
- Anticipate and treat dysrhythmias.
- Check for hypothyroidism (see pp. 1202–1204).

If the patient is awake, with a core temperature of $>32^\circ$C, place in a warm room, use a foil wrap and give warm fluids orally. Outdoors, add extra dry clothing, huddle together and use a warmed sleeping bag. Rewarming may take several hours. Avoid alcohol: this adds to confusion, boosts confidence factitiously, causes peripheral vasodilatation and further heat loss, and can precipitate hypoglycaemia.

Severe hypothermia

In severe hypothermia, people look dead. Always exclude hypothermia before diagnosing brainstem death (see p. 1172). Warm gradually, aiming at a $1^\circ$C/hour increase in $T_{\text{Core}}$. Direct mild surface heat from an electric blanket can be helpful. Treat any underlying condition promptly, such as sepsis. Monitor all vital functions. Correct dysrhythmias. Check for sedative drugs.

Give warm intravenous fluids slowly. Correct metabolic abnormalities. Hypothyroidism, if present, should be treated with liothyronine. Various methods of artificial rewarming exist: inhaled warm humidified air, gastric or peritoneal lavage, and haemodialysis. These are rarely used. Hypothermia is frequently lethal when $T_{\text{Core}}$ falls below 30°C. Survival with full recovery has, however, been recorded with a $T_{\text{Core}}$ of $<16^\circ$C.

Prevention
Hypothermia in the field can often be prevented by forethought and action. For the elderly, improved home heating and insulation, central heating in bedrooms and electric blankets are helpful in cold spells. This can be expensive and unaffordable for some people, so supplemental finance is required.

Peripheral cold injury

Frostbite

Ice crystals form within skin and superficial tissues when the temperature of the tissue ($T_{\text{Tissue}}$) falls to $−3{^\circ}\text{C}$: $T_{\text{Env}}$ generally must be below $−6{^\circ}\text{C}$. Wind chill is frequently a factor. Typically, fingers, toes, nose and ears become frostbitten.

Frostbitten tissue is pale, greyish and initially doughy to the touch. Later, tissue freezes hard, looking like meat from a freezer. Frostbite can easily occur when working or exercising in low temperatures and typically develops without the patient's knowledge. Below a $T_{\text{Env}}$ of $5{^\circ}\text{C}$, hands or feet that have lost their feeling are at risk of cold injury.

Management

Transport the patient – or if this is impossible, make them walk, even on frostbitten feet – to a place of safety before commencing warming. Warm the frozen part by immersion in hand-hot water at 39–42°C, if feasible. Assess hypothermia. Continue warming until obvious thawing occurs; this can be painful. Vasodilator drugs have no part in management. Blisters form in a few days and, depending on the depth of frostbite, a blackened shell – the carapace – develops as blisters regress or burst. Dry, non-adherent dressings and aseptic precautions are essential, though hard to achieve. Frostbitten tissues are anaesthetic and at risk from further trauma and infection. Recovery takes place over many weeks and may be incomplete. Surgery may be needed, but should be avoided in the early stages.

Chilblains

These are small, purplish itchy inflammatory lesions, occurring on toes and fingers. They occur in cold, wet conditions. They are more common in women and heal in 7–14 days. Prevention is by keeping warm and wearing gloves and warm footwear.

Non-freezing cold injury

Non-freezing cold injury (NFCI, trench foot) describes tissue damage following prolonged exposure, usually for several hours or more, at $T_{\text{Env}}$ around or slightly above freezing, but without frostbite. Wet socks and boots are the usual cause. There is severe vasoconstriction, and blotchiness of the lower limbs, with pain and oedema on rewarming. Recovery usually
follows over several weeks. There may be a prolonged late susceptibility to cold. NFCI is a prominent cause of morbidity in troops operating in low temperatures and is a subsequent cause of litigation.

**Prevention** of frostbite and NFCI is largely by education and common sense: avoid damp feet and wet boots. Always carry spare dry socks, gloves and headgear.

**Further reading**

**High Altitude**
The partial pressure of atmospheric oxygen – and hence alveolar and arterial oxygen – falls in a near-linear relationship as barometric pressure drops with increasing altitude (Fig. 5.2).

![FIGURE 5.2 The decrease in oxygen and barometric pressure with increasing altitude.](image)

**Commercial aircraft** are pressurized to around 24 000 m (lowering the oxygen saturation by 3–4%). This trivial reduction is not noticed by healthy individuals. Air travel is discussed on page 61.

**On land**, below 3000 m there are few clinical effects. The resulting hypoxaemia causes breathlessness only in those with severe cardiorespiratory disease. Above 3000–3500 m, hypoxia causes a spectrum of related syndromes that affect high-altitude visitors, principally
climbers, trekkers, skiers and troops (Box 5.2), especially when they exercise. These conditions occur largely during acclimatization, a process that takes several weeks; once completed, this can enable humans to live – permanently, if necessary – up to about 5600 m. At greater heights, although people can survive for days or weeks, deterioration due to chronic hypoxia is inevitable.

### Box 5.2

</table>

The world's highest railway runs to Lhasa in Tibet, reaching altitudes of over 5000 m. Emergency oxygen is provided in the carriages. Roads at similar altitudes in Central Asia are used extensively but since road passengers do not exercise, serious altitude-related illnesses are unusual. Climbing the world's highest summits is just possible without supplementary oxygen, though it is often used on peaks above 7500 m. At the summit of Mount Everest (8848 m), the barometric pressure is 34 kPa (253 mmHg). An acclimatized mountaineer has an alveolar $PO_2$ of 4.0–4.7 kPa (30–35 mmHg) – near humans' absolute physiological limit. In 2007, arterial blood samples from acclimatized doctors on Everest at altitude 8400 m, breathing air, showed an average $PO_2$ of 24.6 mmHg (3.3 kPa).

### Acute mountain sickness

Acute mountain sickness (AMS) describes malaise, nausea, headache and lassitude that affect the majority of people for a few days, above 3500 m. Following arrival at this altitude, there is usually a latent interval of 6–36 hours before symptoms begin. Treatment is rest, with analgesics if necessary. Recovery is usually spontaneous over several days.

Prophylactic treatment with acetazolamide, a carbonic anhydrase inhibitor and respiratory stimulant, is of some value in preventing AMS. Acclimatizing – that is, ascending gradually – provides better and more natural prophylaxis.

In the minority, more serious sequelae – high-altitude pulmonary oedema and high-altitude cerebral oedema – develop.
**High-altitude pulmonary oedema**

Predisposing factors include youth, rapidity of ascent, heavy exertion and severe AMS. Breathlessness, occasionally with frothy blood-stained sputum, indicates established oedema. Unless treated rapidly, this leads to cardiorespiratory failure and death. Milder forms are common. Breathlessness at rest should raise the suspicion of pulmonary oedema.

**High-altitude cerebral oedema**

Cerebral oedema is the result of an abrupt increase in cerebral blood flow that occurs even at modest altitudes of 3500–4000 m. It is unusual below 4500 m, and occurs typically in the first 2 weeks, during acclimatization. Cerebral oedema can also develop suddenly in well-acclimatized climbers above 7000 m. Headache is followed by drowsiness, ataxia and papilloedema, with coma and death if brain oedema progresses.

**Management**

Any but the milder forms of AMS require urgent treatment. Oxygen should be given by mask if available, and descent should take place as quickly as possible. Nifedipine reduces pulmonary hypertension and is used in pulmonary oedema. Dexamethasone is effective in reducing brain oedema. Portable pressure bags inflated by a foot pump are widely used; the patient is enclosed in the bag.

**Retinal haemorrhage**

Small flame haemorrhages within the retinal nerve fibre layer are common above 5000 m and usually symptomless. Rarely, a haemorrhage will cover the macula, causing painless loss of central vision. Recovery is usual.

**Deterioration**

Prolonged residence between 6000 and 7000 m leads to weight loss, anorexia and listlessness after several weeks. Above 7500 m, the effects of deterioration become apparent over several days, although it is possible to survive for a week or more at altitudes near 8000 m without supplementary oxygen.

**Chronic mountain sickness**

Chronic mountain sickness occurs in long-term residents at high altitudes, usually after several decades, and is seen in the Andes and in Central Asia. Headache, polycythaemia, lassitude, cyanosis, finger clubbing, congested cheeks and ear lobes, and right ventricular enlargement develop. Chronic mountain sickness is gradually progressive.
Coronary artery disease and hypertension are rare in high-altitude native populations.

Diving

Free diving by breath-holding is possible to around 5 m, or with practice to greater depths. Air can be supplied to divers by various methods.

A *snorkel* provides air to a depth of about 0.5 m; inspiratory effort is the limiting factor. At depths >0.5 m – that is, with a longer snorkel tube, forced negative-pressure ventilation can cause pulmonary capillary damage with haemorrhagic alveolar oedema.

*Scuba divers* – recreational sports divers descending to 30 m – carry bottled compressed air or a nitrogen–oxygen mixture.

*Commercial divers* who work at great depths breathe helium–oxygen or nitrogen–oxygen mixtures, delivered by hose from the surface.

Ambient pressures at various depths are shown in *Box 5.3*.

</tbody>
</table>
Problems during descent

*Middle ear barotrauma (squeeze)* is common and is due to an inability to equalize pressure in the middle ear; Eustachian tube blockage is the usual cause. Pain and hearing loss occur, sometimes with tympanic membrane rupture and acute vertigo.

*Sinus squeeze* is intense local pain due to blockage of the nasal and paranasal sinus ostia.

*Management* is by holding the nostrils closed and swallowing, or similar manoeuvres, as well as use of decongestants. Diving with a respiratory or sinus infection should be avoided.

### Oxygen narcosis

Pure oxygen is not used for diving because of oxygen toxicity. Lung atelectasis, endothelial cell damage and pulmonary oedema occur when alveolar oxygen pressure exceeds 1.5 atmospheres, at depths of around 5 m. At around 10 m, the central nervous system (CNS) becomes affected: apprehension, nausea and sweating are followed by muscle twitching and generalized convulsions.

### Nitrogen narcosis

When compressed air is breathed below 30 m, the narcotic effects of nitrogen begin to impair brain function. Poor judgement is hazardous; this also occurs with nitrogen–oxygen mixtures in recreational diving. Nitrogen narcosis is avoided by replacing air with helium–oxygen mixtures, enabling descent to 700 m. At these extreme depths, the direct effect of pressure on neurones can cause tremor, hemiparesis and cognitive impairment.

Problems during and following ascent

Free divers who breath-hold often hyperventilate deliberately prior to plunging in. This drives off CO$_2$, reducing the stimulus to inspire. During the subsequent breath-hold, $P_a$CO$_2$ rises and $P_a$O$_2$ falls. On surfacing, decompression lowers $P_a$O$_2$ further. This can lead to syncope, known as a *shallow water blackout*. Since loss of consciousness can take place in the water, this can lead to fatalities.

### Decompression sickness

Decompression sickness (the bends) is caused by the release of bubbles of nitrogen or helium and follows too rapid a return to the surface. Decompression tables indicate the duration for safe return from a given depth to the surface. In general, no decompression is necessary for diving above 30 m; at 30–60 m, decompression is necessary.

Bends can be mild (*type 1, non-neurological bends*), with skin irritation and mottling and/or joint pain. *Type 2, neurological bends*, are more serious and involve the development of cortical blindness, hemiparesis, sensory disturbances or cord lesions.
If bubbles form in pulmonary vessels, divers experience retrosternal discomfort, breathlessness and cough, known as *the chokes*. These develop within minutes or hours of a dive. Decompression problems do not only occur immediately on reaching the surface; they may take some hours to become apparent. Over the subsequent 24 hours, further ascent, such as air travel, can occasionally provoke the bends.

Other problems during ascent include paranasal sinus pain and nosebleeds – medically minor but dramatic, with excruciating pain and a mask full of bloody fluid. Toothache can be caused by gas bubbles within rotten fillings.

### Management

All but the mildest forms of decompression sickness, such as skin mottling alone, require recompression in a pressure chamber, following strict guidelines. Recovery is usual. A long-term problem is aseptic necrosis of the hip due to nitrogen bubbles causing infarction. Focal neurological damage may persist, but complaints of fatigue and poor concentration are issues compounded by litigation that commonly follows diving accidents. Objective, evidence-based assessments are essential.

### Lung rupture, pneumothorax and surgical emphysema

These emergencies occur when divers breath-hold during emergency ascents after gas supplies become exhausted. There is dyspnoea, cough and haemoptysis. Pneumothorax and surgical emphysema resolve with 100% oxygen. Air embolism can also occur and is treated with recompression.

[http://www.divingmedicine.info/ Diving Medicine for Scuba Divers].

### Drowning

Drowning is defined as a process resulting in primary respiratory impairment from submersion or immersion in a liquid medium. Terms such as ‘near-drowning and ‘wet drowning’ should not be used.

Drowning is a common cause of accidental death worldwide. In the UK, some 40% of
drownings occur in children under 5 years of age. Drowning can also follow a seizure or a myocardial infarct. Exhaustion, alcohol, drugs and hypothermia all contribute to deaths following submersion.

Fresh or seawater aspiration destroys pulmonary surfactant, leading to alveolar collapse, ventilation/perfusion mismatch and hypoxaemia. Aspiration of hypertonic seawater (5% NaCl) pulls additional fluid into the alveoli with further ventilation/perfusion mismatch. In practice, there is little difference between saltwater and freshwater aspiration. In both, severe hypoxaemia develops rapidly. Severe metabolic acidosis develops in the majority of survivors.

**Management and prognosis**

Clearance of the airway and ventilation are the major requirements for submerged people, and bystanders should start resuscitation immediately once the person is stable on land. Rescue breaths and chest compression come before the initiation of standard cardiopulmonary resuscitation as used in cardiac arrest (see pp. 956–959). Patients have survived for up to 30 minutes under water without suffering brain damage – and sometimes for longer periods if $T_{\text{Water}}$ is near 10°C. Survival is probably related to the protective role of the diving reflex; submersion causes bradycardia and vasoconstriction. Oxygen consumption is also decreased by hypothermia.

Resuscitation should always be attempted, even with absent pulse and fixed dilated pupils. Patients frequently make a dramatic recovery. All survivors should be admitted to hospital for intensive monitoring, as acute respiratory distress syndrome (ARDS) can develop during the subsequent 48 hours.

Recovery is frequently complete if consciousness is regained within several minutes of commencing resuscitation but poor if a patient remains stuporose or in coma at 30 minutes.

**Prevention**

This includes making sure that all people can swim, particularly young children. Any water can be dangerous, and swimming should only be undertaken in supervised areas.

**Further reading**

**Air Pollution**
Epidemiology

Air pollution is one of the biggest problems facing the world currently. It has become a public health emergency as it leads to chronic diseases and exacerbates respiratory, cardiac and other medical problems. According to the United Nations, air pollution is the cause of 3.7 million premature deaths per year, most of which are from heart attacks and strokes. Annually, pollution is the cause of 1.4 million deaths in China, 645 000 in India and 110 000 in Pakistan, and figures are rising. It is also the single largest environmental risk in Europe, causing 430 000 premature deaths. It has been estimated that air pollution kills more people in a year than malaria and HIV combined and about ten times more deaths than road accidents in some countries. Atmospheric air pollution, due to the burning of coal for energy and heat, has been a feature of urban living in developed countries for at least two centuries. It consists of black smoke and sulphur dioxide (SO$_2$) and, from combustion of hydrocarbon fuels in motor vehicles, nitrogen oxides (NO and NO$_2$), diesel particulates, polyaromatic hydrocarbons and ozone, a secondary pollutant generated by photochemical reactions in the atmosphere. Levels of NO$_2$ can be high in poorly ventilated kitchens and living rooms where gas is used for cooking and in fires.

Particulate matter consists of coarse particles (10–2.5 μm in aerodynamic diameter), produced by construction work and farming, and fine particles (<2.5 μm) generated from burning fossil fuels. Fine particulates (PM$_{2.5}$) remain airborne for long periods and are carried into rural areas. Several respiratory and cardiac problems are exacerbated by these very small particles.

The World Health Organization (WHO) global air-quality guidelines suggest 24-hour values of <25 μg/m$^3$ for PM$_{2.5}$ for the short term and 10 μg/m$^3$ in the long term. In Europe, 70% of the particulates present in urban air result from the combustion of diesel fuel, providing a background concentration of 3–5 μg/m$^3$. The WHO estimates that air pollution causes 800 000 premature deaths worldwide every year.

Deaths from respiratory and cardiovascular disease occur mainly in older populations; air pollution mainly causes bronchitis in children. Pollution from motor vehicles has been linked to increased hospital admissions, reduced lung function in children and younger adults, and an increase in lung cancer (polyaromatic hydrocarbons). Although it has been proposed that air pollution may cause asthma and other allergic diseases, there is no current evidence for this (Box 5.4). However, air pollution does adversely affect lung development in teenage children, while both NO$_2$ and ozone enhance the nasal and lung airway responses to inhaled allergen in people with established allergic disease.

ppb, parts per billion.

### Management

When air quality is poor, asthmatics are advised to avoid exercising outdoors and to increase their anti-inflammatory medication (i.e. inhaled corticosteroids). Short- and long-term measures are required to reduce air pollution, particularly diesel particulates (which are predicted to increase as more diesel engines are used). Such measures include increased motor engine efficiency, catalytic converters, diesel particulate traps and decreased reliance on cars and trucks.

### Further reading

### Ionizing Radiation

Ionizing radiation is either penetrating (X-rays, γ-rays or neutrons) or non-penetrating (α- or β-particles). Penetrating radiation affects the skin and deeper tissues, while non-penetrating radiation affects the skin alone. All radiation effects depend on the type of radiation, the distribution of dose and the dose rate.

*Dosage* is measured in **joules per kilogram** (J/kg): 1 J/kg = 1 gray (1 Gy) = 100 rads.

*Radioactivity* is measured in **becquerels** (Bq); 1 Bq is defined as the activity of a quantity of radioactive material in which one nucleus decays per second; $3.7 \times 10^{10}$ Bq = 1 **curie** (Ci), the older, non-SI unit.
Radiation differs in the density of ionization it causes. Therefore, a dose-equivalent called a sievert (Sv) is used. This is the absorbed dose weighted for the damaging effect of the radiation. The annual background radiation is approximately 2.5 mSv. A chest X-ray delivers 0.02 mSv, and CT of the abdomen/pelvis about 10 mSv (see Box 17.5). A cumulative risk of cancer following repeated imaging procedures has been established and X-ray exposures should be reduced if possible.

Excessive exposure to ionizing radiation follows accidents in industry, nuclear power plants and hospitals, and deliberate nuclear explosions designed to eliminate populations – and exceptionally, by poisoning, with polonium, for example.

### Mild acute radiation sickness

Nausea, vomiting and malaise follow doses of approximately 1 Gy. Lymphopenia occurs within several days, followed 2–3 weeks later by a fall in all white cells and platelets.

### Acute radiation sickness

Many systems are affected; the extent depends on the dose of radiation (Box 5.5).

---

**Box 5.5**

**Systemic radiation effects**

**Acute effects**

- Haemopoietic syndrome
- Gastrointestinal syndrome
- CNS syndrome
- Radiation dermatitis

**Delayed effects**

- Infertility
- Teratogenesis
- Cataract
- Neoplasia:
  - Acute myeloid leukaemia
  - Thyroid
  - Salivary glands
  - Skin
  - Others
**Haemopoietic syndrome**
Absorption of 2–10 Gy is followed by transient vomiting in some individuals, followed by a period of improvement. Lymphocytes are particularly sensitive to radiation damage; severe lymphopenia develops over several days. A decrease in granulocytes and platelets follows 2–3 weeks later, since no new cells are formed in the marrow. Thrombocytopenia develops with bleeding and frequent overwhelming infections; there is a high mortality.

**Gastrointestinal syndrome**
Doses >6 Gy cause vomiting several hours after exposure. This then stops, only to recur some 4 days later, accompanied by diarrhoea. The villous lining of the intestine becomes denuded. Intractable bloody diarrhoea follows, with dehydration, secondary infection and sometimes death.

**CNS syndrome**
Exposures of >30 Gy are followed rapidly by nausea, vomiting, disorientation and coma. Death due to cerebral oedema can follow, usually within 36 hours.

**Radiation dermatitis**
Skin erythema, purpura, blistering and secondary infection occur. Total loss of body hair is a bad prognostic sign and usually follows an exposure of >5 Gy.

**Late effects of radiation exposure**
Survivors of the nuclear bombing of Hiroshima and Nagasaki in 1945 provided data on long-term radiation effects. Risks of acute myeloid leukaemia and cancer, particularly of skin, thyroid and salivary glands, increase. Infertility, teratogenesis and cataract are also late sequelae, developing years after exposure.

**Major nuclear power plant accidents**
Two high-level nuclear accidents have occurred: the first in 1986 in Chernobyl in the Ukraine (part of the Soviet Union at the time), and the second in 2011 in Fukushima in Japan.

In Chernobyl, 30 people died in the first 3 months due to radiation and other factors. The majority of the people in the area received only a very low dose of radiation and only cancer of the thyroid has been found as a long-term consequence.

In the Fukushima disaster, which occurred following an earthquake that generated tsunamis along the east coast of Japan, radiation release was 10–30% of that released in Chernobyl. There were no immediate deaths due to radiation and the long-term effect of radiation is thought likely to be small.

The major problems caused by both disasters relate to psychological and social effects, as a result of the populations' evacuation and removal from their homes for years following the accidents, as well as a general concern about the effects of radiation on themselves and their
children.

*Figure 5.3* shows the measures needed in a nuclear disaster.

![Diagram of disaster cycle](image)

**FIGURE 5.3** General disaster and nuclear disaster cycle. The measures shown in boxes refer to a programme specifically for a nuclear disaster. Those not in boxes are measures required for any large-scale disaster. (From Ohtsuru A, Tanigawa K, Kumagai A et al. Nuclear disasters and health: lessons learned, challenges, and proposals. Lancet 2015; 386:489–499, with permission.)

**Therapeutic radiation**

The sequelae of therapeutic radiation – early, early-delayed and late-delayed radiation effects – are discussed on page 604. Focusing techniques are used to target radiation towards the field being treated, so that radiosensitive structures, such as the ovaries, are protected by shielding.

**Management**

Acute radiation sickness is an emergency. Absorption of the initial radiation dose can be reduced by removing contaminated clothing.

Management is largely supportive: prevention and treatment of infection, haemorrhage and fluid loss. Harvesting of blood products is sometimes carried out.
Accidental ingestion of, or exposure to, bone-seeking radio-isotopes (e.g. $^{90}$strontium and $^{137}$caesium) is treated with chelating agents, such as EDTA and massive doses of oral calcium. Radio-iodine contamination should be treated immediately with potassium iodide to block radio-iodine absorption by the thyroid.

**Further reading**

**Electric Shock**

Electric shock can produce:

- **Pain and psychological sequelae.** The common domestic electric shock is typically painful, but rarely fatal or followed by serious sequelae. Nevertheless, it is an unpleasant and intensely frightening experience. A brief, immediate jerking episode can occur, which is not an epileptic seizure. There is usually no lasting neurological, cardiac or skin damage.

- **More serious effects.** These are distinctly rare following accidents in the home or in industry, but claims by survivors following industrial accidents are frequently made.

- **Cardiac, neurological and muscle damage.** Ventricular fibrillation, muscular contraction and spinal cord damage can follow a major shock.

- **Electrical burns.** These are commonly restricted to the skin. Muscle necrosis and spinal cord damage can also occur.

- **Electrocution.** This means death following ventricular fibrillation, either accidentally, or deliberately as a method of execution. In the USA, at executions, an initial voltage of $>2000$ volts was applied for some 15 s in the electric chair, causing loss of consciousness and ventricular fibrillation, before the voltage was lowered. The T$_{\text{Core}}$ during the execution process would sometimes reach $>50^\circ\text{C}$, leading to severe damage to internal organs.

**Lightning Strike**

*Cloud-to-ground lightning originating in thunderstorms.* Human tissues are directly damaged by the high-voltage DC current of $>10$ million volts that lasts only for a few milliseconds. The result is cardiac arrest due to asystole.

Fern-shaped burns are seen on the skin. The victim's clothes explode off the body and the person is pulseless, not breathing and in coma. The only chance of survival at this stage is bystander cardiopulmonary resuscitation. The mortality is high and those who survive are left with variable CNS damage.
Further reading

Smoke

Smoke is air containing toxic and/or irritant gases and carbon particles, coated with organic acids, aldehydes and synthetic materials. Carbon monoxide, sulphur dioxide, sulphuric and hydrochloric acids, and other toxins may also be present. The highly toxic polyvinyl chloride is no longer used in household goods. Air pollution is discussed on page 56.

On smoke inhalation, patients become breathless and tachypnoeic immediately. Choking and stridor may require intubation. Pulmonary oedema and hypoxia can be fatal.

Breathing through a wet towel or clothing is the best emergency treatment. Remove the victim from the scene as rapidly as possible. Give oxygen and arrange ITU support.

**Prevention.** Smoke alarms, regularly checked, should be installed in every household.

Noise

Sound *intensity* is expressed as the square of *sound pressure*. The *bel* is the ratio equivalent to a 10-fold increase in sound intensity; a *decibel* (dB) is one-tenth of a bel. Sound is made up of a number of frequencies ranging from 30 Hz to 20 kHz, most being between 1 and 4 kHz. In practice, a scale known as *A-weighted sound* is used; sound levels are reported as dB(A). A hazardous sound source is defined as one with an overall sound pressure of >90 dB(A).

Repeated, prolonged exposure to loud noise, particularly between 2 and 6 kHz, causes first temporary and later permanent hearing loss, by physically destroying hair cells in the organ of Corti and, eventually, auditory neurones. Noise-induced hearing loss is a common occupational problem, not only in industry and the armed forces, but also in the home (drills and sanders), in sport (motor racing) and in entertainment (musicians, DJs and their audiences).

Serious noise-induced hearing loss is almost wholly preventable by personal protection (ear muffs, ear plugs). Little can be offered once hearing loss has become established.

Other effects of noise

Noise is intensely irritative, increasing or producing anxiety and anger. Excessive, repetitive noise is used in torture. Excess noise possibly affects child development and reading skills.

Bioterrorism/Biowarfare
Interest in biological warfare and bioterrorism intensified during the 1991 Iraq war and later, following the destruction of the Twin Towers in New York in 2001. The potential of bacteria as weapons is illustrated by a suggestion that several kilograms of anthrax spores might kill as many people as a Hiroshima-sized nuclear weapon.

**Potential pathogens**

The US Centers for Disease Control and Prevention in Atlanta, Georgia, have developed a classification of potential biological agents (*Box 5.6*).

<table>
<thead>
<tr>
<th>Category</th>
<th>Pathogens</th>
</tr>
</thead>
<tbody>
<tr>
<td>A. Very infectious and/or readily disseminated organisms: high mortality with a major impact on public health</td>
<td>Smallpox, anthrax, botulism, plague, tularemia, viruses</td>
</tr>
<tr>
<td>B. Moderately easy to disseminate organisms: moderate morbidity and mortality</td>
<td>Q fever, brucellosis, glanders, food-/water-borne pathogens, influenza</td>
</tr>
<tr>
<td>C. Emerging and possible genetically engineered pathogens</td>
<td>Viral haemorrhagic fevers, encephalitis viruses, drug-resistant tuberculosis</td>
</tr>
</tbody>
</table>

*(Adapted from Khan AS, Morse S, Lillibridge S. Public health preparedness for biological terrorism in the USA. *Lancet* 2000; 356:1179–1182, with permission.)*

**Smallpox**

Smallpox is a highly infectious disease with a mortality of >30%. There is no proven therapy but there is an effective vaccine. Universal vaccination was stopped in the early 1970s; the vast majority of the world's population is now unprotected against the variola virus (see p. 251). The potential exists for a worldwide epidemic of smallpox, possibly initiated by a bioterrorist act.

Smallpox has an incubation period of around 12 days, allowing any initial source of infection to go undetected until the rash (*Fig. 5.4*), similar to that of chickenpox, develops on the second or third day of the illness. Infection is transmitted by the airborne route; the patient becomes infectious to others 12–24 hours before the rash appears, thus allowing a potential infected volunteer to pass infection to others before being recognized as suffering from smallpox. If vaccines were to be administered widely to those potentially infected within 3 days of contact, an epidemic might well be prevented. Smallpox virus is stored in two secure laboratories: in Russia and in the USA. Supplies of vaccine are potentially available worldwide.
**Anthrax**

In late 2001, anthrax organisms (see p. 287) were sent through the US mail and infected 22 individuals. Of these, 11 developed pulmonary anthrax, 5 of whom died; 11 suffered from cutaneous anthrax.

A simulated anthrax attack postulated release of anthrax powder from a truck passing a sports stadium with 74,000 spectators; 16,000 were estimated to have become infected, with a death rate of 25%. In Russia, following accidental release of anthrax from a bioweapons factory, the death rate was substantial in those nearby, especially downwind.

**Botulism**

The toxin produced by *Clostridium botulinum* is one of the most potent poisons known (see p. 280).

As a bioweapon, botulinum toxin could be transmitted in food or by air: for example, from a crop-spraying light aircraft. The toxin is inactivated by chlorine in domestic water supplies. There is no vaccine available.

**Plague**

Plague (see p. 291) could potentially be used as a bioweapon either by airborne dissemination or by transmission by infected rats. Immunization is of limited value.

Other potential infective agents are listed in *Box 5.6*.

**Emergency planning**

Many countries have plans to deal with bioterrorist attacks. These include training of healthcare staff and police. Such plans indicate the governments' awareness of the possibility of these threats. Stockpiling of vaccines, antibiotics and protective clothing is essential.

## Travel

### Motion sickness

This common problem is caused by repetitive stimulation of the labyrinth. Motion sickness occurs frequently at sea and in cars (especially in children), but also with less usual forms of transport such as camels or elephants. Nowadays, motion sickness is rare during commercial flights, but it is a problem during space travel and on airships – one reason why the airship industry has not flourished.

Nausea, sweating, dizziness, vertigo and profuse vomiting occur, accompanied by an irresistible desire to stop moving. Prostration and intense incapacitating malaise can develop: for example, in seasickness.

Prophylactic antihistamines, vestibular sedatives (hyoscine or cinnarizine) and stem ginger are of some value.

### Air travel

The incidence of deep venous thrombosis and pulmonary embolism is slightly greater in sedentary passengers on long-haul flights than in a similar population at sea level. Dehydration and alcohol probably contribute. Prophylactic aspirin is not recommended but moving the legs regularly and walking around the cabin every hour may be beneficial.

Commercial aircraft cabins are pressurized (see p. 54). Patients with respiratory disease, particularly chronic obstructive pulmonary disease, may well require oxygen therapy. They should seek advice from their airline.

All patients must be sure to take tablets and other therapy with them in the cabin in case they are required during the flight. Always consult the airline if there is any concern regarding health issues.

### Inflight medical emergencies

Half of inflight emergencies are attended by doctors. The main problems are syncope, chest symptoms (cough and pain) and gastrointestinal symptoms. Most patients are managed successfully but approximately 25% require hospitalization on arrival at their destination.
Jet-lag (circadian dyschronism) is the well-known phenomenon that follows travelling through time-zones, particularly from west to east. Intense insomnia, fatigue, poor concentration, irritability and loss of appetite are common. Headaches may occur. Symptoms last several days.

Mechanisms relate to the hypothalamic body clock within the suprachiasmatic nuclei. The clock is regulated by various *Zeitgebers* (time-givers), such as light and melatonin.

Management of jet-lag includes its acceptance as a phenomenon causing poor performance – and thus waiting for 3–5 days to recover, drinking plenty of fluid and avoiding alcohol. Various hypnotics can help insomnia but their value is disputed. Oral melatonin is widely used to reduce jet-lag but is not available on prescription in the UK. Melatonin probably hastens resetting of the body clock.

Building-Related Illnesses

Non-specific building-related illness

Multi-storey buildings typically have a controlled environment, often with automated heating and air-conditioning, and no ready access to external ventilation. More than half the adult workforce in developed countries works in such buildings.

Headache, fatigue and difficulty concentrating, sometimes in epidemics, are the main complaints but these have become less frequent. Psychological factors are thought to play a substantial role. Temperature, humidity, dust, volatile organic compounds, such as paints and solvents, and even low-level carbon monoxide toxicity have all been blamed, none with any scientific foundation.

Specific building-related illness

*Legionnaires’ disease* (see p. 1105) can follow contamination of air-conditioning systems. *Humidifier fever* (see p. 1117) is also due to contaminated systems, probably by fungi, bacteria and protozoa. Many common viruses are potentially transmissible in an enclosed
environment, such as the common cold, influenza and, rarely, pulmonary tuberculosis. Allergic disorders, like rhinitis, asthma and dermatitis, also occur following exposure to indoor allergens such as dust mites and plants. Office equipment – for example, fumes from photocopiers – has also been implicated. Passive smoking (see p. 1075) is no longer an issue in Europe and North America, following legislation against smoking.

Introduction

In developed countries, poisoning is responsible for approximately 10% of acute hospital medical presentations and 1% of admissions. In such cases, poisoning is usually by self-administration of prescribed and over-the-counter medicines, or illicit drugs.
• **Poisoning in children** aged <6 months is most commonly iatrogenic, e.g. with paracetamol. Children between 8 months and 5 years of age may ingest poisons accidentally (due to inappropriate storage of drugs such as digoxin or quinine, and drugs of misuse purchased or prescribed for a parent or carer). Drugs may also be administered deliberately to cause harm (abuse by proxy).

• **Self-poisoning in adults** is commonly a ‘cry for help’. Those involved are most often females <35 years in good physical health. They take an overdose in circumstances where they are likely to be found or in the presence of others. In the over-55s, there is a preponderance of men who are suffering from a depressive illness or are in poor physical health.

• **Occupational poisoning** due to dermal or inhalational exposure to chemicals is more common in the developing world.

• Poisoning may be **iatrogenic**, e.g. digoxin toxicity.

• The **type of agent** taken in overdose is heavily influenced by availability and culture. In the UK, paracetamol poisoning is responsible for approximately one-third of all admissions, whereas in Sri Lanka, for example, the agents ingested are more often pesticides (e.g. organophosphorus insecticides) or plants (e.g. oleander), and in South India, copper sulphate is a problem. In addition, ingestion of heating fuels (e.g. petroleum distillates), antimalarials, antituberculous drugs and traditional medicine is reported frequently in the developing world. Poisoning from snake venoms is also a problem in rural areas.

A third of patients admitted with an overdose in the UK state that they are unaware of the toxic effects of the substance involved; the majority take whichever drug is easily available at home (*Box 6.1*, p. 66). Studies reveal that:

• Acute overdoses often involve more than one agent; alcohol is the most commonly implicated second agent.

• There is often a poor correlation between the drug history and the toxicological analytical findings. Therefore, a patient’s statement about the type and amount of drug ingested cannot always be relied on.

---

**Box 6.1**

**Prevention of self-poisoning**

Patients usually take what is readily available at home.

- Only small amounts of drugs should be sold
- Foil-wrapped drugs are less likely to be taken in overdose
- Drugs should always be kept in a safe place
- Drugs and liquids should be kept in their original containers
- Child-resistant drug containers should be used
• Care should be taken in prescribing all drugs
• Prescriptions for any susceptible patient (e.g. the depressed) must be monitored carefully
• Household products should be labelled and kept safely away from children

The majority of patients do not require intensive medical management, as they ingest relatively non-toxic agents. All patients require a sympathetic and caring approach, with a psychiatric and social assessment. Fatalities in the UK are due predominantly to antidepressants, paracetamol, analgesic combinations containing paracetamol and an opioid, heroin, methadone or cocaine.

**Clinical approach to the poisoned patient**

### History

More than 80% of adults are conscious on arrival at hospital and the diagnosis of self-poisoning can usually be made from the history *(Box 6.2, p. 66)*. In any patient with an altered level of consciousness, acute poisoning must always be considered in the differential diagnosis.

#### Box 6.2

**History-taking in poisoning (record in notes)**

- Obtain history (if possible) from patient, relatives, friends, paramedics, witnesses
- Seek evidence of overdose
- Establish whether suicide note was left
- Ascertaining what drugs/poisons were taken
- Establish time/route taken
- Ask about additional drugs, e.g. alcohol
- Seek details from GP, e.g. prescribed medicines
- Assess suicide risk
- Assess capacity to make decisions
- Record a general history – past history, allergies, family history, social history

### Examination

On arrival at hospital, the patient must be assessed urgently *(Box 6.3, p. 66)*. The ‘cluster of features’ on presentation may be distinctive and diagnostic. For example, sinus tachycardia, fixed dilated pupils, exaggerated tendon reflexes, extensor plantar responses and coma suggest
tricyclic antidepressant poisoning (see Box 6.4).

**Box 6.3**

Quick examination guide for the poisoned patient

1. A B C D E (see p. 826)
2. Level of consciousness (Glasgow Coma Scale; see p. 825)
3. Ventilation – pulse oximetry
4. Blood pressure and pulse rate
5. Pupil size and reaction to light
6. Temperature
7. Head injury complicating poisonings
8. If patient is unconscious, check cough and gag reflex

Some physical signs help to identify the poison – see Box 6.4

**Some Poison-Specific Clinical Features**

**Central nervous system**

**Reduced conscious level**
- Anticonvulsants
- Antimuscarinic drugs
- Benzodiazepines
- Ethanol
- Opiates
- Tricyclic antidepressants

**Agitation/confusion/delirium**
- Antimuscarinic drugs
- Cannabis
- Ethanol
- Novel psychoactive substances
- Other drugs of misuse

**Psychosis**
- Antimuscarinic drugs
- Cannabis
- Novel psychoactive substances

**Ataxia**
- Carbamazepine
- Ethanol
• Tricyclic antidepressants

**Seizures**
• Carbamazepine
• Mefenamic acid
• Tramadol

**Peripheral nervous system**

**Decreased tone**
• Benzodiazepines
• Ethanol

**Increased tone**
• Antimuscarinic drugs
• Antipsychotic drugs
• Tricyclic antidepressants

**Decreased power**
• Barium salts
• Nerve agents
• Organophosphorus insecticides

**Decreased reflexes**
• Benzodiazepines
• Ethanol

**Increased reflexes**
• Antipsychotic drugs
• Tricyclic antidepressants

**Extensor plantar responses**
• Tricyclic antidepressants

**Tremor**
• Lithium
• Mercury and mercury salts
• Nerve agents
• Organophosphorus insecticides

**Muscle fasciculation**
• Nerve agents
• Organophosphorus insecticides

**Myoclonus**
• Baclofen
**Temperature**

**Hypothermia**
- Central nervous system depressant drugs
- Environmental exposure

**Hyperthermia**
- Cocaine
- Ecstasy and other amfetamines
- Salicylates
- Selective serotonin reuptake inhibitors (SSRIs)

**Muscles**

**Rhabdomyolysis**
- Cocaine
- Drugs causing coma
- Drugs causing seizures
- Ecstasy

**Respiratory system**

**Decreased respiratory rate**
- Benzodiazepines
- Opioids

**Increased respiratory rate**
- Salicylates

**Low O₂ saturations**
- Benzodiazepines
- Opiates

**Crackles**
- Aspiration of gastric contents
- Non-cardiogenic pulmonary oedema (heroin, inhaled irritant chemicals)
- Pulmonary oedema (cardiotoxic drugs)

**Cardiovascular system**

**Low blood pressure**
- Beta-blockers
- Calcium-channel blockers
- Tricyclic antidepressants
- Antimalarials
**High blood pressure**
- Adrenoceptor agonists
- Cocaine
- Amfetamines

**Bradycardia**
- Beta-blockers
- Calcium-channel blockers
- Digoxin

**Tachycardia**
- Stimulant drugs
- Vasodilators

**Abdomen**

**Liver tenderness**
- Paracetamol

**Abdominal pain/tenderness**
- Antimuscarinic drugs
- Body stuffers
- Corrosives
- Non-steroidal anti-inflammatory drugs (NSAIDs)

**Absent bowel sounds (ileus)**
- Antimuscarinic drugs
- Colchicine

**Palpable bladder**
- Antimuscarinic drugs

**Kidney tenderness**
- Paracetamol

**Eyes**

**Small pupils**
- Nerve agents
- Opioids
- Organophosphorus insecticides

**Large pupils**
- Amfetamines and other stimulants
- Cocaine
• Tricyclic antidepressants
• Antimuscarinic drugs

**Diplopia**
• Tricyclic antidepressants

**Divergent squint/strabismus**
• Tricyclic antidepressants

**Nystagmus**
• Carbamazepine
• Ethanol
• Phenytoin

**Lacrimation**
• Nerve agents
• Organophosphorus insecticides

**Visual loss**
• Methanol
• Quinine

**Papilloedema**
• Carbon monoxide
• Methanol

**Hearing**

**Tinnitus/deafness**
• Quinine
• Salicylates

**Mouth**

**Dry mouth**

**Principles of Management of Poisoning**

Most people with self-poisoning require only general care and support of the vital systems (**Box 6.5**). However, for a few poisons, additional therapy is required.
Box 6.5

Management strategy in acute poisoning

Immediate decisions

• Supportive treatment
• Is an antidote appropriate? (see Box 6.6)
• Is it appropriate to try to reduce poison absorption?
• Is it appropriate to perform toxicological investigations?
• Is it appropriate to try to enhance elimination?

Practical points – contact with poison

Eyes
• Remove contact lenses
• Wash eyes with 0.9% saline or water for about 15 min
• Assess corneal damage (if necessary) with slit lamp and fluorescein stain

Skin
• Remove clothing
• Wash thoroughly with soap and water if, e.g., chemical exposure

Care of the unconscious patient

(See also pp. 826–829.) In all cases, the patient should be nursed in the lateral position with the lower leg straight and the upper leg flexed; in this position, the risk of aspiration is reduced. A clear passage for air should be ensured by the removal of any obstructing object, vomit or dentures, and by head tilt and chin lift or jaw thrust. Nursing care of the mouth and pressure areas should be instituted. Immediate catheterization of the bladder is usually unnecessary, as it can be emptied by gentle suprapubic pressure. Insertion of a venous cannula is usual, but administration of intravenous fluids is unnecessary unless the patient has been unconscious for more than 12 hours, is dehydrated or is hypotensive.

Ventilatory support

If respiratory depression is present, as determined by pulse oximetry or preferably by arterial blood gas analysis, an oropharyngeal airway should be inserted and supplemental oxygen should be administered. Pulse oximetry alone will not detect hypercapnia. Loss of the cough or gag reflex is the prime indication for intubation. The gag reflex can be assessed by positioning the patient on one side and making him or her gag using a suction tube. In many severely poisoned patients, the reflexes are depressed sufficiently to allow intubation without the use of sedatives or relaxants. The complications of endotracheal tubes are discussed on pages 1163–
If ventilation remains inadequate after intubation, as shown by hypoxaemia and hypercapnia, intermittent positive-pressure ventilation (IPPV) should be instituted.

Cardiovascular support

Although hypotension (systolic blood pressure <80 mmHg) is a recognized feature of acute poisoning, the classic features of shock – tachycardia and pale, cold skin – are observed only rarely.

Hypotension and shock may be caused by:

- **a direct cardio-depressant action** of the poison (e.g. beta-blockers, calcium-channel blockers, tricyclic antidepressants)
- **vasodilatation and venous pooling** in the lower limbs (e.g. angiotensin-converting enzyme (ACE) inhibitors, phenothiazines)
- **a decrease in circulating blood volume** because of gastrointestinal losses (e.g. profuse vomiting from salicylate poisoning), increased insensible losses (e.g. salicylate poisoning), increased renal losses (e.g. poisoning due to diuretics) and increased capillary permeability.

Hypotension may be exacerbated by coexisting hypoxia, acidosis and dysrhythmias. In people with marked hypotension, volume expansion with crystalloids should be used. Urine output (aiming for 35–50 mL/h) is a useful guide to the adequacy of the circulation. If a patient fails to respond to the above measures, more intensive therapy is required. In such individuals, it is helpful to initiate central venous pressure monitoring to confirm that adequate volume replacement has been administered. Volume replacement and the use of inotropes are discussed on page 1148. All patients with cardiogenic shock should have electrocardiographic (ECG) monitoring.

Systemic hypertension can be caused by a few drugs taken in overdose. If this is mild and associated with agitation, treatment with a benzodiazepine may suffice. In more severe cases – for example, severe cocaine or amphetamine poisoning – there may be a risk of arterial rupture, particularly intracranially. To prevent this, intravenous nitrates such as glyceryl trinitrate are given, starting at a dose of 1–2 mg/h, gradually increasing the dose to a maximum of 12 mg/h until blood pressure is controlled. Calcium antagonists, such as verapamil 240–480 mg daily in divided doses, are an alternative second-line therapy. Sodium nitroprusside 0.5–1.5 µg/kg/min (to a maximum of 8 µg/kg/min) is an option for patients with increased blood pressure when there is no evidence of cardiac ischaemia, but caution is required as it may cause a rapid fall in blood pressure.

Arrhythmias can occur, such as tachyarrhythmias following ingestion of a tricyclic antidepressant or theophylline, or bradyarrhythmias with digoxin poisoning. Known arrhythmogenic factors, such as hypoxia, acidosis and hypokalaemia, should be corrected.

Other problems

**Hypothermia**
A rectal temperature <35°C is a recognized complication of poisoning, especially in older patients or those who are comatose. The patient should be covered with a ‘space blanket’ and, if necessary, given intravenous and intragastric fluids at normal body temperature. The administration of heated (37°C), humidified oxygen delivered by face mask is also useful.

Hyperthermia

Body temperature can rarely increase to being potentially fatal after poisoning with central nervous stimulants such as cocaine and amphetamines, including ecstasy (MDMA). Muscle tone is often increased and convulsions and rhabdomyolysis are common. Cooling measures, sedation with diazepam and, in severe cases, dantrolene (a skeletal muscle relaxant) 1 mg/kg body weight i.v. should be given.

Skin blisters

Skin blisters may be found in poisoned patients who are, or have been, unconscious and do not move. Such lesions are not diagnostic of specific poisons but are sufficiently common in poisoned patients (and sufficiently uncommon in patients unconscious from other causes) to be of diagnostic value.

Rhabdomyolysis

Rhabdomyolysis can occur from pressure necrosis in drug-induced coma, or it may complicate poisoning in the absence of coma, such as in ecstasy (MDMA) abuse. People with rhabdomyolysis are at risk of developing, firstly, acute kidney injury from myoglobinemia, particularly if they are hypovolaemic and have an acidosis; and, secondly, wrist or ankle drop from the development of a compartment syndrome (see p. 662).

Convulsions

These may occur in poisoning from many drugs, including tricyclic antidepressants, mefenamic acid and opioids. Usually seizures are short-lived but, if they are prolonged, diazepam 10–20 mg i.v. or lorazepam 4 mg i.v. should be administered. Persistent fits must be controlled rapidly to prevent severe hypoxia, brain damage and laryngeal trauma. If diazepam or lorazepam in repeated dose is ineffective, second-line treatments include intravenous phenytoin (loading dose 20 mg/kg at not more than 50 mg/min) or intravenous phenobarbital sodium (10 mg/kg at not more than 100 mg/min). Phenytoin is contraindicated in cases of poisoning with sodium channel-blocking drugs (such as tricyclic antidepressants) and is relatively contraindicated in all cases of poisoning with cardiotoxic drugs.

Stress ulceration and bleeding

Intravenous omeprazole or ranitidine should be given to prevent stress ulceration of the stomach in the elderly and patients with a previous history of ulceration.
Body ‘packers’ and body ‘stuffers’

Body ‘packers’ (sometimes called ‘mules’ or ‘swallowers’) are those who swallow a substantial number of packages containing illicit drugs for the purpose of smuggling. Heroin used to be the drug of choice but this has been superseded by cocaine. Although each package contains a potentially lethal amount of drug, packets are now usually machine-manufactured using a material that does not leak. Body packers may ingest up to 100–200 packages.

Body ‘stuffers’ swallow a small number of packages containing an illicit drug, usually heroin, cocaine, cannabis or an amphetamine, in an unplanned attempt to conceal evidence when on the verge of being arrested. These drugs are usually either unpackaged or poorly packaged and, as a consequence, leakage may occur over the ensuing 3–6 hours and cause significant symptoms. Some also hide illicit drug packages in their rectum or vagina with the same intent (these are sometimes known as body ‘pushers’).

The role of imaging is usually confined to body packers; imaging has little role in the care of body stuffers or pushers. Ultrasound is of similar accuracy to abdominal X-ray in locating packages but is less accurate than computed tomography (CT). A urine screen for drugs of misuse should be performed. A screen that is positive for one or more drugs of misuse suggests that either the patient has used the drug in the previous few days, or at least one packet is leaking. A negative screen strongly suggests that no packet is leaking. Screens should be repeated daily, or immediately if the patient develops features of intoxication, to confirm the diagnosis.

Management.

Packages can be removed most expeditiously in body stuffers by employing whole-bowel irrigation (see p. 68). In the past, early surgery was advocated in body packers. However, with the development of improved packaging, a more conservative approach using whole-bowel irrigation can now be adopted, with which there is a complication rate of <5%. Immediate surgery is indicated if acute intestinal obstruction develops, or when packets can be seen radiologically and there is clinical or analytical evidence to suggest leakage, particularly if the drug involved is cocaine.

Packets in the vagina can usually be removed manually.

Specific management of the poisoned patient

Antidotes

Specific antidotes are available for a small number of poisons only (Box 6.6).

DMPS, dimercaptopropanesulphonate; DMSA, dimercaptosuccinic acid.

Antidotes may exert a beneficial effect by:

- **forming an inert complex** with the poison (e.g. desferrioxamine, D-penicillamine, dicobalt edetate, digoxin-specific antibody fragments, dimercaprol, HI-6, hydroxocobalamin, obidoxime, pralidoxime, protamine, Prussian (Berlin) blue, sodium calcium edetate, succimer (dimercaptosuccinic acid; DMSA), Unithiol (dimercaptopropanesulphonate; DMPS))
- **accelerating detoxification** of the poison (e.g. acetylcysteine, sodium thiosulphate)
- **reducing the rate of conversion** of the poison to a more toxic compound (e.g. ethanol, fomepizole)
- **competing with the poison** for essential receptor sites (e.g. oxygen, naloxone, phytomenadione)
- **blocking essential receptors** through which the toxic effects are mediated (e.g. atropine)
bypassing the effect of the poison (e.g. oxygen, glucagon).

Gut decontamination

While it appears logical to assume that removal of unabsorbed drug from the gastrointestinal tract will be beneficial (gut decontamination), the efficacy of gastric lavage and syrup of ipecacuanha (to induce vomiting) remains unproven and efforts to remove small amounts of non-toxic drugs are clinically not worthwhile or appropriate.

Gastric lavage should only be performed if a patient has ingested a potentially life-threatening amount of a poison, e.g. iron, and the procedure can be undertaken within 60 minutes of ingestion. Intubation is required if airway protective reflexes are lost. Lavage is contraindicated if a hydrocarbon with high aspiration potential or a corrosive substance has been ingested.

Syrup of ipecacuanha to induce vomiting should not be used, as the amount of drug recovered is highly variable and diminishes with time; there is no evidence that it improves the outcome of poisoned patients.

Single-dose activated charcoal is able to adsorb a wide variety of compounds. Exceptions are strong acids and alkalis, ethanol, ethylene glycol, iron, lithium, mercury and methanol. In studies in volunteers given 50 g activated charcoal, the mean reduction in absorption was 40%, 16% and 21%, at 60 min, 120 min and 180 min, respectively, after ingestion. Based on these studies, activated charcoal should be given to those who have ingested a potentially toxic amount of a poison (known to be adsorbed by charcoal). There are insufficient data to support or exclude its use after 1 hour. There is no evidence that administration of activated charcoal improves clinical outcome.

Cathartics have no role in the management of the poisoned patient.

Whole-bowel irrigation requires the insertion of a nasogastric tube into the stomach and the introduction of polyethylene glycol electrolyte solution 1500–2000 mL/h in an adult, which is continued until the rectal effluent is clear. Whole-bowel irrigation may be used for potentially toxic ingestions of sustained-release or enteric-coated drugs, or to remove illicit drug packets.

Increasing poison elimination

Multiple-dose activated charcoal (MDAC) involves the repeated administration of oral activated charcoal to increase elimination of a drug that has already been absorbed. Most absorbed drugs re-enter the gut from the villi capillaries by passive diffusion (a few by an active process) if the concentration in the gut is lower than that in the blood (this is called the entero-enteric circulation). Some drugs are also secreted in the bile (enterohepatic circulation). Activated charcoal will bind any drug that is in the gut lumen, so keeping the concentration in the gut low and favouring further diffusion from blood to gut lumen.

Elimination of drugs with a small volume of distribution (<1 L/kg), low pKa (which maximizes transport across membranes), low binding affinity and prolonged elimination half-life following overdose is particularly likely to be enhanced by MDAC. MDAC also improves total body clearance of the drug when endogenous processes are compromised by liver and/or
renal failure.

Although MDAC has been shown to increase drug elimination significantly, it has not reduced morbidity and mortality in controlled studies. At present, MDAC should be used only in patients who have ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine or theophylline.

In adults, charcoal should be administered in an initial dose of 50–100 g and then at a rate of not less than 12.5 g/h, preferably via a nasogastric tube; usually, 200 g is sufficient. If the patient has ingested a drug that induces protracted vomiting (e.g. theophylline), intravenous ondansetron 4–8 mg is an effective antiemetic and thus enables MDAC administration.

**Urine alkalization** enhances elimination of salicylate, phenobarbital and chlorophenoxy herbicides (e.g. 2,4-dichlorophenoxyacetic acid) by mechanisms that are not clearly understood. Urine alkalization is not recommended as first-line therapy for poisoning with phenobarbital, as MDAC is superior. A substantial diuresis is required in addition to urine alkalization to achieve clinically relevant elimination of chlorophenoxy herbicides.

Urine alkalization is a metabolically invasive procedure requiring frequent biochemical monitoring and medical and nursing expertise. Before urine alkalization is commenced, plasma volume depletion, electrolytes (administration of sodium bicarbonate exacerbates pre-existing hypokalaemia) and metabolic abnormalities should be corrected. Sufficient bicarbonate is administered to ensure that the pH of the urine, which is measured by narrow-range indicator paper or a pH meter, is >7.5 and preferably close to 8.5. In one study, sodium bicarbonate 225 mmol was the mean amount required initially. This is most conveniently administered as 225 mL of an 8.4% solution (1 mmol bicarbonate/mL) i.v. over 1 hour.

**Haemodialysis and haemodiafiltration** are of little value in patients poisoned with drugs that have large volumes of distribution (e.g. tricyclic antidepressants) because the plasma contains only a small proportion of the total amount of drug in the body. These methods are indicated in patients with severe clinical features and high plasma concentrations of ethanol, ethylene glycol, isopropanol, lithium, methanol and salicylate: that is, drugs with small volumes of distribution.

**Lipid emulsion therapy** involves the intravenous administration of 20% Intralipid® (fractionated soya oil) 1.5 mL/kg, followed by 0.25–0.5 mL/kg/min for 30–60 min to an initial maximum of 500 mL. Use of lipid emulsion as an antidote for severe poisoning with highly lipid-soluble drugs is based on experience of its efficacy in local anaesthetic poisoning. It is believed to increase the intravascular lipid phase, so creating a ‘lipid sink’ to reduce the amount of active drug in plasma. Other proposed mechanisms of benefit include increasing myocardial fatty acid energy substrate and improving the function of cell membrane-bound ion channels (particularly Ca$^{2+}$ and Na$^+$. The role of Intralipid® in the management of poisoning with highly lipid-soluble drugs is not well defined but case reports suggest some benefit in life-threatening cardiotoxicity that is resistant to other measures.

**Investigations**
Box 6.7 sets out investigations that may be helpful in poisoned patients. On admission, or at an appropriate time post overdose, a timed blood sample should be taken if it is suspected that aspirin, digoxin, ethylene glycol, iron, lithium, methanol, paracetamol, paraquat, quinine or theophylline has been ingested (Box 6.8). The determination of the concentrations of these drugs will be valuable in management. Drug screens on blood and urine are occasionally indicated in severely poisoned patients in whom the cause of coma is unknown. A poison information service will advise.

**Box 6.7**

**Investigations that may be helpful in poisoned patients**

- Urea, electrolytes, creatinine, estimated glomerular filtration rate
- Creatine kinase activity
- Acid–base assessment (arterial gas, unless no concern regarding ventilation; see p. 66)
- Blood for specific poisons (see p. 69)
- Electrocardiography (see p. 70)
- Urine saved (plain tube) for possible drug screen
- Radiology (see p. 70)

**Box 6.8**

**Laboratory analysis for toxins**

- Carbon monoxide (carboxyhaemoglobin)
- Ethanol (when monitoring treatment in glycol and methanol poisoning)
- Ethylene glycol
- Iron
- Lithium
- Methanol
- Paracetamol
- Salicylate
- Theophylline

Some routine investigations (Box 6.9) are of value in the differential diagnosis of coma or the detection of poison-induced hypokalaemia, hyperkalaemia, hypoglycaemia, hyperglycaemia, hepatic or renal failure or metabolic acidosis (Box 6.10). Measurement of carboxyhaemoglobin, methaemoglobin and cholinesterase activities are of assistance in the diagnosis and management of cases of poisoning due to carbon monoxide, methaemoglobin-
inducing agents such as nitrites, and organophosphorus insecticides, respectively.

- Paracetamol
- Salicylates
Tricyclic antidepressants

ECG
Routine ECG is of limited diagnostic value, but continuous ECG monitoring should be undertaken in those ingesting potentially cardiotoxic drugs; for example, sinus tachycardia with prolongation of the PR and QRS intervals in an unconscious patient suggests tricyclic antidepressant overdose. QT interval prolongation is an adverse effect of several drugs (e.g. quetiapine and quinine).

Radiology
Routine radiology is of little diagnostic value. It can confirm ingestion of metallic objects (e.g. coins, button batteries) or injection of globules of metallic mercury. Some enteric-coated or sustained-release drugs or ingested packets of illicit substances may be seen on plain abdominal X-rays. Radiology can confirm complications of poisoning, such as aspiration pneumonia, non-cardiogenic pulmonary oedema (salicylates) and acute respiratory distress syndrome (ARDS).

Further reading

Specific Poisons

Drugs and other chemicals
• All patients must be reviewed by senior medical staff.
• All should have relevant blood tests and monitoring when appropriate.
• The general principles of management of self-poisoning outlined above will always need to be applied.

In this section, only the specific treatment regimens are outlined. The physical signs of the effects of individual drugs are shown on p. 65.
Amfetamines, including Ecstasy (MDMA)

The medicinal product is the dextro-isomer, dexamfetamine. The N-methylated derivative, metamfetamine (the crystalline form of this salt is known as ‘crystal meth’ or ‘ice’), and 3,4-methylenedioxymetamfetamine (MDMA), commonly known as Ecstasy, are misused worldwide.

Amfetamines are central nervous system (CNS) and cardiovascular stimulants. These effects are mediated by increasing synaptic concentrations of adrenaline (epinephrine) and dopamine.

Clinical features

Amfetamines cause euphoria, extrovert behaviour, a lack of desire to eat or sleep, tremor, dilated pupils, tachycardia and hypertension. More severe intoxication is associated with agitation, paranoid delusions, hallucinations and violent behaviour. Convulsions, rhabdomyolysis, hyperthermia and cardiac arrhythmias may develop in severe poisoning. Rarely, intracerebral and subarachnoid haemorrhage may occur and can be fatal.

Ecstasy poisoning is characterized by agitation, tachycardia, hypertension, widely dilated pupils, trismus and sweating. In more severe cases, hyperthermia, disseminated intravascular coagulation, rhabdomyolysis, acute kidney injury and hyponatraemia (secondary to inappropriate antidiuretic hormone secretion) predominate.

Management

Agitation is controlled by diazepam 10–20 mg i.v. or haloperidol 5 mg i.m. The peripheral sympathomimetic actions of amfetamines can be antagonized by β-adrenoceptor-blocking drugs. If hyperthermia is present, dantrolene 1 mg/kg body weight i.v. should be considered (see ‘Hyperthermia’ on p. 67).

Anticonvulsants

Clinical features

The clinical features of poisoning with anticonvulsant drugs are summarized in Box 6.11.

Box 6.11

Clinical features of poisoning with anticonvulsant drugs
### Antidepressants: tricyclics and selective serotonin reuptake inhibitors

**Tricyclic antidepressants** block the reuptake of monoamines (e.g. norepinephrine (noradrenaline) and serotonin) into peripheral and intracerebral neurones, thereby increasing the concentration of these neurotransmitters in these areas (see Fig. 22.3). They also have antimuscarinic actions and class 1 antiarrhythmic (quinidine-like) sodium-channel-blocking activity.

**Selective serotonin reuptake inhibitors (SSRIs)** (e.g. citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine and sertraline) lack the antimuscarinic and sodium-channel-blocking actions of tricyclic antidepressants.

### Clinical features

**Tricyclic antidepressants.** Mild poisoning commonly causes drowsiness, sinus tachycardia, dry mouth, dilated pupils, urinary retention (all antimuscarinic effects), and increased reflexes.
and extensor plantar responses. Severe intoxication leads to coma, convulsions, and occasionally divergent strabismus. Plantar, oculocephalic and oculovestibular reflexes may be abolished temporarily. An ECG will often show a wide QRS interval and there is a reasonable correlation between the width of the QRS complex and the severity of poisoning. Life-threatening arrhythmias may ensue. Metabolic acidosis and cardiorespiratory depression are observed in severe cases.

SSRIs. Even in large overdoses, SSRIs appear to be relatively safe unless potentiated by ethanol. Most patients will show no signs of toxicity but drowsiness, nausea, diarrhoea and sinus tachycardia have been reported. Rarely, junctional bradycardia, seizures and hypertension have been encountered and influenza-like symptoms may develop.

The serotonin syndrome occasionally occurs (see p. 910).

Management

The majority of patients recover with supportive therapy alone (adequate oxygenation, control of convulsions and correction of acidosis), although a small percentage who ingest a tricyclic will require assisted ventilation for 24–48 hours. The onset of supraventricular tachycardia and ventricular tachycardia should be treated with sodium bicarbonate (8.4%) 50 mmol i.v. over 20 min, even if there is no acidosis present; a second bolus may be required.

Antidiabetic drugs

Insulin (if injected but not if ingested) and sulphonylureas cause hypoglycaemia. This is not seen with metformin, since its mode of action is to increase glucose utilization, but lactic acidosis is a potentially serious complication of metformin poisoning.

Clinical features

Features of severe hypoglycaemia include drowsiness, coma, convulsions, depressed limb reflexes, extensor plantar responses and cerebral oedema. Hypokalaemia also occurs. Cranial (neurogenic) diabetes insipidus and persistent vegetative states are possible long-term complications if hypoglycaemia is prolonged.

Management

The blood or plasma glucose concentration should be measured urgently and intravenous glucose given, if necessary. Glucagon produces only a slight rise in blood glucose, although it can reduce the amount of glucose required (see p. 1258).

Severe insulin poisoning. A continuous infusion of 10–20% glucose (with K+ 10–20 mmol/L) is required, together with carbohydrate-rich meals, though there may be difficulty in maintaining normoglycaemia.

Sulphonylurea poisoning. The administration of glucose increases already high circulating
insulin concentrations. Octreotide (50 µg i.v.), which inhibits insulin release, should be given as well as glucose.

### Antimalarials

#### Clinical features

**Chloroquine.** Hypotension is often the first clinical manifestation of chloroquine poisoning. It may progress to acute heart failure, pulmonary oedema and cardiac arrest. Agitation, acute psychosis, convulsions and coma may ensue. Hypokalaemia is common and is due to chloroquine-induced potassium-channel blockade. Bradyarrhythmias and tachyarrhythmias are common, and ECG conduction abnormalities are similar to those seen in quinine poisoning.

**Quinine.** Cinchonism (tinnitus, deafness, vertigo, nausea, headache and diarrhoea) is common. In more severe poisoning, convulsions, hypotension, pulmonary oedema and cardiorespiratory arrest are seen (due to ventricular arrhythmias that are often preceded by ECG conduction abnormalities, particularly QT prolongation). Quinine cardiotoxicity is due to sodium-channel blockade. Patients may also develop ocular features, including blindness, which can be permanent.

**Primaquine.** The main concern is primaquine's propensity to cause methaemoglobinaemia and haemolytic anaemia.

#### Management

Multiple-dose oral activated charcoal increases quinine and probably chloroquine clearance. Hypokalaemia should be corrected. Sodium bicarbonate 50–100 mmol i.v. is given if the ECG shows QRS prolongation but it will exacerbate hypokalaemia, which should be corrected first. Mechanical ventilation, the administration of an inotrope (see pp. 1158–1160) and high doses of diazepam (1 mg/kg as a loading dose and 0.25–0.4 mg/kg per hour maintenance) may reduce the mortality in severe chloroquine poisoning. Overdrive pacing may be required if torsades de pointes (see p. 975) occurs in quinine poisoning and does not respond to magnesium sulphate infusion (see p. 975). If clinically significant methaemoglobinaemia (generally above 30%) develops in primaquine poisoning, methylthioninium (methylene blue) 1–2 mg/kg body weight should be administered.

### Arsenic

Arsenic poisoning worldwide is commonly caused by contamination of the ground water by inorganic arsenates, particularly in Asia. Occasionally, arsenic is found in Chinese and Indian traditional remedies.

#### Clinical features
**Acute ingestion** causes abdominal pain, vomiting and diarrhoea. Hypovolaemic shock and acute tubular necrosis occur in severe cases.

**Chronic exposure** to lower doses produces gastrointestinal effects, accompanied by skin changes (hyperkeratosis of palms and soles, ‘raindrop’ pattern of hyperpigmentation and alopecia), neurological features (headache, sensorimotor neuropathy), abnormal liver biochemistry (non-cirrhotic portal hypertension is recognized), peripheral vascular arteriosclerosis and haematological abnormalities (pancytopenia).

### Management
The identification of, and removal from, the source of exposure to arsenic is vital. Chelation therapy with oral DMSA 30 mg/kg per day or DMPS 30 mg/kg per day i.v. may be indicated.

### Benzodiazepines
Benzodiazepines are commonly taken in overdose but rarely produce severe poisoning, except in the elderly or those with chronic respiratory disease.

#### Clinical features
Benzodiazepines produce drowsiness, ataxia, dysarthria and nystagmus. Coma and respiratory depression develop in severe intoxication.

#### Management
If respiratory depression is present in patients who have severe benzodiazepine poisoning, flumazenil 0.5–1.0 mg i.v. is given in an adult and this dose often needs repeating. Flumazenil use often avoids the need for assisted ventilation. It is relatively contraindicated in patients with mixed proconvulsant (e.g. tricyclic antidepressants)/benzodiazepine poisoning and those with a history of epilepsy because it may cause convulsions.

### Beta-adrenoceptor-blocking drugs

#### Clinical features
In mild poisoning, sinus bradycardia is the only feature, but if a substantial amount has been ingested, coma, convulsions and hypotension develop. Less commonly, delirium, hallucinations and cardiac arrest supervene. Bronchospasm and hypoglycaemia are rare complications.

#### Management
Glucagon 50–150 µg/kg (typically 5–10 mg in an adult), followed by an infusion of 5–10 mg/h,
is the most effective agent. It acts by bypassing the blocked beta-receptor, thus activating adenylyl cyclase and promoting formation of cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP); cAMP, in turn, exerts a direct beta-stimulant effect on the heart. Atropine 0.6–1.2 mg i.v. can be used to treat bradycardia but is usually less effective. High-dose insulin (initial intravenous bolus of 1.0 IU/kg, followed by 0.5–2.0 IU/kg/h) with hypertonic glucose to avoid hypoglycaemia, has been shown to improve myocardial contractility and systemic perfusion.

### Calcium-channel blockers

Calcium-channel blockers all act by blocking voltage-gated calcium channels. Dihydropyridines (e.g. amlodipine, felodipine, nifedipine) are predominantly peripheral vasodilators, while verapamil (a phenylalkylamine) and diltiazem (a benzothiazepine) also have significant cardiac effects. Poisoning, particularly with verapamil and diltiazem, causes heart block and hypotension; in severe poisoning, there is a substantial fatality rate. When a sustained-release preparation has been ingested, the onset of severe features is delayed, sometimes for more than 12 hours. Overdose with even small amounts can have profound effects.

### Clinical features

Hypotension occurs due to peripheral vasodilatation, myocardial depression and conduction block. The ECG may progress from sinus bradycardia through first, then higher, degrees of block, to asystole. Cardiac and non-cardiac pulmonary oedema may ensue in severely poisoned patients. Other features include nausea, vomiting, seizures and a lactic acidosis.

### Management

Intravenous atropine 0.6–1.2 mg, repeated as required, should be given for bradycardia and heart block. The initial dose can be repeated every 3–5 min, but if there is no response in pulse rate or blood pressure after three such doses, it is unlikely that further boluses will be helpful. The response to atropine is sometimes improved following intravenous 10% calcium chloride, 5–10 mL (at 1–2 mL/min). If there is an initial response to calcium, a continuous infusion is warranted; this is given as 10% calcium chloride, 1–10 mL/h.

Cardiac pacing has a role if there is evidence of atrioventricular conduction delay but failure to capture occurs.

Treat hypotension initially with intravenous crystalloid. If significant hypotension persists despite volume replacement, administer glucagon, which activates myosin kinase independent of calcium. Give glucagon 5–10 mg (150 µg/kg) i.v. as a slow bolus and repeat, if necessary. If there is a favourable response in blood pressure, an infusion of 5–10 mg/h can be commenced.

Insulin–glucose euglycaemia has been shown to improve myocardial contractility and systemic perfusion, and should be considered in cases of resistant hypotension. Insulin is given
as a bolus dose of 1 U/kg, followed by an infusion of 1–10 U/kg per hour with 10% glucose and frequent monitoring of blood glucose and potassium.

### Cannabis (marijuana) and cannabinoids

Cannabis is usually smoked but may be ingested as a ‘cake’, made into a tea or injected intravenously. The major psychoactive constituent is δ-11-tetrahydrocannabinol (THC). THC possesses activity at the benzodiazepine, opioid and cannabinoid receptors.

A number of synthetic cannabinoids have been developed recently and are sold as herbal incense or ‘spice’. Typically, these are considerably more potent than THC.

### Clinical features

Initially, there is euphoria, followed by distorted and heightened images, colours and sounds, altered tactile sensations and sinus tachycardia. Visual and auditory hallucinations and acute psychosis are particularly likely to occur after substantial ingestion in naive cannabis users. Intravenous injection leads to watery diarrhoea, tachycardia, hypotension and arthralgia.

Heavy users suffer impairment of memory and attention, and poor academic performance. There is an increased risk of anxiety and depression. Regular users are at risk of dependence. Cannabis use results in an overall increase in the relative risk for later schizophrenia and psychotic episodes (see p. 924). Cannabis smoke is probably carcinogenic.

### Management

Reassurance is usually the only treatment required, although sedation with intravenous diazepam 10–20 mg i.v. in an adult or haloperidol 2–5 mg i.m./oral in an adult is sometimes required. Hypotension requires intravenous fluids.

### Carbamate insecticides

Carbamate insecticides inhibit acetylcholinesterase but the duration of this inhibition is comparatively short-lived in comparison with organophosphorus insecticides (see p. 79), since the carbamate–enzyme complex tends to dissociate spontaneously.

### Clinical features

Although carbamate insecticide poisoning is generally less severe than organophosphorus insecticide poisoning, acute poisoning with a carbamate can be severe and fatal. Cholinergic symptoms usually develop within a few minutes. In the most severe cases, muscle twitching, profound weakness, profuse sweating, incontinence, mental confusion and progressive cardiac and respiratory failure ensue. In less severe cases, cholinergic symptoms are usually evident within 2 hours and typically resolve within 24 hours. Seizures are relatively uncommon, since
carbamate penetration into the CNS is limited.

**Management**

Mild cases require no specific treatment other than the removal of soiled clothing. Atropine 2 mg i.v. should be given every 3–5 min if necessary to reduce increased secretions, rhinorrhea and bronchorrhoea. If this measure fails, the patient should be intubated and mechanical ventilation instituted. Since carbamates have a shorter duration of action than organophosphorus insecticides, pralidoxime should be used only rarely in carbamate poisoning. If intoxication is life-threatening, give pralidoxime chloride 30 mg/kg body weight i.v. over 5–10 min, followed by an infusion of 8–10 mg/kg per hour.

**Carbon monoxide**

The most common source of carbon monoxide is an improperly maintained and poorly ventilated heating system. In addition, inhalation of methylene chloride (found in paint strippers) may also lead to carbon monoxide poisoning, as methylene chloride is metabolized in vivo to carbon monoxide. Carbon monoxide has a greater affinity for haemoglobin and forms carboxyhaemoglobin (COHb), thereby reducing the oxygen-carrying capacity. The affinity of the remaining haem groups for oxygen is increased. This shifts the oxyhaemoglobin dissociation curve to the left, impairing liberation of oxygen to the cells and leading to tissue hypoxia. In addition, carbon monoxide also inhibits cytochrome oxidase a₃.

**Clinical features**

Symptoms of mild to moderate exposure to carbon monoxide may be mistaken for a viral illness.

- A peak COHb concentration of <10% is not normally associated with symptoms
- A peak COHb concentration of 10–30% usually causes headache and mild exertional dyspnoea.
- Higher concentrations of COHb are associated with coma, convulsions and cardiorespiratory arrest. Metabolic acidosis, myocardial ischaemia, hypertonia, extensor plantar responses, retinal haemorrhages and papilloedema also occur.

Neuropsychiatric features may develop after apparent recovery from carbon monoxide exposure.

**Management**

In addition to removing the patient from carbon monoxide exposure, high-flow oxygen should be administered using a tightly fitting face mask (see p. 1166). Endotracheal intubation and mechanical ventilation are required in those who are unconscious. Several controlled studies
of hyperbaric oxygen have been published but none has shown long-term clinical benefit.

**Cathinones**

Cathinone (khat) is a naturally occurring stimulant derived from the plant *Catha edulis*. The drug is released during prolonged chewing of plant leaves. An increasing number of synthetic cathinone derivatives are available, the best-known of which is mephedrone (4-methyl methcathinone). While typically sold as ‘plant foods’ or ‘bath salts’, these ‘legal highs’ are purchased for their recreational abuse potential. Synthetic cathinones may be taken by mouth, nasal insufflation or injection.

**Clinical features**

Cathinones can cause euphoria, extrovert behaviour, a lack of desire to eat or sleep, tremor, dilated pupils, tachycardia and hypertension. More severe intoxication is associated with marked agitation, paranoid delusions, and hallucinations. Convulsions, rhabdomyolysis, hyperthermia and cardiac arrhythmias may develop in severe poisoning.

**Management**

Agitation is controlled by diazepam 10–20 mg i.v. or haloperidol 5 mg i.m. The peripheral sympathomimetic actions can be antagonized by β-adrenoceptor-blocking drugs. If hyperthermia persists despite sedation and cooling measures, expert advice should be sought and dantrolene 1 mg/kg body weight i.v. should be given.

**Cocaine**

Cocaine hydrochloride (‘street’ cocaine, ‘coke’) is a water-soluble powder or granule that can be taken orally, intravenously or intranasally (‘snorting’). ‘Freebase’ or ‘crack’ cocaine comprises crystals of relatively pure cocaine without the hydrochloride moiety and is obtained in rocks (150 mg of cocaine). It is more suitable for smoking in a pipe or mixed with tobacco; it can also be heated on foil and the vapour inhaled (approximately 35 mg of drug per ‘line’ or a ‘rail’). The effects of cocaine are experienced almost immediately after intravenous administration or smoking, about 10 min following intranasal administration and 45–90 min after oral ingestion. The effects start to resolve in about 20 min but may last up to 90 min. In severe poisoning, death occurs in minutes but survival beyond 3 hours is not usually fatal.

Cocaine blocks the reuptake of biogenic amines:

- Inhibition of dopamine reuptake is responsible for the psychomotor agitation that commonly accompanies cocaine use.
- Blockade of noradrenaline (norepinephrine) reuptake produces tachycardia.
- Inhibition of serotonin reuptake induces hallucinations.
• CNS arousal is enhanced by potentiating the effects of excitatory amino acids.
• Cocaine is a powerful local anaesthetic and vasoconstrictor.

Clinical features
After initial euphoria, cocaine produces agitation, tachycardia, hypertension, sweating, hallucinations, convulsions, metabolic acidosis, hyperthermia, rhabdomyolysis and ventricular arrhythmias. Dissection of the aorta, myocarditis, myocardial infarction, dilated cardiomyopathy, subarachnoid haemorrhage, and cerebral haemorrhage or infarction may occur. If a young person presents with a stroke or myocardial infarction, cocaine poisoning, because of its vasoconstrictor effect, is a possible cause.

Management
• Diazepam 10–20 mg i.v. is used to control agitation and convulsions.
• Active external cooling should be employed for hyperthermia.
• Hypertension and tachycardia usually respond to sedation and cooling. If hypertension persists, give glyceryl trinitrate starting at 1–2 mg/h and gradually increase the dose (maximum 12 mg/h) until the blood pressure is controlled.
• Calcium-channel blockers, such as nifedipine, verapamil or diltiazem, are an alternative second-line therapy. The use of beta-blockers is controversial.
• Early use of a benzodiazepine is often effective in relieving cocaine-associated non-cardiac chest pain.
• Myocardial ischaemia/infarction should be treated conventionally.

Copper sulphate
Copper sulphate is used in fungicides, algicides, electroplating, dyes, inks, disinfectants and wood preservatives.

Clinical features
Ingestion causes vomiting, abdominal pain, diarrhoea, headache, dizziness and a metallic taste. Gastrointestinal haemorrhage, intravascular haemolysis, methaemoglobinaemia, rhabdomyolysis, coma, convulsions and hepatorenal failure may ensue and fatalities have occurred. Body secretions may be blue/green.

Management
Treatment is supportive with replenishment of lost fluids/blood. Blood copper concentrations correlate with the severity of poisoning; a copper concentration of >8 mg/L is indicative of
severe poisoning. Early endoscopy (or CT scan with contrast if endoscopy is not possible) is recommended if corrosive damage is suspected. Methaemoglobinemia of >30% should be treated with intravenous methylthionium chloride 2 mg/kg. Renal failure may require extracorporeal support.

### Corrosive agents

Strong acids and alkalis cause chemical burns. Inorganic acids such as hydrochloric and sulphuric acid are generally more toxic than organic acids such as acetic acid. Hydrofluoric acid is considered separately (see p. 76). Some household products, such as water-sterilizing tablets, are strong alkalis. Following corrosive ingestion, the vital aspects of management are early (within 24 h) assessment of the severity of injury (ideally with endoscopy, or alternatively with CT imaging) and prompt surgical intervention to remove necrotic tissue, if indicated.

### Cyanide

Cyanide and its derivatives are used widely in industry. Hydrogen cyanide is also released during the thermal decomposition of polyurethane foams, such as that in mattresses. Cyanide reversibly inhibits cytochrome oxidase $a_3$, so that cellular respiration ceases.

#### Clinical features

Inhalation of hydrogen cyanide produces symptoms within seconds and death within minutes. By contrast, the ingestion of a cyanide salt may not produce features for 1 hour. After exposure, initial symptoms are non-specific and include a feeling of constriction in the chest and dyspnoea. Coma, convulsions and metabolic acidosis may then supervene.

#### Management

Oxygen should be administered and, if it is available, dicobalt edetate 300 mg should be administered intravenously; the dose is repeated in severe cases. Dicobalt edetate (and the free cobalt contained in the preparation) complexes free cyanide. An alternative but expensive antidote is hydroxocobalamin 5 g i.v., which enhances endogenous cyanide detoxification; a second dose may be required in severe cases. If these two antidotes are not available, sodium thiosulphate 12.5 g i.v., which acts by enhancing endogenous detoxification, and sodium nitrite 300 mg i.v. should be administered. Sodium nitrite produces methaemoglobinemia; methaemoglobin combines with cyanide to form cyanmethaemoglobin.

### Digoxin

Toxicity occurring during chronic administration is common, though acute poisoning is
infrequent. Oleander poisoning (see p. 84) produces similar features.

**Clinical features**

These include nausea, vomiting, dizziness, anorexia and drowsiness. Rarely, confusion, visual disturbances and hallucinations occur. Sinus bradycardia is often marked and may be followed by supraventricular arrhythmias with or without heart block, ventricular premature beats and ventricular tachycardia. Hyperkalaemia occurs due to inhibition of the sodium–potassium activated ATPase pump.

**Management**

- Atropine 1.2–2.4 mg i.v. is given to reduce sinus bradycardia, atrioventricular block and sinoatrial standstill.
- Digoxin-specific antibody fragments (digoxin-Fab) should be given intravenously for significant hyperkalaemia, marked arrhythmias (usually severe bradycardia compromising the cardiac output) and asystole. In both acute and chronic poisoning, only half the estimated dose required for full neutralization (calculated from amount of drug taken or serum digoxin concentration) need be given initially; a further dose is given if clinically indicated.

**Ethanol**

Ethanol is commonly ingested in beverages and deliberately with other substances in overdose. It is also present in many cosmetic and antiseptic preparations. Following absorption, ethanol is oxidized to acetaldehyde and then to acetate. Ethanol is a CNS depressant and the features of ethanol intoxication are generally related to blood concentrations *(Box 6.12)*.

**Box 6.12**

|                |                   | Death (from respiratory or circulatory failure, or from aspiration)  |

### Clinical features

In children in particular, severe hypoglycaemia may accompany alcohol intoxication due to inhibition of gluconeogenesis. Hypoglycaemia is also observed in those who are malnourished or who have fasted in the previous 24 hours. In severe cases of intoxication, coma and hypothermia are often present, and lactic acidosis, ketoacidosis and acute kidney injury have been reported.

### Management

As ethanol-induced hypoglycaemia is not responsive to glucagon, glucose 10–20% i.v. should be infused at a rate determined by the blood sugar. Haemodialysis should be considered if the blood ethanol concentration exceeds 7500 mg/L and if a severe metabolic acidosis (see p. 1150) is present, which has not been corrected by fluids and intravenous bicarbonate.

### Ethylene and diethylene glycol

Ethylene and diethylene glycol are found in a variety of common household products, including antifreeze, windshield washer fluid, brake fluid and lubricants. The features observed in poisoning with these agents are due to metabolites predominantly, not the parent chemical. Ethylene glycol (Fig. 6.1) is metabolized to glycolate, the cause of the acidosis. A small proportion of glyoxylate is metabolized to oxalate. Calcium ions chelate oxalate to form insoluble calcium oxalate, which is responsible for renal toxicity. Diethylene glycol is metabolized to 2-hydroxyethoxyacetate (Fig. 6.2), which is the cause of metabolic acidosis, and diglycolic acid (the cause of kidney injury).
Clinical features

Initially, the features of ethylene glycol poisoning are similar to those of ethanol intoxication (though there is no ethanol on the breath). Coma and convulsions follow and a variety of neurological abnormalities, including nystagmus and ophthalmoplegias, are seen. Severe metabolic acidosis, hypocalcaemia and acute kidney injury are well-recognized complications.

In diethylene glycol poisoning, nausea and vomiting, headache, abdominal pain, coma, seizures, metabolic acidosis and acute kidney injury commonly occur. Pancreatitis and hepatitis, together with cranial neuropathies and demyelinating peripheral neuropathy, are also seen.

Management

If the patient presents early after ingestion, the priority is to inhibit metabolism using either intravenous fomepizole or ethanol; the former does not require monitoring of blood concentrations.

- **Fomepizole** 15 mg/kg body weight should be administered, followed by four 12-hourly doses of 10 mg/kg, then 15 mg/kg every 12 h until glycol concentrations are not detectable. Following a substantial ingestion, haemodialysis or haemodiafiltration should be employed to remove the glycol and metabolites. If dialysis is used, the frequency of fomepizole dosing should be increased to 4-hourly because fomepizole is dialysable.

- **Ethanol** Alternatively, a loading dose of ethanol 50 g can be administered, followed by an intravenous infusion of ethanol 10–12 g/h to produce blood ethanol concentrations of 500–1000 mg/L (11–22 mmol/L). The infusion is continued until the glycol is no longer detectable in the blood. If haemodialysis is employed, the rate of ethanol administration will need to be increased to 17–22 g/h, as ethanol is dialysable.
Supportive measures to combat shock, hypocalcaemia and metabolic acidosis should be instituted.

**Gamma-hydroxybutyric acid**

Gamma-hydroxybutyric acid (GHB) occurs naturally in mammalian brain, where it is derived metabolically from gamma-aminobutyric acid (GABA). GHB, as well as gamma-butyrolactone (another sedative agent with psychedelic effects), is a major recreational drug for body building, weight loss and production of a ‘high’. Street names include ‘cherry meth’ and ‘liquid X’. They are taken as a colourless liquid dissolved in water.

**Clinical features**

Poisoning is characterized by aggressive behaviour, ataxia, amnesia, vomiting, drowsiness, bradycardia, respiratory depression and apnoea, seizures and coma, which characteristically is short-lived.

**Management**

In a patient who is breathing spontaneously, the management of GHB poisoning is primarily supportive, with oxygen supplementation and the administration of atropine for persistent bradycardia, as necessary. Those who are severely poisoned will require mechanical ventilation, although recovery is usually complete within 6–8 hours.

**Household products**

The agents most commonly involved are bleach, cosmetics, toiletries, detergents, disinfectants, and petroleum distillates such as paraffin and white spirit. Ingestion of household products is usually accidental and is most common among children less than 5 years of age.

**Clinical features**

If ingestion is accidental, features very rarely occur, except in the case of petroleum distillates where aspiration is a recognized complication because of their low surface tension. Powder detergents, sterilizing tablets, denture cleaning tablets and industrial bleaches (which contain high concentrations of sodium hypochlorite) are corrosive to the mouth and pharynx if ingested. Nail polish and nail polish remover contain acetone, which may produce a coma if ingested in substantial quantities. Inhalation by small children of substantial quantities of talcum powder has occasionally given rise to severe pulmonary oedema and death.

**Hydrofluoric acid and hydrogen fluoride**
Hydrofluoric acid, a solution of hydrogen fluoride in water, is a colourless, fuming liquid that is widely used in industry. It is particularly dangerous because of its unique ability among acids to penetrate tissue.

Clinical features

Dermal exposure to hydrofluoric acid results in rapid liquefactive necrosis and erosion of bone. If more than 1% of the body surface area is contaminated with a 50% or higher solution of hydrofluoric acid, there is a high risk of hypocalcaemia from the formation of calcium fluoride. This may lead to cardiac conduction disturbances, notably QT interval prolongation and an increased risk of ventricular arrhythmias, particularly torsades de pointes (see p. 975).

Ingestion of hydrofluoric acid causes severe corrosive injury to the gastrointestinal tract.

Inhalation of hydrogen fluoride causes irritation of the eyes and nose, with sore throat, cough, chest tightness, headache, ataxia and confusion. Dyspnoea and stridor due to laryngeal oedema may follow, depending on the concentration of hydrogen fluoride. Haemorrhagic pulmonary oedema with increasing breathlessness, wheeze, hypoxia and cyanosis may take up to 36 hours to develop.

Management

• Dermal exposure. Immediate irrigation of the skin with copious volumes of water is the priority, followed by the prompt application of calcium gluconate gel to reduce pain and limit skin damage.
• Ingestion. This is a medical emergency with the need for immediate assessment for surgery after endoscopy or CT.
• Inhalation. If the patient has clinical features of bronchospasm after inhalation, then treat conventionally with nebulized bronchodilators and steroids. Treat pulmonary oedema and/or ARDS (see pp. 1168–1169) with continuous positive airway pressure (CPAP), or in severe cases with intermittent positive pressure ventilation (IPPV).

Iron

Unless more than 60 mg of elemental iron per kg of body weight is ingested (a ferrous sulfate tablet contains 60 mg of iron), features are unlikely to develop. As a result, poisoning is seldom severe but deaths still occur. Iron salts have a direct corrosive effect on the upper gastrointestinal tract.

Clinical features

The initial features are characterized by nausea, vomiting (the vomit may be grey or black in colour), abdominal pain and diarrhoea. Severely poisoned patients develop haematemesis, hypotension, coma and shock at an early stage. Usually, however, most patients suffer only
mild gastrointestinal symptoms. A small minority deteriorate 12–48 hours after ingestion and develop shock, metabolic acidosis, acute tubular necrosis and hepatocellular necrosis. Rarely, up to 6 weeks after ingestion, intestinal strictures occur due to corrosive damage. The serum iron concentration should be measured some 4 hours after ingestion; if the concentration exceeds the predicted normal iron-binding capacity (usually >5 mg/L; 90 µmol/L), free iron is circulating and treatment with desferrioxamine is required.

**Management**

The majority of patients ingesting iron do not require desferrioxamine therapy. If a patient develops coma or shock, desferrioxamine should be given without delay in a dose of 15 mg/kg per hour i.v. (the total amount of infusion usually not to exceed 80 mg/kg in 24 h). If the recommended rate of administration is continued for several days, adverse effects, including pulmonary oedema and ARDS (see pp. 1167–1169), have been reported.

**Isopropanol**

Isopropanol is found in aftershave lotions, disinfectants and window-cleaning solutions, and is used as a sterilizing agent and ‘rubbing’ alcohol. It is usually ingested, but inhalation and topical exposure have led to poisoning. Isopropanol is oxidized to acetone by hepatic alcohol dehydrogenase.

**Clinical features**

Coma, which may be prolonged, and respiratory depression are the major sequelae of substantial exposure. Other features following ingestion include haemorrhagic gastritis, haematemesis, acetone on the breath, hypotension, hypothermia, sinus tachycardia, frequent premature ventricular beats, renal tubular necrosis, acute myopathy and haemolytic anaemia. Ataxia, headache, dizziness, drowsiness, stupor, hallucinations, areflexia and muscle weakness may occur.

Hypoglycaemia or hyperglycaemia, haemolysis, ketonuria, renal tubular acidosis, hepatic dysfunction and rhabdomyolysis have been reported. Prolonged skin contact and inhalation may also result in systemic features.

**Management**

The mainstay of treatment is supportive care. In addition, since isopropanol has a small volume of distribution (0.6–0.7 L/kg) and is responsible together with its metabolite, acetone, for toxicity, there is a role for haemodialysis in the management of severely poisoned patients.

**Lead**
Exposure to lead occurs occupationally, children may eat lead-painted items in their homes (pica), and the use of lead-containing cosmetics or ‘drugs’ has also resulted in poisoning.

Clinical features
Mild intoxication may result in no more than lethargy and occasional abdominal discomfort, though abdominal pain, vomiting, constipation and encephalopathy (seizures, delirium, coma) may develop in more severe cases. Encephalopathy is more common in children than in adults but is rare in the developed world. Typically, though very rarely, lead poisoning results in foot drop attributable to peripheral motor neuropathy.

Anaemia (normally normochromic normocytic) occurs due both to inhibition by lead of several enzymes involved in haem synthesis, and to haemolysis. The latter results from damage to the red cell membrane by aggregates of RNA that accumulate owing to inhibition by lead of pyrimidine-5-nucleotidase, causing characteristic ‘basophilic stippling’ of erythrocytes.

Management
The social and occupational dimensions of lead poisoning must be recognized. Simply giving patients chelation therapy and then returning them to a contaminated environment is of no value.

The decision to use chelation therapy is based not only on the blood lead concentration but also on the presence of symptoms. Parenteral sodium calcium edetate 75 mg/kg per day or oral succimer (DMSA) 30 mg/kg per day is of similar efficacy. At least 5 days' treatment is usually required. As chelation of zinc may occur with sodium calcium edetate, serum zinc concentrations should be checked.

Lithium
Lithium toxicity is usually the result of therapeutic dosing (chronic toxicity) rather than deliberate self-poisoning (acute toxicity). However, single large doses are occasionally ingested by individuals on long-term treatment with the drug (acute-on-therapeutic toxicity). The target therapeutic plasma lithium concentration range is narrow (0.8–1.2 mmol/L).

Clinical features
Features of intoxication include diarrhoea and vomiting, tremor, malaise, thirst, polyuria and, in more serious cases, impairment of consciousness, hypertonia and convulsions; irreversible neurological damage may occur. Measurement of the serum lithium concentration confirms the diagnosis. Acute massive overdose may produce concentrations of 5 mmol/L (34.7 mg/L) without causing toxic features, whereas chronic toxicity may be associated with neurological features at plasma concentrations as low as 1.5 mmol/L (6.9 mg/L).
Management

Since lithium is eliminated unchanged via the kidneys, diuresis with sodium chloride 0.9% is effective in increasing clearance. Haemodialysis is far superior and is used if neurological features are present and/or if renal function is impaired. It is employed particularly in cases of chronic toxicity.

Lysergic acid diethylamide

Clinical features

Lysergic acid diethylamide (LSD) is a potent synthetic hallucinogen. When ingested, usually on impregnated absorbent paper, effects appear within 30 minutes and last 8–12 hours. Visual disturbances are common and may be associated with life-threatening behaviour. Dilated pupils, tachycardia and hypertension are usually present. Psychosis may last several days and subsequent ‘flashbacks’ are common.

Management

Treatment is supportive, with reassurance and benzodiazepines if required. Antipsychotics are best avoided, as they may lower the seizure threshold.

Mercury

Mercury is the only metal that is liquid at room temperature. It exists in three oxidation states (elemental/metallic Hg⁰, mercurous Hg₂⁺ and mercuric Hg²⁺) and can form inorganic (e.g. mercuric chloride) and organic (e.g. methylmercury) compounds. Metallic mercury is very volatile; when spilled, it has a large surface area so that high atmospheric concentrations may be produced in enclosed spaces, particularly when environmental temperatures are high. Thus, great care should be taken in clearing up a spillage. If ingested, metallic mercury will usually be eliminated per rectum, though small amounts may settle in the appendix and remain there for years. Mercury salts are well absorbed following ingestion, as is mercury vapour following inhalation.

Clinical features

Acute inhalation of mercury vapour causes headache, nausea, cough, chest pain and, occasionally, a chemical pneumonitis. Proteinuria and nephrotic syndrome are observed rarely. Ingestion of inorganic or organic mercury compounds causes an irritant gastroenteritis. Mercurous (Hg₂⁺) compounds are less corrosive and less toxic than mercuric (Hg²⁺) salts.

Systemic accumulation of mercury from any source and by any route of exposure leads to
characteristic neurological features, including a fine tremor, lethargy, memory loss, insomnia, personality changes and ataxia. Peripheral nerve damage has also been observed, as has renal tubular damage.

### Management

Unithiol (DMPS) is the antidote of choice and is given in a dose of 30 mg/kg i.v. per day. At least 5 days' treatment is usually required.

### Methanol

Methanol is used widely as a solvent and is found in antifreeze solutions. Methanol is metabolized to formaldehyde and formate (**Fig. 6.3**). The concentration of formate increases greatly and is accompanied by accumulation of hydrogen ions, leading to metabolic acidosis.

![Figure 6.3](image-url)  
*Figure 6.3 The metabolism of methanol. Fomepizole and ethanol inhibit ADH. ADH, alcohol dehydrogenase; FDH, formaldehyde dehydrogenase; 10-FTS, 10-formyl tetrahydrofolate synthetase.*

### Clinical features

Methanol causes inebriation and drowsiness. After a latent period, coma supervenes. Blurred vision and diminished visual acuity occur due to formate accumulation. The presence of dilated pupils that are unreactive to light suggests that permanent blindness is likely to ensue. A severe metabolic acidosis may develop and be accompanied by hyperglycaemia and a raised serum amylase activity. A blood methanol concentration of 500 mg/L (15.6 mmol/L) confirms severe poisoning. The mortality correlates well with the severity and duration of metabolic acidosis. Survivors may show permanent neurological sequelae, including parkinsonian-like signs as well as blindness.

### Management

Treatment is similar to that of ethylene glycol poisoning (see pp. 75–76) with the addition of folinic acid 30 mg i.v. 6-hourly for 48 h, which accelerates formate metabolism, thereby reducing ocular toxicity.

### Neuroleptics and atypical neuroleptics
Neuroleptic (antipsychotic) drugs are thought to act predominantly by blockade of dopamine D₂ receptors. The **first-generation neuroleptics** include the phenothiazines (chlorpromazine), the butyrophenones (benperidol, haloperidol) and the substituted benzamides (sulpiride). More **selective second-generation (or ‘atypical’) antipsychotics** include amisulpride, aripiprazole, clozapine, olanzapine, quetiapine and risperidone.

### Clinical features

These include impaired consciousness, hypotension, respiratory depression, hypothermia or hyperthermia, antimuscarinic effects such as tachycardia, dry mouth and blurred vision, occasionally seizures, rhabdomyolysis, cardiac arrhythmias (both atrial and ventricular) and ARDS. Extrapyramidal effects, including acute dystonic reactions, occur but are not dose-related. Most ‘atypical’ antipsychotics have less profound sedative actions than the older neuroleptics. QT interval prolongation and subsequent ventricular arrhythmias (including torsades de pointes) have occurred following overdose with the atypical neuroleptics. Unpredictable fluctuations in conscious level, with variations between agitation and marked somnolence, have been particularly associated with olanzapine overdose.

### Management

Procyclidine 5–10 mg i.v. in an adult is occasionally required for the treatment of dyskinesia and oculogyric crisis. After acidosis has been corrected with sodium bicarbonate, the preferred treatment for arrhythmias caused by antipsychotic drugs (usually torsades de pointes) is intravenous magnesium (see **p. 1005**) or cardiac pacing (**p. 960**).

### Nerve agents

Nerve agents are related chemically to organophosphorus insecticides (see below) and have a similar mechanism of toxicity but a much higher mammalian acute toxicity, particularly via the dermal route. In addition to inhibition of acetylcholinesterase, a chemical reaction known as ‘aging’ also occurs rapidly and more completely than in the case of insecticides. This makes the enzyme resistant to spontaneous reactivation or treatment with oximes (pralidoxime, obidoxime or HI-6).

Two classes of nerve agent are recognized: G agents (named after Gerhard Schrader, who synthesized the first agents) and V agents (V allegedly standing for venomous). G agents include tabun, sarin, soman and cyclosarin. The V agents, e.g. VX, were introduced later. The G agents are both dermal and respiratory hazards, whereas the V agents, unless aerosolized, are contact poisons.

Agents used in bioterrorism are described on **page 60**.

### Clinical features
Systemic features include increased salivation, rhinorrhoea, bronchorrhoea, miosis (which is characteristic) and eye pain, abdominal pain, nausea, vomiting and diarrhoea, involuntary micturition and defecation, muscle weakness and fasciculation, tremor, restlessness, ataxia and convulsions. Bradycardia, tachycardia and hypotension occur, depending on whether muscarinic or nicotinic effects predominate. Death occurs from respiratory failure within minutes but mild or moderately exposed individuals usually recover completely. Diagnosis is confirmed by measuring the erythrocyte cholinesterase activity.

## Management

The administration of atropine 2 mg i.v., repeated every 3–5 min as necessary, to patients presenting with rhinorrhoea and bronchorrhoea may be life-saving. In addition, an oxime should be given to all those requiring atropine as soon as possible after exposure before ‘aging’ has occurred: for example, pralidoxime chloride 30 mg/kg i.v., followed by an infusion of pralidoxime chloride 8–10 mg/kg per hour. Alternatively, boluses of pralidoxime chloride 30 mg/kg may be given 4- to 6-hourly. Intravenous diazepam 10–20 mg, repeated as required, is useful in controlling apprehension, agitation, fasciculation and convulsions.

## Non-steroidal anti-inflammatory drugs

Self-poisoning with non-steroidal anti-inflammatory drugs (NSAIDs) has increased, particularly now that ibuprofen is available without prescription, over the counter, in many countries.

## Clinical features and management

In most cases, minor gastrointestinal disturbance is the only feature but, in more severe cases, coma, convulsions and acute kidney injury have occurred. Transient renal impairment is common after ibuprofen overdose. Poisoning with mefenamic acid commonly results in convulsions, though these are usually short-lived.

Treatment is symptomatic and supportive.

## Opiates and opioids

### Clinical features

Cardinal signs of opiate poisoning are pinpoint pupils, reduced respiratory rate and coma. Hypothermia, hypoglycaemia and convulsions are occasionally observed in severe cases. Non-cardiogenic pulmonary oedema has been reported in severe heroin overdose.

### Management
Naloxone 1.2–2.0 mg i.v. will reverse severe respiratory depression and coma, at least partially. In severe poisoning, larger initial doses or repeat doses will be required. The duration of action of naloxone is often less than the drug taken in overdose: for example, methadone, which has a very long half-life. For this reason, an infusion of naloxone is often required. Non-cardiogenic pulmonary oedema should be treated with mechanical ventilation.

### Organophosphorus insecticides

Organophosphorus (OP) insecticides are used widely throughout the world and are a common cause of poisoning, leading to thousands of deaths annually in the developing world. Intoxication may follow ingestion, inhalation or dermal absorption. OP insecticides inhibit acetylcholinesterase, causing accumulation of acetylcholine at central and peripheral cholinergic nerve endings, including neuromuscular junctions. Many OP insecticides require biotransformation before becoming active and so the features of intoxication may be delayed.

### Clinical features

Poisoning is characterized by anxiety and restlessness, which is typically followed by nausea, vomiting, abdominal colic, diarrhoea (particularly if exposure is by ingestion), tenesmus, sweating, hyper-salivation and chest tightness. Respiratory failure will ensue in severe cases and is exacerbated by the development of bronchorrhoea and pulmonary oedema. Miosis is characteristic. Muscle fasciculation and flaccid paresis of limb muscles, and, occasionally, paralysis of extraocular muscles are observed. Coma and convulsions occur in severe poisoning.

**Diagnosis** is confirmed by measuring the erythrocyte acetylcholinesterase activity; plasma cholinesterase activity is less specific but may also be depressed.

The **intermediate syndrome** usually becomes established 1–4 days after exposure, when the symptoms and signs of the acute cholinergic syndrome are no longer obvious. The characteristic features of the syndrome are weakness of the muscles of respiration (diaphragm, intercostal muscles and accessory muscles, including neck muscles) and of proximal limb muscles. Accompanying features often include weakness of muscles innervated by some cranial nerves.

**Delayed polyneuropathy** is a rare complication of acute exposure to some OP insecticides not marketed in most countries. It presents with glove and stocking paraesthesiae some 1–4 weeks after exposure, followed by an ascending motor polyneuropathy in many cases. It is initiated by phosphorylation, and subsequent aging, of at least 70% of an esterase – neuropathy target esterase (NTE) – in peripheral nerves. Most mild cases improve with time but severe cases can be left with an upper motor neurone syndrome and permanent disability.

### Management

Mild cases require no specific treatment other than the removal of soiled clothing. Atropine
2 mg i.v. should be given every 3–5 min if necessary, to reduce increased secretions, rhinorrhea and bronchorrhea.

Symptomatic patients should also be given an oxime (pralidoxime, obidoxime) to reactivate inhibited acetylcholinesterase: for example, pralidoxime chloride 30 mg/kg by slow intravenous injection, followed by an infusion of pralidoxime chloride 8–10 mg/kg per hour. There is no specific treatment for the intermediate syndrome apart from supportive care, including prolonged ventilation, though a prospective trial suggested that early treatment with oximes could reduce the likelihood of the syndrome developing. Most patients recover in 2–3 weeks.

### Paracetamol (acetaminophen)

In *therapeutic doses*, paracetamol is conjugated with glucuronide and sulphate. A small amount of paracetamol is metabolized by mixed-function oxidase enzymes to form a highly reactive toxic compound (*N*-acetyl-*p*-benzoquinoneimine, NAPQI), which is then immediately conjugated with glutathione and subsequently excreted as cysteine and mercapturic conjugates.

In *overdose*, large amounts of paracetamol are metabolized by oxidation because of saturation of the sulphate conjugation pathway. Liver glutathione stores become depleted so that the liver is unable to deactivate NAPQI. Paracetamol-induced kidney injury probably results from a mechanism similar to that responsible for hepatotoxicity.

### Clinical features

Following the ingestion of an overdose of paracetamol, patients usually remain asymptomatic for the first 24 hours or, at the most, develop anorexia, nausea and vomiting. Liver damage is not usually detectable by routine liver function tests until at least 18 hours after ingestion of the drug. Liver damage usually reaches a peak, as assessed by measurement of alanine transferase (ALT) activity and prothrombin time (INR), at 72–96 hours after ingestion. Without treatment, a small percentage of patients will develop fulminant hepatic failure. Acute kidney injury due to acute tubular necrosis occurs in 25% of patients who have severe hepatic damage and in a few without evidence of serious disturbance of liver function.

### Management

Acetylcysteine is an effective protective agent, provided that it is administered within 8–10 hours of ingestion of the overdose. It acts by replenishing cellular glutathione stores, though it may also repair oxidation damage caused by NAPQI. The treatment regimen is shown in **Box 6.13**.
### Regimen for acetylcysteine

- Acetylcysteine 150 mg/kg in 200 mL 5% glucose over 60 min, then 50 mg/kg in 500 mL of 5% glucose over the next 4 h and then 100 mg/kg in 1000 mL of 5% glucose over the ensuing 16 h
- Total dose 300 mg/kg over 21 h

There are now two main approaches to treatment worldwide. In the UK, following a decision by the Medicines and Healthcare products Regulatory Agency (MHRA) in 2012 to abandon a detailed risk assessment in the decision to treat, it is deemed that patients with concentrations above a ‘treatment line’ starting at 100 mg/L 4 hours after ingestion (Fig. 6.4) should be given treatment with acetylcysteine. In most other countries, a parallel line starting at 150 mg/L 4 hours after ingestion is used, though some still follow the original treatment line starting at 200 mg/L 4 hours after ingestion. The treatment lines (Fig. 6.4) are uncertain if the patient presents 15 hours or more after ingestion, or has taken a modified-release preparation of paracetamol. Although these lines are often extended to 24 hours (dotted lines), the concentrations are not based on clinical trial data.
Patients who ingest multiple overdoses or take repeated therapeutic excess are at greater risk of liver damage, and decisions to treat are generally based on the dose ingested. In the UK, treatment with acetylcysteine is given if more than 75 mg/kg has been ingested in 24 hours.

Up to 15% of patients treated with intravenous acetylcysteine develop a rash, angio-oedema, hypotension and bronchospasm. These reactions, which are related to the initial bolus, are seldom serious and discontinuing the infusion is usually all that is required. In more severe cases, chlorphenamine 10–20 mg i.v. in an adult should be given.

If liver or renal failure ensues, this should be treated conventionally, though there is evidence that a continuing infusion of acetylcysteine (continue 16-h infusion until recovery) will improve the morbidity and mortality. Liver transplantation has been performed successfully in patients who have paracetamol-induced acute hepatic failure (see p. 463).

**Phosphides**

Aluminium and zinc phosphides are used as rodenticides and insecticides. They react with
moisture in the air (and the gastrointestinal tract) to produce phosphine, the active pesticide. Acute poisoning with these compounds may be direct, due to ingestion of the salts, or indirect, from accidental inhalation of phosphine generated during their approved use.

---

**Clinical features**

*Ingestion* causes vomiting, epigastric pain, peripheral circulatory failure, severe metabolic acidosis, acute kidney injury and disseminated intravascular coagulation, in addition to the features induced by phosphine.

*Exposure* to phosphine causes lacrimation, rhinorrhea, cough, breathlessness, chest tightness, dizziness, diplopia, headache, nausea, drowsiness, intention tremor and ataxia. Acute pulmonary oedema, hypertension, cardiac arrhythmias, convulsions and jaundice have been described in severe cases.

---

**Management**

Treatment is symptomatic and supportive. Gastric lavage should not be used, as it can speed up the rate of disintegration of the product ingested and increase toxicity. Activated charcoal may bind metal phosphides. The mortality is high, despite supportive care.

---

**Salicylates**

*Aspirin* is metabolized to salicylic acid (salicylate) by esterases present in many tissues, especially the liver, and subsequently to salicyluric acid and salicyl phenolic glucuronide (*Fig. 6.5*); these two pathways become saturated, with the consequence that the renal excretion of salicylic acid increases after overdose; this excretion pathway is extremely sensitive to changes in urinary pH.
**Clinical features**

Salicylates stimulate the respiratory centre, increase the depth and rate of respiration, and induce a respiratory alkalosis. Compensatory mechanisms, including renal excretion of bicarbonate and potassium, result in a metabolic acidosis. Salicylates also interfere with carbohydrate, fat and protein metabolism, and disrupt oxidative phosphorylation, producing increased concentrations of lactate, pyruvate and ketone bodies, all of which contribute to the acidosis.

Thus, tachypnoea, sweating, vomiting, epigastric pain, tinnitus and deafness develop. Respiratory alkalosis and metabolic acidosis supervene and a mixed acid–base disturbance is commonly observed. Rarely, in severe poisoning, non-cardiogenic pulmonary oedema, coma and convulsions ensue.

The severity of salicylate toxicity is dose-related.

**Management**

Fluid and electrolyte replacement is required and special attention should be paid to potassium supplementation. Severe metabolic acidosis requires at least partial correction, with the administration of sodium bicarbonate intravenously. Mild cases of salicylate poisoning are managed with parenteral fluid and electrolyte replacement only. Patients whose plasma salicylate concentrations are in excess of 500 mg/L (3.6 mmol/L) should receive urine alkalinization (see p. 69). Haemodialysis is the treatment of choice for severely poisoned patients (plasma salicylate concentration >700 mg/L; >5.1 mmol/L), particularly those with coma and metabolic acidosis.

**Marine animals**

### Amnesic shellfish (domoic acid) poisoning

The syndrome should be known more accurately as domoic acid poisoning because amnesia is not always present. In one outbreak, the first symptoms were experienced between 15 minutes and 38 hours after mussel consumption. There are now legal limits on the domoic acid concentrations allowed in mussels.

### Clinical features and management

The most common symptoms are nausea, vomiting, abdominal cramps, headache, diarrhoea and short-term memory loss. Axonal sensory motor neuropathy, seizures, coma and death have also been reported. Treatment is symptomatic and supportive.

### Diarrhoeic shellfish (okadaic) poisoning

Okadaic poisoning occurs worldwide, often after eating bivalve molluscs such as mussels and scallops. Okadaic acid is produced by dinoflagellates belonging to the genera *Dinophysis* spp. It inhibits the activity of the protein phosphatases 1 and 2a. As a result, increased phosphorylation of intestinal transport proteins, with increased permeability to solutes, leads to diarrhoea.
Clinical features and management

The predominant symptoms are diarrhoea, nausea, vomiting and abdominal pain. Symptoms tend to occur between 30 minutes and a few hours after shellfish consumption, with patients recovering within 2–3 days. Treatment is symptomatic and supportive.

Neurotoxic shellfish (brevetoxin) poisoning

Neurotoxic shellfish poisoning is caused by brevetoxins produced by the dinoflagellate Gymnodinium breve. Brevetoxins open voltage-gated sodium ion channels in cell walls and enhance the inward flow of sodium ions into the cell.

Clinical features and management

The symptoms of neurotoxic shellfish poisoning occur within 30 minutes to 3 hours and last a few days; they include nausea, vomiting, diarrhoea, chills, sweats, reversal of temperature sensation, hypotension, arrhythmias, numbness, tingling, paraesthesiae of the lips, face and extremities, cramps, bronchoconstriction, paralysis, seizures and coma. Treatment is symptomatic and supportive.

Paralytic shellfish (saxitoxin) poisoning

This is caused by bivalve molluscs being contaminated with neurotoxins, including saxitoxin, produced by toxic dinoflagellates on which the molluscs graze. Saxitoxin blocks voltage-gated sodium channels in nerve and muscle cell membranes, thereby blocking nerve signal transmission.

Clinical features and management

Symptoms develop within 30 minutes. The illness is characterized by paraesthesiae of the mouth, lips, face and extremities, and is often accompanied by nausea, vomiting and diarrhoea. In more severe cases, dystonia, dysphagia, muscle weakness, paralysis, ataxia and respiratory depression occur. In one outbreak involving 187 cases, there were 26 deaths. Treatment is symptomatic and supportive.

Ciguatera fish poisoning

Over 400 fish species have been reported as ciguatoxic (cigua is Spanish for poisonous snail), though barracuda, red snapper, amberjack and grouper are most commonly implicated. Ciguatera fish contain ciguatoxin, maitotoxin and scaritoxin, which are lipid-soluble, heat-stable compounds that are derived from dinoflagellates such as Gambierdiscus toxicus. Ciguatoxin opens voltage-sensitive sodium channels at the neuromuscular junction and
maitotoxin opens calcium channels of the cell plasma membrane.

### Clinical features and management

The onset of symptoms occurs from a few minutes to 30 hours after ingestion of toxic fish. Typically, features appear between 1 and 6 hours, and include abdominal cramps, nausea, vomiting and watery diarrhoea. In some cases, numbness and paraesthesiae of the lips, tongue and throat occur. Other features described include malaise, dry mouth, metallic taste, myalgia, arthralgia, blurred vision, photophobia and transient blindness. In more severe cases, hypotension, cranial nerve palsies and respiratory paralysis have been reported. Treatment is symptomatic and supportive. Recovery takes from 48 hours to 1 week in the mild form, and from 1 to several weeks in the severe form. The mortality in severe cases may be as high as 12%.

### Scombroid fish poisoning

This is due to the action of bacteria such as *Proteus morgani* and *Klebsiella pneumoniae* in the decomposing flesh of fish such as tuna, mackerel, mahi-mahi, bonito and skipjack stored at insufficiently low temperatures. The spoiled fish can contain excessively high concentrations of histamine (muscle histidine is broken down by the bacteria to histamine), though the precise role of histamine in the pathogenesis of the clinical syndrome is uncertain.

### Clinical features and management

Clinically, the mean incubation period is 30 minutes. The illness is characterized by flushing, headache, sweating, dizziness, burning of the mouth and throat, abdominal cramps, nausea, vomiting and diarrhoea; it is usually short-lived, the mean duration being 4 hours. Treatment is symptomatic and supportive. Antihistamines may alleviate the symptoms.

### Stings from marine animals

Several species of fish have venomous spines in their fins. These include the weaver fish, short-spine cotto, spiny dogfish and stingray. Bathers and fishermen may be stung if they tread on or handle these species. The immediate result of a sting is intense local pain, swelling, bruising, blistering, necrosis and, if the poisoned spine is not removed, chronic sepsis (although this is uncommon). Occasionally, systemic symptoms, including vomiting, diarrhoea, hypotension and tachycardia, occur. Treatment by immersing the affected part in hot water may relieve local symptoms, as this denatures the thermolabile toxin.

### Jellyfish stings

Most of the jellyfish found in North European coastal waters are non-toxic, as their stings
cannot penetrate human skin. A notable exception is the ‘Portuguese man-o’-war’ (*Physalia physalis*), whose sting contains a toxic peptide, phospholipase A, and a histamine-liberating factor. Toxic jellyfish are found more frequently in Australia and some, notably the box jellyfish, *Carukia barnesi*, cause the Irukandji syndrome (see below).

### Clinical features and management

Local pain occurs, followed by myalgia, nausea, griping abdominal pain, dyspnoea and even death. The cluster of severe systemic symptoms that constitute the Irukandji syndrome occur some 30 minutes after the jellyfish sting. The symptoms include severe low back pain, excruciating muscle cramps in all four limbs, abdomen and chest, sweating, anxiety, restlessness, nausea, vomiting, headache, palpitations, life-threatening hypertension and cardiogenic pulmonary oedema.

Adhesive tape may be used to remove any tentacles still adherent to the bather. Local application of 5% acetic acid is said to prevent stinging cells adherent to the skin discharging. Local analgesia and antihistamine creams provide symptomatic relief. Other features should be treated symptomatically and supportively.

### Further reading

### Venomous animals

#### Insect stings and bites

Insect stings from wasps and bees, and bites from ants produce pain and swelling at the puncture site. Following the sting or bite, patients should be observed for 2 hours for any signs of evolving urticaria, pruritus, bronchospasm or oropharyngeal oedema. The onset of anaphylaxis requires urgent treatment (see pp. 143–144).

#### Scorpions

Scorpion stings are a serious problem in North Africa, the Middle East and the Americas. Scorpion venoms stimulate the release of acetylcholine and catecholamines, causing both cholinergic and adrenergic symptoms.

### Clinical features and management
Severe pain occurs immediately at the site of puncture, followed by swelling. Signs of systemic involvement, which may be delayed for 24 hours, include vomiting, sweating, piloerection, abdominal colic and diarrhoea. In some cases, depending on the species, cardiogenic shock, respiratory depression and pulmonary oedema may develop.

Local infiltration with anaesthetic or a ring block will usually alleviate local pain, though systemic analgesia may be required. Specific antivenom, if available, should be administered as soon as possible.

### Spiders

The black widow spider (*Latrodectus mactans*) is found in North America, the tropics and, occasionally, in Mediterranean countries.

### Clinical features and management

The bite quickly becomes painful, and generalized muscle pain, sweating, headache and shock may occur. No systemic treatment is required except in cases of severe systemic toxicity, when specific antivenom should be given, if this is available.

### Venomous snakes

Approximately 15% of the 3000 species of snake found worldwide are considered to be dangerous to humans. Snake bite is common in some tropical countries; rural areas of West Africa, South-east Asia, the Indian subcontinent, New Guinea and the Amazon region are particularly affected. Bites by venomous snakes cause more than 100,000 deaths and many permanent sequelae each year (some 46,000 people are killed each year in India alone).

There are three main groups of venomous snakes, representing some 200 species, which have in their upper jaws a pair of enlarged teeth (fangs) that inject venom into the tissues of their victim. These are:

- **Viperidae** (with two subgroups: Viperinae – European adders and Russell's vipers; and Crotalinae – American rattlesnakes, moccasins, lance-headed vipers and Asian pit vipers)
- **Hydrophiidae** (sea snakes).

In addition, some members of the family *Colubridae* are mildly venomous (mongoose snake).

### Clinical features

The main effects of envenoming are:
• local swelling, bruising, blistering, regional lymph node enlargement and necrosis
• anti-haemostatic defects: consumption coagulopathy and spontaneous systemic bleeding from gums, nose, skin, gut, genitourinary tract and intracranial haemorrhage
• shock (hypotension) and myocardial damage
• descending paralysis: progressing from ptosis and external ophthalmoplegia to bulbar, respiratory muscle and total flaccid paralysis
• generalized rhabdomyolysis with myoglobinuria
• intravascular haemolysis
• acute kidney injury.

Viperidae (Viperinae and Crotalinae)
Russell's viper causes most of the snake-bite mortality in India, Pakistan and Myanmar. There is local swelling at the site of the bite (Fig. 6.6), which may become massive. Local tissue necrosis may occur. Evidence of systemic involvement (envenomation) occurs within 30 minutes, including vomiting, shock and hypotension. Haemorrhage due to incoagulable blood can be fatal. Envenomation by European adders (Vipera berus) is rarely fatal.

![FIGURE 6.6 Snake bite showing swelling at the site.](image)

Elapidae
There is not usually any swelling at the site of the bite, except with Asian cobras and African spitting cobras; in these cases, the bite is painful and is followed by local tissue necrosis. Vomiting occurs first, followed by shock and then neurological symptoms and muscle weakness, with paralysis of the respiratory muscles in severe cases. Cardiac muscle can be involved.

Hydrophiidae
Envenomation produces muscle involvement, myalgia and myoglobinuria, which can lead to acute kidney injury. Cardiac and respiratory paralysis may occur.
Management

Following a snake bite, all efforts should be made to transport the patient quickly to a hospital or dispensary. Traditional methods should be discouraged, as they are often ineffective and may harm the patient. Arterial tourniquets should not be used, and incision or excision of the bite area should not be performed.

As a first aid measure, a firm pressure bandage should be placed over the bite and the limb immobilized, as this may delay the spread of the venom. Local wounds often require little treatment. If necrosis is present, antibiotics should be given. Skin grafting may be required later. Anti-tetanus prophylaxis must be given. The type of snake should be identified, if possible.

In about 50% of cases, no venom has been injected by the bite but, nevertheless, careful observation for 12–24 hours is necessary in case envenomation develops. General supportive measures should be carried out, as necessary. These include intravenous fluids with volume expanders for hypotension and diazepam for anxiety. Treatment of acute respiratory, cardiac and kidney injury is instituted as necessary.

Antivenoms are not generally indicated unless envenomation is present, as they can cause severe allergic reactions. Antivenoms can rapidly neutralize venom, but only if an amount in excess of the amount of venom is given. Large quantities of antivenom may be required; as antivenoms cannot reverse the effects of the venom, they must be given early to minimize some of the local effects and may prevent necrosis at the site of the bite. Antivenoms should be administered intravenously by slow infusion, the same dose being given to children and adults.

Allergic reactions are frequent, and adrenaline (epinephrine) 1 in 1000 solution should be available. In severe cases, the antivenom infusion should be continued even if an allergic reaction occurs, with subcutaneous injections of adrenaline being given as necessary. Some forms of neurotoxicity, such as those induced by the death adder, respond to anticholinesterase therapy with neostigmine and atropine.

Plants

Life-threatening poisoning from plant ingestion is rare, though many plants contain potentially toxic substances. These include antimuscarinic agents, calcium oxalate crystals, cardiogenic glycosides, pro-convulsants, cyanogenic compounds, mitotic inhibitors, nicotine-like alkaloids, alkylating agent precursors, sodium channel activators and toxic proteins (toxalbumins). While many plants contain gastrointestinal toxins, these rarely give rise to life-threatening sequelae. In contrast, other botanical poisons may cause specific organ damage, and death may occur from only small ingestions of yew (genus: Taxus), oleander (Thevetia
peruviana and Nerium oleander) and cowbane (Cicuta).

**Atropa belladonna**

*Atropa belladonna* (deadly nightshade) contains hyoscyamine and atropine. It causes antimuscarinic effects – a dry mouth, nausea and vomiting – leading to blurred vision, hallucinations, confusion and hyperpyrexia.

**Cicuta species**

*Cicuta* spp. (water hemlock) and the related genus *Oenanthe* contain cicutoxin, a potent CNS stimulant that produces violent seizure activity. The CNS effects of cicutoxin are similar to those of picrotoxin, a known inhibitor of GABA. Severe gastrointestinal symptoms, diaphoresis, salivation and skeletal muscle stimulation may precede the seizure activity.

**Conium maculatum**

*Conium maculatum* (poison hemlock) contains a variety of volatile piperidine alkaloids, which have a toxic activity similar to that of nicotine. Large doses produce non-polarizing neuromuscular blockade, which may result in respiratory depression and death.

**Datura stramonium**

*Datura stramonium* (jimsonweed) and other *Datura* spp. contain l-hyoscyamine and atropine. These alkaloids are potent antagonists of acetylcholine at muscarinic receptors and produce the anticholinergic syndrome. While morbidity is significant, fatalities are rare and are the consequence of hyperthermia, seizures and/or arrhythmias.

**Digitalis purpurea, Nerium oleander, Thevetia peruviana (yellow oleander)**

Ingestion of *Digitalis purpurea* or the common (*Nerium oleander*) or yellow (*Thevetia peruviana*) oleander can produce a syndrome similar to digoxin poisoning (see p. 74). A randomized controlled trial has shown that digoxin-specific antibody fragments can rapidly and safely reverse yellow oleander-induced arrhythmias, restore sinus rhythm, and rapidly reverse bradycardia and hyperkalaemia. The administration of multiple doses of activated charcoal is used but the effect on survival is debated.

**Further reading**

Mushrooms

Poisoning due to mushrooms is usually accidental, though ingestion of hallucinogenic (‘magic’) mushrooms is invariably intentional.

**Cytotoxic mushrooms**

Cytotoxic mushroom poisoning is caused by amatoxins and orelalanin. Amatoxins are found in *Amanita phalloides*, *A. virosa* and *A. verna*, and in some *Galerina* and *Lepiota* spp. Amatoxins inhibit transcription from DNA to mRNA by the blockade of nuclear RNA polymerase II; this results in impaired protein synthesis and cell death.

**Clinical features and management**

Intense watery diarrhoea starts 8–24 hours after ingestion and persists for 24 hours or longer. Patients often become severely dehydrated. Signs of liver damage appear during the second day and hepatic failure may ensue. Impaired kidney function is often seen both because of fluid loss and as a result of direct kidney injury. In all patients, fluid, electrolyte and acid–base disturbances should be corrected and renal and hepatic function supported. The value of silibinin and benzylpenicillin is not proven. Occasionally, liver transplantation is necessary.

**Gyromitrin poisoning**

Gyromitrin is found in *Gyromitra* spp., including in particular the false morel (*Gyromitra esculenta*) and *Cudonia circinans*. Gyromitrin decomposes in the stomach, to form hydrazines that inhibit pyridoxine kinase and thus produce functional pyridoxine deficiency. GABA deficiency ensues since pyridoxine is an essential co-factor in GABA synthesis. Seizures may result. Hydrazines also cause haemolysis, methaemoglobin formation and hepatorenal toxicity.

**Clinical features and management**

Vapours from the mushrooms are irritating to the eyes and respiratory tract. Gastrointestinal symptoms appear 5–8 hours after exposure. Vertigo, sweating, diplopia, headache, dysarthria, incoordination, ataxia and seizures may follow. Symptomatic and supportive care is required. Pyridoxine 25 mg/kg as an infusion over 30 min should be given if severe CNS toxicity develops; repeat doses may be required.

**Hallucinogenic mushroom poisoning**

Psilocybin produces pharmacological effects similar to those of LSD (see p. 77) and is found in *Psilocybe* and *Panaeolus* spp.
Clinical features and management
Symptoms occur within 20–60 min. Effects include altered time and space sense, depersonalization, hallucinations, derealization and euphoria. Symptoms are usually maximal within 2 hours and disappear within 4–6 hours, though ‘flashbacks’ may recur after weeks or months. Anxiety and agitation should be treated with diazepam, 10–20 mg i.v., repeated as necessary.

Isoxazole poisoning
Isoxazoles (e.g. ibotenic acid, muscimol, muscazone) occur in Amanita muscaria and A. pantherina, and act as GABA agonists.

Clinical features and management
Nausea, vomiting, inebriation, euphoria, confusion, anxiety, visual disturbances and hallucinations occur often within 30 minutes. Drowsiness is common and a coma-like state may ensue. Severe agitation and violent behaviour are seen occasionally. Other features include myoclonic jerks, muscle fasciculation, and seizures. Symptomatic and supportive care should be given as necessary. Diazepam 10–20 mg i.v., repeated as required, should be administered for anxiety, agitation and seizures.

Neurotoxic mushroom poisoning
Muscarine is found in, for example, Inocybe spp., Clitocybe spp. and Mycena pura. Muscarine stimulates cholinergic receptors in the autonomic nervous system.

Clinical features and management
Diarrhoea, abdominal pain, diaphoresis, salivation, lacrimation, miosis, bronchorrhoea, bronchospasm, bradycardia and hypotension occur. Atropine 0.6–2 mg i.v. should be given to manage the cholinergic syndrome.

Orellanin poisoning
Orellanin is a potent nephrotoxin found in, for example, Cortinarius ocellanus and C. speciosissimus. A metabolite of orellanin inhibits protein synthesis in the kidneys.

Clinical features and management
Symptoms are typically delayed for 2–4 days. Some patients suffer a mild gastrointestinal disturbance before developing signs of renal impairment, headache, fatigue, intense thirst,
chills, myalgia and abdominal, lumbar and flank pain. Transient polyuria with proteinuria, haematuria and, characteristically, leucocyturia is followed by oliguria and then anuria. Renal function may recover only partially; chronic kidney disease is reported in about 10–40% of cases. Management involves careful monitoring and haemodialysis/haemofiltration if renal failure supervenes. Renal transplantation may be required.

Cell Biology

Cells consist of cytoplasm enclosed within a lipid sheath (the plasma membrane). The cytoplasm contains a variety of organelles (subcellular compartments enclosed within their own membranes) in a mixture of salts and organic compounds (the cytosol). These are held within an adaptive internal scaffold (the cytoskeleton) that radiates from the nucleus outwards to the cell surface (Fig. 7.1). Many cells have special functions and their size, shape and behaviour adapt to meet their physiological roles. Cells can be organized into tissues and organs in which the individual component cells are in contact and able to send and receive messages, both directly and indirectly. Coordinated cellular responses can be achieved through systemic signalling – for example, via steroid or protein signalling molecules (hormones or cytokines), or near-acting, short-lived cyclic lipids (eicosanoids).
FIGURE 7.1 Diagrammatic representation of the cell. The major organelles and receptor activation, intracellular messengers, protein formation and secretion, endocytosis of large molecules and production of adenosine triphosphate (ATP) are shown. cAMP, cyclic adenosine monophosphate.

**Cell Structure**

**Cellular membranes**

**Lipid bilayers**

Lipid bilayers separate the cell contents from the external environment and compartmentalize distinct cellular activities into organelles. The membranes comprise a large variety of glycerophospholipids and sphingolipids, which usually have two hydrophobic acyl chains, linked via glycerol or serine to polar hydrophilic head groups *(Fig. 7.2)*. Their cylindrical shape and their amphiphilic nature, with a ‘water-loving’ head and a ‘water-hating’ tail, mean that, in aqueous solution, membrane lipids self-associate into a tail-to-tail bilayer, with their hydrophobic chains separated from the aqueous phase by their polar head groups.
Plasma membrane and organelle lipids

Plasma membrane and organelle (except that surrounding the endoplasmic reticulum) lipids are organized asymmetrically in the bilayer, with the outer leaflet of the plasma membrane enriched in phosphatidylcholine (PC) and sphingolipids, whereas the inner leaflet is enriched in phosphatidylserine (PS), phosphatidylinositol (PI) and phosphatidylethanolamine (PE). This arrangement is required for barrier function and also normal physiology. For example, PC is extracted from the outer leaflet of the canalicular membrane of hepatocytes to form the lipid/bile-salt micelles of bile. The appearance of PS in the outer leaflet of the membrane is an early step in the apoptotic pathway and signals to macrophages to clear the dying cell, while PI and PE, once cleaved by phospholipase, each produce two signalling molecules as second messengers (see p. 96), diacylglycerol and the polar head group. Cholesterol is also an essential component of the plasma membrane and cannot be substituted by plant sterols, which have a subtly different shape. For this reason, the liver secretes plant sterols back into the gut. Membrane lipids are also exploited by pathogens. For example, the sphingolipid GM1-ganglioside is the receptor for cholera toxin (see pp. 288–289).

Membrane proteins

Cells can absorb gases or small hydrophobic compounds directly across the plasma membrane by passive diffusion, but membrane proteins are required to take up hydrophilic nutrients or secrete hydrophilic products, to mediate cell–cell communication and to respond to endocrine, paracrine and cytokine signals. Membrane proteins can be integral to the membrane (i.e. their protein chain traverses the membrane one or multiple times) or they can be anchored to the
membrane by an acyl chain (Fig. 7.2).

The major classes are membrane channel proteins, transporters and receptors.

**Membrane channel proteins (Fig. 7.3)**

Membrane proteins that form solute channels through the membrane only work downhill and only to equilibrium. Solute moves down its electrochemical gradient, a combined force of the electric potential and the solute concentration gradient across the membrane. The bulk flow can be very high, the opening and closing of the channel can be regulated, and they can be selective for specific solutes. For example, the cystic fibrosis transmembrane regulator (CFTR; see Fig. 7.26), the protein whose malfunction causes cystic fibrosis, is a chloride channel found on the apical surface of epithelial cells. CFTR functions to regulate the fluidity of the extra-epithelial mucous layer. When the channel opens in the gut and lung, millions of negatively charged chloride ions typically flow out of the cell down their electrochemical gradient. This induces positively charged sodium ions to flow between the cells of the epithelium (via a paracellular pathway) to balance the electrical charge. Water follows the efflux of sodium chloride by osmosis, thus maintaining the fluidity of the mucus.

![Figure 7.3](image)

**Transporters**

In contrast to channels, transporters (Fig. 7.3) have a low capacity and work by binding solute on one side of the membrane; this induces a conformational change that exposes the solute binding site on the other side of the membrane for release.

- **Passive transporters** work without an energy source and can only transport downhill to equilibrium.
- **Active transporters** use energy and can work uphill to concentrate a solute.
  - **Primary active transporters** use adenosine triphosphate (ATP) hydrolysis to drive the translocation cycle. ATP binding cassette (ABC) transporters are a major class of primary-active transporters whose malfunction causes dozens of human diseases,
including a spectrum of liver, eye and skin diseases, bleeding disorders and adrenoleukodystrophy.

– **Secondary-active pumps** are driven by ion gradients, which are themselves made and maintained by primary-active pumps; thus primary and secondary active pumps often work in concert, as illustrated for the transcellular uptake of glucose across the intestinal epithelium.

**Receptors**

There are three major receptor categories: receptors that mediate endocytosis, anchorage receptors (e.g. integrins; see p. 94) and signalling receptors (see ‘Cell signalling’, p. 96).

There are two forms of receptor-mediated endocytosis:

• **Phagocytosis**. Specialized phagocytic cells such as macrophages and neutrophils can engulf, or phagocytose approximately 20% of their surface in pursuit of large particles such as bacteria or apoptotic cells for digestion and recycling. Phagocytosis is only triggered when specific cell surface receptors – such as the macrophage Fc receptor – are occupied by their ligand.

• **Pinocytosis**. Pinocytosis is phagocytosis on a small scale and occurs continually in all cells. Smaller molecular complexes, such as low-density lipoprotein (LDL) *(Fig. 7.4a)*, are internalized during pinocytosis via clathrin-coated pits. The LDL receptor has a large extracellular domain that binds circulating LDL. This induces a conformational change in the intracellular domain, which allows it to bind clathrin from the cytosol. Clathrin bends the membrane to form a pit that pinches inwards to become an intracellular clathrin-coated vesicle. Loss of the clathrin coat can allow fusion with other intracellular organelles or vesicles (e.g. with lysosomes to catabolize the cargo), or the coat can be retained during transcellular transport. Defects in each step of pinocytosis can lead to disease. For example, hypercholesterolaemia (see pp. 1280–1282) can result from mutation to the LDL receptor's extracellular domain that prevents LDL binding, but the most common LDL receptor mutation results in loss of the intracellular domain and prevents recruitment of clathrin.
Organelles

Cytoplasmic organelles

Endoplasmic reticulum
Endoplasmic reticulum (ER) is an array of interconnecting tubules or flattened sacs (cisternae) that is contiguous with the outer nuclear membrane (see Fig. 7.1). There are three types of ER:

- **Rough ER** carries ribosomes on its cytosolic surface, which synthesize secreted or membrane proteins.
- **Smooth ER** is where lipids and sterols are synthesized, and where steroids and drugs are metabolized. It is also a store of calcium that can be released into the cytosol via channel proteins for signalling.
- **Sarcoplasmic reticulum** is a form of ER found in muscle, where calcium release on excitation is necessary for muscle contraction (see Fig. 23.3).

Golgi apparatus (**Fig. 7.5A**)
The Golgi apparatus has flattened cisternae similar to those of the ER but arranged in a stack (see Fig. 7.1). Vesicles that bud from the ER with cargo destined for secretion, for the plasma membrane or for other organelles, fuse with the Golgi stack. The proteins, lipids and sterols synthesized in the ER are exported to the Golgi apparatus to complete maturation (for example,
the final stages of membrane protein glycosylation occurs here). The mature products are then sorted into vesicles that bud from the Golgi for transport to their final destination (see Fig. 7.4b and c). Golgin proteins control the morphology of the Golgi and vesicle trafficking. Achondrogenesis type 1A is caused by mutation of golgin GMAP-210, which disrupts the Golgi architecture, particularly in bone cells.

**FIGURE 7.5** Cell organelles. A. Golgi apparatus. B. Mitochondria. C. Nucleus showing dark regions of heterochromatin and lighter euchromatin. (Courtesy of Louisa Howard, Dartmouth EM Facility)

**Lysosomes**

Lysosomes mature from vesicles that bud from the Golgi. They contain digestive enzymes such as lipases, proteases, nucleases and amylases that work in an acidic environment. The membrane of the lysosome therefore includes a proton ATPase pump to acidify the lumen of the organelle. Lysosomes fuse with phagocytotic vesicles (endosomes) to digest their contents (Fig. 7.6). This is crucial to the function of macrophages and polymorphs (neutrophils and eosinophils) in killing and digesting infective agents, in tissue remodelling during
development, and osteoclast remodelling of bone. Not surprisingly, many metabolic disorders result from impaired lysosomal function (see pp. 1287–1288).
FIGURE 7.6  A cell showing the action of lysosomes in catabolizing engulfed nutrients and recycling cellular contents. (a) Nutrients taken up by receptor-mediated endocytosis are internalized into vesicles called endosomes. As these mature, the lumen is acidified, causing the receptor to release its cargo. The receptor is trafficked back to the plasma membrane but the cargo may be catabolized by acid hydrolysis in the lysosome (b) in which the lumen is acidified by the vacuolar adenosine triphosphatase (V-ATPase). Lysosomes are also involved in autophagy (c). Vesicles (phagophores) bud from the ER and nucleate to engulf cellular components (cytosol and organelles) in an autophagosome. The autophagosome, which has an unusual double membrane, fuses with lysosomes to degrade and recycle the engulfed contents. ADP, adenosine diphosphate; Pi, phosphate.

Peroxisomes
Peroxisomes contain enzymes for the catabolism of long-chain fatty acids and other organic substrates like bile acids and D-amino acids. Hydrogen peroxide (H$_2$O$_2$), a by-product of these reactions, is a highly reactive oxidizing agent, so peroxisomes also contain catalase to detoxify the peroxide. Catalase can reduce H$_2$O$_2$ to water while oxidizing harmful phenols and alcohols, thus beginning their detoxification. Peroxisome dysfunction can lead to rare metabolic disorders such as leukodystrophies and rhizomelic dwarfism.

Mitochondria (Fig. 7.5B)
Mitochondria are the engines of the cell, providing energy in the form of ATP. They can be small, discrete and few in number in cells with low energy demand, or large and abundant in cells with a high energy demand like hepatocytes or muscle cells. The mitochondrion has its own genome encoding 13 proteins. The other proteins (approximately 1000) required for mitochondrial function are encoded by the nuclear genome and imported into the mitochondrion. The mitochondrion has a double membrane surrounding a central matrix. The central matrix contains the enzymes for the Krebs cycle, which accepts the products of sugar and fatty acid catabolism and uses them to produce co-factors that donate their electrons into the electron transport chain of the inner membrane (see pp. 103–104). The inner membrane is highly folded into cristae to increase its effective surface area. The protein complexes of the electron transport chain accept and donate electrons in redox reactions, releasing energy to efflux protons (H$^+$) into the inter-membrane space. ATP synthase, another integral membrane protein, uses this H$^+$ electrochemical gradient to drive formation of ATP. Mitochondria have many additional functions, including roles in apoptosis (see p. 105) and supply of substrates for biosynthesis. Mitochondria are also necessary for the synthesis of porphyrin, deficiency of which causes a range of diseases collectively called porphyrias (see pp. 1289–1291).

Nucleus
The most prominent cellular organelle, the nucleus (Fig. 7.5C), has a double membrane (the outer membrane is continuous with the ER) enclosing the human genome. The double membrane contains nuclear pores, through which gene regulatory proteins, transcription factors and ribonucleic acid (RNA) that has been transcribed from the deoxyribonucleic acid (DNA) are transported. The nuclear matrix is highly organized. Microscopically dense regions of heterochromatin represent highly compacted chromosomal DNA, which tends to be transcriptionally repressed. Lighter regions of euchromatin contain extended chromosomes,
which tend to be transcriptionally active. The most prominent nuclear compartment, the nucleolus, is where ribosomal RNA (rRNA) is synthesized and ribosomal subunits are assembled.

**The cytoskeleton**

A complex network of structural proteins regulates the shape, strength and movement of the cell, and the traffic of internal organelles and vesicles. The major components are microtubules, intermediate filaments and microfilaments.

**Microtubules**

Microtubules (20–25 nm diameter) are polymers of α- and β-tubulin. These tubular structures resist bending and stretching, and are polar with plus and minus ends. Their minus ends are anchored in the microtubule organizing centre (MTOC), a complex of centrioles, γ-tubulin and other proteins, with their plus ends extending into the cell. At their plus ends, repeated cycles of assembly and disassembly permit rapid changes in length. Microtubules form a ‘highway’, transporting organelles and vesicles through the cytoplasm. The two major microtubule-associated motor proteins (kinesin and dynein) allow movement of cargo towards the plus and minus ends, respectively. During cell division, the MTOC forms the mitotic spindle (see p. 101). Drugs that disrupt microtubule assembly (e.g. colchicine and vinca alkaloids) or stabilize microtubules (taxanes) preferentially kill dividing cells by preventing mitosis.

**Intermediate filaments**

Intermediate filaments (approximately 10 nm) form a network around the nucleus extending to the periphery of the cell. They make cell-to-cell contacts with adjacent cells via desmosomes, and with basement matrix via hemidesmosomes (*Fig. 7.7*; see also *Fig. 31.34*). Their function is structural integrity; they are prominent in cellular tissues under stress and their disruption in genetic disease can cause structural defects or cell collapse. More than 40 different types of proteins polymerize to form intermediate filaments specific to particular cell types. For example, keratin intermediate fibres are found only in epithelial cells whilst vimentin is in mesothelial (fibroblastic) cells. Lamin intermediate filaments form the nuclear membrane
Microfilaments

Microfilaments (3–6 nm) are polymers of actin, one of the most abundant proteins in all cells. The actin microfilament network (*Fig. 7.8*) controls cell shape, prevents cellular deformation, and is involved in cell–cell and cell–matrix adhesion, in cell movements such as crawling and cytokinesis (cell division), and in intracellular vesicle transport. Bundles of actin filaments form the structural core of cellular protrusions such as microvilli, lamellipodia and filopodia (see below). Actin microfilament bundles within the cell can associate with myosin II to form contractile stress fibres, similar to muscle sarcomeres. Stress fibres are often found as circumferential belts around the apical surfaces of epithelial cells where cells associate with adjacent cells via adherens junctions, permitting reaction to external stresses as a cellular sheet. Stress fibres also form where actin interacts via accessory proteins with the extracellular matrix at sites of focal adhesion (see *Fig. 7.11c*). This occurs when cells move and is prominent during inflammation, wound healing and metastasis. During cytokinesis, actin–myosin II bundles form the contractile ring separating dividing cells. Like microtubules, microfilaments are polar, so can be used to transport secretory vesicles, endosomes and mitochondria, powered by motor proteins, including myosin I and V.
Cell shape and motility

The cytoskeleton determines cell shape and surface structures.

Microvilli

The apical surface of some epithelial cells is covered in tiny microvilli (approximately 1 µm long), forming a brush border of thousands of small, finger-like projections of the plasma membrane that increase the surface area for uptake or efflux (Fig. 7.9). At their core are 20–30 cross-linked actin microfilaments.

Motile cilia
Motile cilia are also fine, finger-like protrusions but these are longer (approximately 10–20 μm long) (Fig. 7.9). At their core is an axoneme, a bundle of nine cross-linked tubulin microtubule doublets surrounding a central pair. The action of the motor domain dynein serves to bend the cilium. Neighbouring cilia tend to beat in unison, generating waves of motion that move fluid over the cell surface in the gut and airways (see Fig. 24.9), and also in the fallopian tubes.

Non-motile or primary cilia

Most cells also have a single primary cilium. These cilia have a variant axoneme with no central pair of microtubules and, while they have dynein, they are non-motile (the dynein is used to traffic cargo along the axoneme). Rich in receptor proteins, the primary cilia are used for signalling during development and in the adult. Other related non-motile cilia are found in specialized cells: for example, in the photoreceptors of the retina, the sensory neurones of the olfactory system, and the sensory hair cells of the cochlea. A range of human ciliopathies (Fig. 7.10) has been described, with pleiotropic symptoms depending on which cilia are affected. These include polycystic kidney disease, Bardet–Biedl syndrome, Joubert syndrome and Ellis–van Creveld syndrome.

![FIGURE 7.10 Structure of a cilium showing ciliopathy proteins and intraflagellar transport (IFT). Some single-gene ciliopathies are shown, along with their gene products, situated in the cilia–centrosome complex (CCC). Receptors on cilia receive external cell signals that are processed via sonic hedgehog (SHH) and Wnt pathways. The gene mutation can act during morphogenesis (e.g. Meckel syndrome) or during tissue maintenance and repair, leading to degenerative disorders. The IFT system transports axoneme and membrane compounds in raft macromolecular particles (IFT cargo and complex). Retrograde transport occurs via cytoplasmic dynein. ADPKD, autosomal dominant polycystic kidney disease; NPHP1, nephronophthisis type 1; TRPR1 and 2, polycystin 1 and 2. (Adapted from Hildebrandt F, Benzing T, Katsanis N. Ciliopathies. New England Journal of Medicine 2011; 364:1533–1543.)](image-url)
Flagella
The single flagellum – for example, that found on sperm – is structurally related to cilia but is longer (approximately 40 µm) and has a whip-like motion.

Cell motility
Cell motility is essential during development and in the adult: for example, when macrophages migrate to sites of infection, keratinocytes migrate to close wounds, osteoclasts and osteoblasts tunnel into and remodel bone, and fibroblasts migrate to sites of injury to repair the extracellular matrix. Most cell motility in the adult human takes the form of cell crawling, which is dependent on remodelling of the actin cytoskeleton. How the actin cytoskeleton is remodelled determines the mode of migration:

- **Filopodia.** Actin remodelled essentially in one dimension produces a long filament, pushing the leading edge of the plasma membrane forwards as spikes, similar to long, thin villi.
- **Lamellipodia.** If remodelled in two dimensions, a network of cross-linked actin microfilaments forms a broad, flat skirt or lamellipodium.
- **Pseudopodia.** These are more three-dimensional projections, as the actin cytoskeleton is remodelled into a gel-like lattice.

Movement
A similar mechanism involving the coordinated remodelling of the cytoskeleton and the formation and release of cell adhesive proteins underlies all three modes of migration. Essentially, actin is polymerized at the leading edge, extending the plasma membrane forwards. New adhesions are formed with the substratum (to other cells and/or extracellular matrix) at the leading edge to provide purchase. Release of attachments and depolymerization of the actin filaments at the trailing edge allow the cell to move forwards. Myosin and myosin motor proteins may also be involved at the trailing edge, providing the tractive force to pull the cell body forwards. The complex coordination of these processes is controlled by signalling pathways involving members of the Rho protein family of guanosine triphosphatases (GTPases). Key signalling targets are the WASp family of proteins, which stimulate actin polymerization. The significance of cell motility in humans is illustrated by mutation of the WASp expressed in blood cell lineages, which causes Wiskott–Aldrich syndrome (see p. 140), and is characterized by severe immunodeficiency and thrombocytopenia (platelet deficiency).

**Further reading**

**The Cell and Its Environment**
Most cells differentiate or specialize to perform particular functions within tissues where they interact with the extracellular matrix (ECM) or other cells. The major tissue types are
epithelia, connective tissue, muscle and neural tissue.

• **Epithelial tissues** comprise layers of cells held tightly together by intercellular junctions and are usually separated from underlying tissue by specialized ECM called the basal lamina. Epithelia cover surfaces (e.g. epidermis, tongue surface) and line passageways (airways, digestive tract, blood vessels), providing protection and regulating absorption and secretion.

• **Connective tissues** support other tissues and give organs shape. Connective tissue is a non-rigid matrix of fibres such as collagen, in which cells are embedded (primarily fibroblasts that secrete the matrix but also other cell types, depending on the type of tissue). Matrix such as bone will include osteoblasts and osteoclasts; cartilage will include chondrocytes and chondroblasts, which reshape and remodel the connective tissue.

### Extracellular matrix

The ECM is the gel matrix outside the cell, usually secreted by fibroblasts. ECM determines tissue properties; for example, in bone it is calcified, in tendons it is tough and rope-like, and in neural tissue it is almost absent. However, ECM is more than just a support matrix. It affects cell shape, migration, cell–cell communication and signalling, proliferation and survival.

The gel or ground substance of the ECM is made from polysaccharides (glycosaminoglycans, GAGs), usually bound to proteins to form proteoglycans. These are a diverse group of molecules conferring different matrix properties in different tissues. They form hydrated gels that resist compression yet permit diffusion of metabolites and signalling molecules.

• **Hyaluronan**, a very large hydrated GAG, is secreted into the joint space in synovial joints (see p. 647), which it lubricates and which helps reduce compressive forces.

• **Aggrecan**, a very large proteoglycan, forms part of the articular cartilage of joints (see p. 647) and also contributes to compression resistance.

• **Decorin** is a much smaller proteoglycan from the loose connective tissue of skin and has structural and signalling functions (through binding and regulating growth factor activity).

Fibrous proteins of ECM include collagens and tropoelastin, which polymerize into collagen and elastin fibres, and fibronectin, which is insoluble in many tissues but soluble in plasma. Collagen provides tensile strength, while elastin confers elasticity. The widely distributed fibronectin adheres to both cells and ECM, thus positioning cells within the ECM. Collagens, the most abundant proteins in the body, are also widespread and play structural roles in skin and bone, where collagen defects and disorders often manifest. Elastin fibres, abundant in arteries, lung and skin, have a fibrillin sheath (fibrillin mutations underlie Marfan syndrome; see pp. 1028–1029). The ECM can be degraded and remodelled by proteins of the matrix metalloproteinase (MMP) family. These are needed for angiogenesis and morphogenesis, and are also involved in the pathophysiology of cancer, cirrhosis and arthritis.

**Basal lamina** or basement membrane (lamina propria) is a specialized form of ECM, which separates cells from underlying tissue and plays a supportive, anchoring and protective role. Basal lamina can also act as molecular filters (e.g. glomerular filtration barrier; see Fig. 20.2)
and mediate signalling between adjacent tissues (e.g. epidermal–dermal signalling in skin). Type IV collagen, heparan sulphate proteoglycan, laminin and nidogen are key basal lamina proteins. Inherited abnormalities in these proteins cause skin blistering diseases (see Fig. 31.34). Breach of the basal lamina by invading cancer cells is a key stage in progression of epithelial carcinoma in situ to a malignant carcinoma.

**Cell–cell adhesion**

Cells need to interact directly for barrier function, tissue strength and communication. This is mediated by several types of protein that form junctions between cells.

**Cell–cell adhesion proteins** *(Fig. 7.11a)*

Cells adhere to each other through multiprotein junctions and also individual transmembrane proteins.

---

**FIGURE 7.11** Cell adhesion molecules and cellular junctions. (a) Major groups of adhesion molecules. (b) Adjacent cells form focal adhesion junctions. (c) Basement membrane adhesion.

---

**Immunoglobulin-like cell adhesion molecules**
Immunoglobulin-like cell adhesion molecules (iCAMs or CAMs) (Fig. 7.11a) are structurally related to antibodies. The neural cell adhesion molecule (N-CAM) is found predominantly in the nervous system, where it mediates homophilic (like–like) adhesion. When bound to an identical molecule on another cell, N-CAM can also associate laterally with a fibroblast growth factor receptor and stimulate its tyrosine kinase activity to induce neurite growth, thus triggering cellular responses by indirect activation of the recipient.

Selectins
Unlike most adhesion molecules, which bind to other proteins, the selectins interact with carbohydrate ligands or mucin complexes on leucocytes and endothelial cells (vascular and haematological systems).

- **Leucocyte-selectin** (CD62L) mediates the homing of lymphocytes to lymph nodes.
- **Endothelial-selectin** (CD62E) is expressed after activation by inflammatory cytokines; the small basal amount of E-selectin in many vascular beds appears to be necessary for the migration of leucocytes.
- **Platelet-selectin** (CD62P) is stored in the alpha granules of platelets and the Weibel–Palade bodies of endothelial cells, but it moves rapidly to the plasma membrane upon cell stimulation.

All three selectins play a part in leucocyte rolling (see Fig. 8.9).

Integrins
Integrins are membrane glycoproteins with α and β subunits that exist as active and inactive forms. The amino acid sequence arginine–glycine–aspartic acid (RGD) is a potent recognition system for integrin binding.

Focal adhesion junctions between adjacent cells
See Figure 7.11b.

Tight junctions (zonula occludens)
These are mediated by the claudin and occluden integral membrane proteins that hold cells together. They form at the top (apical) side of epithelial cells in intestine, skin and kidney, and in endothelial cells of blood vessels (Fig. 7.11) to provide a regulated barrier to the movement of ions and solutes between cells (paracellular flow). Tight junctions also confer polarity to cells by acting as a barrier between the apical and the basolateral membranes, preventing diffusion of membrane lipids and proteins. Twenty-four claudins are differentially expressed in different cell types to regulate paracellular transport. For example, changes in claudin expression in the kidney nephron correlate with permeability changes. Mutations in claudin 16 (previously named parcellin-1) and 19, expressed in the thick ascending limb of the loop of Henle in the kidney, cause an inherited renal disorder, familial hypomagnesaemia with hypercalciuria and nephrocalcinosis (FHHNC; see p. 169).
**Gap junctions**

Gap junctions (Fig. 7.11) allow low-molecular-weight substances to pass directly between cells, permitting metabolic and electric coupling (e.g. in cardiomyocytes). Protein channels made of six connexin proteins (as well as claudins and occludens) are aligned between adjacent cells and allow the passage of solutes of up to 1000 kDa (e.g. amino acids, sugars, ions, chemical messengers). The channels are regulated by many factors such as intracellular Ca$^{2+}$, pH and voltage. Gap junctions form in almost all interacting cells but connexin family members are differentially expressed. Connexin mutations underlie many inherited disorders, such as the X-linked form of Charcot–Marie–Tooth disease (GJB1; see p. 886) and are also a major cause of genetic hearing loss (GJB2).

**Adherens junctions**

Adherens junctions are multiprotein intercellular adhesive structures, prominent in epithelial tissues such as the fascia adherens in cardiac muscle (Fig. 7.11b). They attach principally to actin microfilaments inside the cell with the aid of multiple additional proteins, and also attach and stabilize microtubules. At the apical sides of epithelial cells, a prominent type of adherens junction, the zonula adherens, attaches to the circumferential actin stress fibres. Transmembrane proteins of the cadherin family provide the adhesion through homotypic interaction of their extracellular domains. Downregulation of cadherins is a feature of cancer progression in many cells.

**Desmosomes (macula adherens)**

Desmosomes provide strong attachment between cells and are prominent in tissues subject to stress, such as skin and cardiac muscle (see Fig. 7.7, Fig. 7.11b and Fig. 31.1). Like adherens junctions, they are multiprotein complexes, where adhesion is provided by transmembrane cadherin proteins, desmogleins and desmocollins. However, within the cell, desmosomes interact principally with intermediate filaments rather than microfilaments and microtubules. Germline mutations in genes encoding desmosomal associated proteins are a cause of cardiomyopathy with or without cutaneous features and in pemphigus vulgaris and pemphigus foliaceus (see pp. 1368–1369).

**Basement membrane adhesion**

Cells adhere (Fig. 7.11c) to non-basal lamina ECM via secreted proteins such as fibronectin and collagen, and to basal lamina proteins via focal adhesion and hemidesmosome multiprotein complexes (e.g. keratin or vimentin). Here, integrins replace cadherins as the key surface adhesive proteins. Integrins are transmembrane sensors or receptors, which change shape upon binding to ECM. Inside the cell, integrins interact with the cytoskeleton and a complex array of over 150 proteins that influence intracellular signalling pathways affecting proliferation, survival, shape, mobility and gene expression.

- **Outside-in signalling.** This forms the basis for anoikis or apoptotic death, such as occurs in
cancer cells that inappropriately lose cell–substratum adhesion.

- **Inside-out signalling.** Intracellular changes can also cause integrins to switch from an inactive to an adhesive conformation. This ‘inside-out’ signalling occurs when platelet integrins glycoprotein IIb-IIIa (GPIIb-IIa) are activated to bind fibrinogen at sites of vessel injury, resulting in platelet aggregation (see p. 565 and *Fig. 16.39*).

  Defective integrins are associated with many immunological and clotting disorders such as Bernard–Soulier syndrome and Glanzmann's thrombasthenia (see *Box 16.31*).

**Cellular Mechanisms**

**Cell signalling**

Signalling or communication between cells is often via extracellular molecules or ligands, which can be proteins (e.g. hormones, growth factors), small molecules (e.g. lipid-soluble steroid hormones such as oestrogen and testosterone) or dissolved gases such as nitric oxide. The signal is usually received by membrane protein receptors, although some signals, such as steroid hormones, enter the target cell, where they interact with intracellular receptors (*Fig. 7.12*). Some signalling, especially in the immune system, relies on cell–cell contact, where the signalling molecule (ligand) and receptor are on adjacent cells.
Receptors

Receptors transduce signals across the membrane to an intracellular pathway or second messengers to change cell behaviour, often ultimately affecting gene expression (Figs 7.12 and 7.13). The membrane-bound receptors fall into three main groups based on downstream signalling pathways:

- **Ion channel-linked receptors** (voltage- or ligand-activated ion channels; see Fig. 7.3). At synaptic junctions between neurones (see Fig. 21.1), these receptors open in response to neurotransmitters such as glutamate, adrenaline (epinephrine) or acetylcholine to cause a rapid depolarization of the membrane.

- **G-protein-linked receptors**, such as the odorant and light (opsin) family of receptors. These belong to a large family of seven-pass transmembrane proteins (see Figs 7.2 and 7.12). On activation by ligand, G-protein-linked receptors bind a GTP-binding protein (G-protein),
which activates adjacent enzyme complexes or ion channels (Figs 7.12 and 21.1). The adjacent enzyme can be adenylcyclase (see below).

**Enzyme-linked receptors** (Figs 7.2 and 7.12) typically have an extracellular ligand-binding domain, a single transmembrane-spanning region, and a cytoplasmic domain that has intrinsic enzyme activity or which will bind and activate other membrane-bound or cytoplasmic enzyme complexes. This group of receptors is highly variable but many have kinase activity or associate with kinases, which act by phosphorylating substrate proteins, usually on a tyrosine (e.g. the platelet-derived growth factor (PDGF) receptor) or a serine/threonine (e.g. the transforming growth factor-beta (TGF-β) receptor).

![Signal transduction showing the Hedgehog and Wnt signalling pathway.](image)

**FIGURE 7.13** Signal transduction showing the Hedgehog and Wnt signalling pathway. (a) Wnt signalling has three pathways: the canonical (β-catenin), Wnt/Ca²⁺ and planar cell polarity pathways. Wnt binds to the Frizzled protein, and then Dishevelled activity via other pathways inhibits phosphorylation of β-catenin. This alters gene transcription. (b) Hedgehog ligand (Hh) binds to a 12-transmembrane protein receptor Patched (Ptc). This acts as an inhibitor of smoothened (Smo), another transmembrane protein related to the Frizzled family of Wnt receptors. In the presence of Hh, the inhibitory effects of Ptc on Smo are removed and Smo is phosphorylated by protein kinase A and other kinases. This prevents cleavage of cubitus interruptus, a zinc finger protein (Ci), which enters the nucleus, inducing the transcription of Hh target genes. APC, adenomatous polyposis coli protein; TCF, T-cell factor.

**Signal transduction**

Signal transduction from the receptor to the site of action in the cell is mediated by small signalling molecules called second messengers, or by signalling proteins (Fig. 7.12). Changes
in activity of signalling proteins by acquired mutation occur in cancer, and many anticancer drugs target signalling pathways. For example, the *Hedgehog* pathway is involved in human development, tissue repair and cancer (*Fig. 7.13*). Inhibitors of this pathway are being developed for therapeutic interventions. The *Wnt* pathway is also involved in bone formation (see p. 708).

**Second messengers**

These include cyclic adenosine monophosphate (cAMP) and membrane lipid-derived inositol triphosphate (IP$_3$) and diacylglycerol (*Fig. 7.12*). These molecules diffuse from the receptor to bind and change the activity of downstream proteins propagating the signal. Cyclic-AMP triggers a protein signalling cascade by activating a cAMP-dependent protein kinase. Diacylglycerol activates protein kinase C while IP$_3$ mobilizes calcium from intracellular stores (e.g. from the ER; see *Fig. 23.9*).

**G-proteins**

G-proteins or GTP-binding proteins are signalling proteins that switch between an active state when GTP is bound and an inactive state when bound to guanosine diphosphate (GDP). The best-known members are the Ras superfamily, comprising Ras, Rho, Rab, Arf and Ran families. Activation of Ras members by somatic mutation is found in approximately 33% of human cancers. Ras members are often activated downstream of tyrosine kinase receptors, and they transmit signals by activating a cascade of protein kinases, including mitogen-activated protein (MAP) kinase (*Fig. 7.12*). Ras signalling molecules have roles in many cellular activities, including regulation of the cell cycle, intracellular transport, and apoptosis.

**Kinase and phosphatase signalling proteins**

These are enzymes that respectively phosphorylate or dephosphorylate residues on proteins to alter their activity. Phosphorylation cascades transduce and amplify signals from the membrane receptor to the site of action in the cell. The tyrosine kinase receptors phosphorylate each other after ligand binding causes the receptor to dimerize (see *Fig. 7.12*). The membrane-bound and cytosolic targets of these activated receptor complexes are most commonly the Ras family members, or protein kinase C, which often transduce signals through the MAP kinase cascade, or which phosphorylate the inhibitor of kappa B (IκB), causing it to release its DNA-binding protein, nuclear factor kappa B (NFκB). For example, activated Ras binds and activates the kinase Raf, the first of a set of three MAP kinases that transmit signals by successive phosphorylation of target proteins that ultimately effect transcription (*Fig. 7.12*). The receptors for cytokines, such as interleukins, interferons, growth hormone and erythropoietin, transduce signals through the Janus kinase–signal transducer and activator of transcription (JAK-STAT) pathways. Cytokine binding to the receptor activates the associated JAK, which phosphorylates its STAT. The phosphorylated STATs dimerize and translocate to the nucleus to alter gene expression. Kinases and phosphatases are frequently mutated in cancers or underlie developmental conditions. Somatic mutations in *B-Raf* occur in approximately 60% of
malignant melanomas (usually the mutation V600E) and are common in other cancers (see pp. 1373–1374). Mutations in the Ras-MAPK signal transduction pathway are the cause of Noonan syndrome.

**Nuclear control**

**DNA and RNA structure**

Hereditary information is contained in the sequence of the building blocks of double-stranded deoxyribonucleic acid (DNA) (*Fig. 7.14*). Each strand of DNA is made up of a deoxyribose-phosphate backbone and a series of purine (adenine (A) and guanine (G)) and pyrimidine (thymine (T) and cytosine (C)) bases; because of the way the sugar–phosphate backbone is chemically coupled, each strand has a polarity, with a phosphate at one end (the 5′ end) and a hydroxyl at the other (the 3′ end). The two strands of DNA are held together by hydrogen bonds between the bases. A can only pair with T, and G can only pair with C; therefore each strand is the antiparallel complement of the other (*Fig. 7.14A*). This is key to DNA replication because each strand can be used as a template to synthesize the other.
DNA and its relationship to human chromosomes. A. Individual nucleotides form a polymer linked via the deoxyribose sugars to form a single-strand DNA (ssDNA). The 5′ carbon of the sugar is covalently joined to phosphate. The 3′ carbon links the phosphate on the 5′ carbon of the ribose of the next nucleotide, forming the sugar–phosphate backbone of the nucleic acid. The 5′ to 3′ linkage gives orientation to a sequence of DNA. B. Double-stranded DNA. The two strands of DNA are held together by hydrogen bonds between the bases. T pairs with A, and G with C. The orientation of the complementary ssDNA is thus complementary and antiparallel. The helical three-dimensional structure has major and minor grooves, and a complete turn of the helix contains 12 base-pairs. The grooves are structurally important: DNA-binding proteins predominantly interact with the major grooves. C. Supercoiling of DNA. The large helical DNA is coiled into nucleosomes by winding around nuclear proteins (histones), and further condensed by coiling and supercoiling into the chromosomes that are visible at metaphase. D. At the end of the metaphase, DNA replication results in a twin chromosome joined at the centromere. Chromosomes are assigned a number or X or Y, plus short arm (p) or long arm (q). The region or subregion is defined by the transverse light and dark bands observed when staining with Giemsa (hence G-banding) or quinacrine, and numbered from the centromere outwards.

The two strands twist to form a double helix with a major and a minor groove, and the large stretches of helical DNA are coiled around histone proteins to form nucleosomes (Fig. 7.14C). They can be condensed further into the chromosomes that can be visualized by light microscopy at metaphase (see below, and Figs 7.14 and 7.23).

To express the information in the genome, cells transcribe the code into the single-stranded ribonucleic acid (RNA). RNA is similar to DNA in that it comprises four bases – A, G and C but with uracil (U) instead of T – and a sugar–phosphate backbone with ribose instead of deoxyribose. Several types of RNA are made by the cell. Messenger RNA (mRNA) codes for proteins that are translated on ribosomes. Ribosomal RNA (rRNA) is a key catalytic component of the ribosome, and amino acids are delivered to the nascent peptide chain on transfer RNA (tRNA) molecules. There are also a variety of RNAs that regulate gene expression or RNA processing. These include microRNA (miRNA) and small interfering RNA (siRNA) (see p. 99) that typically bind to a subset of mRNAs and inhibit their translation and/or initiate their degradation (siRNA only initiates degradation). Other non-coding RNAs are involved in X-inactivation and telomere maintenance or RNA splicing and maturation.

**DNA transcription**

A gene is usually 20–40 kilobases of DNA (but the muscle protein dystrophin is 2.4 Mb long)
that contains the code for a polypeptide sequence. Three adjacent nucleotides (a codon) specify a particular amino acid, such as AGA for arginine. There are only 20 common amino acids, but 64 possible codon combinations make up the genetic code. This redundancy means that most amino acids are encoded by more than one triplet, and additional codons are used to signal initiation or termination of polypeptide-chain synthesis.

RNA is transcribed from the DNA template by an enzyme complex of more than 100 proteins, including RNA polymerase, transcription factors and enhancer proteins. Promoter regions upstream of the gene dictate the start point and direction of transcription. The complex binds to the promoter region, the nucleosomes are remodelled to allow access, and a DNA helicase unwinds the double helix. RNA, like DNA, is synthesized in the 5′ to 3′ direction as ribonucleotides are added to the growing 3′ end of a nascent transcript. RNA polymerase does this by base-pairing the ribonucleotides to the DNA template strand it is reading in the 3′ to 5′ direction. Messenger RNA is modified as it is synthesized (Fig. 7.15). It is capped at the 5′ end with a modified guanine that is required for efficient processing of the mRNA and translation. The 3′ end of the mRNA is modified with up to 200 A nucleotides by the enzyme poly-A polymerase. This 3′ poly-A tail is essential for nuclear export (through the nuclear pores), stability and efficient translation into protein by the ribosome. Human protein coding sequences (exons) are interrupted by intervening sequences that are non-coding (introns) at multiple positions (Fig. 7.15). These are spliced from the nascent message in the nucleus by an RNA/protein complex called a spliceosome. Differential splicing can cause exons to be spliced alongside their intervening introns. This contributes significantly to the complexity of the human transcriptome, as proteins translated from these messages lack particular domains and therefore have different activity.
**FIGURE 7.15** Transcription and translation (DNA to RNA to protein). RNA polymerase transcribes an RNA copy of the DNA gene sequence. The transcript is capped at the 5’ end by the addition of an inverted guanine residue, which is then methylated to form 7-methylguanosine. At the 3’ end, the sequence AAUAAA is recognized by endonuclease, and the transcript cleaved 20 base-pairs further downstream. Poly-A polymerase then adds adenosine residues to the 3’ end, forming a poly-A tail (polyadenylation). The introns are then spliced to produce the mature messenger RNA (mRNA), which is trafficked to the cytosol via nuclear pores. Ribosomal subunits assemble on the 5’ end of the mRNA to translate the message into protein for which transfer RNAs (tRNAs) deliver the amino acid building blocks.

**Control of gene expression**

The genome of all cells in the body encodes the same genetic information, yet different cell types express very different subsets of proteins. Gene expression is controlled at many steps from transcription to protein degradation. However, for many genes, transcription is the key point of regulation. This is controlled primarily by proteins, which bind to short sequences within the promoter regions that either repress or activate transcription, or to more distant sequences where proteins bind to enhance expression. These transcription factors and
Enhancers are often the end-points of signalling pathways that transduce extracellular signals to change gene expression (see Fig. 7.12).

This level of regulation often involves the translocation of an activated factor from the cytoplasm to the nucleus. In the nucleus, these DNA binding proteins recognize the shape and position of hydrogen bond acceptor and donor groups within the major and minor grooves of the double helix (i.e. the double helix does not need to unwind). There are several classes of DNA binding protein that differ in the protein structural motif that allows them to interact with the double helix. These primarily include helix-turn-helix, zinc finger and leucine zipper motifs, although protein loops and β-sheets are used by some proteins. More permanent control of gene expression patterns can be achieved epigenetically.

The term ‘epigenetics’ is used to explain changes in gene expression that do not involve changes in the underlying DNA sequence. Despite not altering the decoding sequence, the effects of epigenetic changes are stable over rounds of cell division, and sometimes between generations. A number of systems initiate and sustain these changes:

- **Modifications to DNA's surface structure**, but not its base pair sequence – DNA methylation resulting in cytosine being converted to 5-methyl cytosine. This occurs mainly in sites where a cytosine molecule is next to a guanidine nucleotide, a CpG site. When CpG islands (groups of CpG sites) in the promoter region are methylated, gene expression is repressed.

- **Modification of chromatin proteins** (in particular, acetylation of histones), which will not only support DNA but bind it so tightly as to regulate gene expression. At the extreme, such binding can permanently prevent the DNA sequences being exposed to, let alone acted on by, gene transcription (DNA-binding) proteins.

Most of the genome is transcribed but only a minority of transcripts encode proteins (see ‘Human genetics’, p. 106). The non-coding RNAs (ncRNAs) include a group that regulate gene expression (see ‘DNA and RNA structure’, pp. 97–98). miRNAs and siRNAs are short ncRNAs (19–29 base-pairs (bp)) that together regulate expression of approximately 30% of genes by degradation of transcripts or repression of protein synthesis. A growing range of additional regulatory ncRNA classes are being identified, many of which control gene expression by epigenetic mechanisms.

Epigenetic modification is also ‘heritable’, meaning that a dividing liver cell, for example, can give rise to two daughter cells with the same epigenetic signals, such that they express the appropriate transcriptome for a liver cell. Epigenetic change forms the basis of genomic imprinting (see p. 115).

Epigenetic change in gene expression also occurs in cancer. An example is DNA methylation repressing tumour suppressor genes. Targeted therapy is already playing a big role in the control of malignant disease

The cell cycle and mitosis

The cell duplication cycle has four phases – G1, S, G2 and mitosis (Fig. 7.16) – and takes about 20–24 hours to complete for a rapidly dividing adult cell. G1, S and G2 are collectively known as interphase, during which the cell doubles in mass (the two gap phases are for growth) and duplicates its 46 chromosomes (S phase). Mitosis describes, in four subphases (prophase, metaphase, anaphase and telophase; Fig. 7.17), the process of chromosome separation and nuclear division before cytokinesis (division of the cytoplasm into two daughter cells).

**FIGURE 7.16** The cell cycle. Cells are stimulated to leave non-cycle G0 to enter G1 phase by growth factors. During G1, transcription of the DNA synthesis molecules occurs. Rb is a ‘checkpoint’ (inhibition molecule) between G1 and S phases and must be removed for the cycle to continue. This is achieved by the action of the cyclin-dependent kinase produced during G1. During the S phase, any DNA defects will be detected and p53 will halt the cycle (see p. 119). Following DNA synthesis (S phase), cells enter G2, a preparation phase for cell division. Mitosis takes place in the M phase. The new daughter cells can now either enter G0 and differentiate into specialized cells, or re-enter the cell cycle.
Synthesis phase: DNA replication

DNA synthesis by a multi-enzyme complex is initiated simultaneously at multiple replication forks in the genome. The key components of the replication machinery are DNA helicase, DNA primase, DNA polymerase and single-stranded DNA binding proteins.

**DNA helicase**

DNA helicase hydrolyses ATP to unwind the double helix and expose each strand as a template for replication. The two strands are antiparallel, and DNA can only be extended by addition of nucleotide triphosphates to the hydroxyl of the 3’ end of the growing chain. For the leading template strand, the replication fork moves in a 3’ to 5’ direction along the template, meaning that the newly synthesized strand is synthesized in a 5’ to 3’ direction. At the same replication fork, the antiparallel strand is being exposed in a 5’ to 3’ direction and therefore requires a distinct priming process.

**DNA primase**

DNA primase synthesizes a short (approximately 10 nucleotide) RNA molecule annealed to the DNA template, which acts as a primer for DNA polymerase.

**DNA polymerase**

DNA polymerase extends the primer by adding nucleotides to the 3’ end. For the leading template strand, the RNA primer is only required to initiate synthesis once and polymerization continues just behind the replication fork. For the antiparallel strand, DNA primase synthesizes RNA primers at approximately every 200 nucleotides to prime DNA synthesis in the opposite direction to the movement of the replication fork. To allow for this, the synthesis against this template is delayed and so it is called the lagging strand and requires more of the strand to be exposed for DNA primase and DNA polymerase to engage.

**Single-stranded DNA binding proteins**

These are required to bind to the exposed single-stranded DNA and stabilize it. DNA
polymerase extends the RNA primer to cover the 200 nucleotides between each RNA primer on the lagging strand. These RNA/DNA hybrids are called Okazaki fragments.

• RNAase H removes the RNA primer from the preceding Okazaki fragment; DNA polymerase extends the new strand over the gap.

• DNA ligase joins the two DNA fragments together.

The phases of mitosis

Prophase
The two sister chromatids (the replicated chromosomes held together by proteins called cohesins) condense in the nucleus. The two centrosomes, between which the microtubules of the mitotic spindle will form, move apart in the cytoplasm. At the end of prophase (sometimes known as prometaphase), the nuclear membrane breaks down and the spindle microtubules attach to the kinetochore protein complex bound to the sister chromatids.

Metaphase
The chromosomes are aligned on a central plane with the two centrosomes at opposite poles. The sister chromatids are attached to microtubules from different centrosomes via the kinetochore.

Anaphase
The cohesins break down and the sister chromatids are pulled in opposite directions as the microtubules shorten towards their respective spindle poles.

Telophase
Each set of daughter chromosomes is held at a spindle pole and the nuclear envelope reforms around the genome of each new daughter cell.

Cytokinesis
Binary fission of the cytoplasm begins in telophase, before the completion of mitosis, with the appearance of a ring of actin and myosin filaments around the equator of the cell. Cytokinesis is completed as the ring contracts to create a cleavage furrow and separate the two daughter cells.

Control of the cell cycle and checkpoints
Cells can exit the cell cycle and become quiescent. Indeed, most terminally differentiated adult cells are in a phase termed G0, in which the cycling machinery is switched off. In some cell types, the switch is irreversible (e.g. in neurones), but others, like hepatocytes, retain the ability to re-enter the cell cycle and proliferate. This gives the liver a significant ability to regenerate following damage.
**Cyclin-dependent kinases (Cdks), Retinoblastoma protein (Rb) and p53**

Progression through the cell cycle is tightly controlled and punctuated by three key checkpoints when the cell interprets environmental and cellular signals to determine whether it is appropriate or safe to proceed (Fig. 7.16). The switches that allow progression beyond these checkpoints are a family of small protein complexes called cyclin-dependent kinases (Cdks) that phosphorylate serines or threonines in key target proteins at each stage. It is the regulatory cyclin subunit of the Cdks that oscillates during the cell cycle (the actual kinase subunit may be present throughout but only activated by the transient expression of its cognate cyclin).

**Checkpoints**

**Restriction point (G1 checkpoint)**

The restriction point works to ensure that the cell cycle does not progress into S-phase unless growth conditions are favourable and the genomic DNA is undamaged. The cyclin-Cdk complexes active early in S-phase are denoted S-Cdk (cyclin A with Cdk1 or Cdk2).

*S-Cdks* have two roles:

- to phosphorylate their target proteins to initiate helix unwinding of the DNA at origins of replication, allowing the replication complex to begin DNA synthesis
- to prevent re-initiation at the same origin during the same cell cycle (because it would be deleterious to copy parts of the genome more than once).

S-Cdks are themselves subject to regulation by G1-Cdk (cyclin D1–3 with Cdk4 or Cdk5) and G1/S-Cdk (cyclin E with Cdk2), both of which can stimulate cyclin A synthesis. Two major cancer pathways converge on this checkpoint via the cyclin-Cdks:

- **G1-Cdk** responds positively to mitogenic (pro-growth) environmental signals like platelet-derived growth factor (PDGF) or epidermal growth factor (EGF). Activated G1-Cdk phosphorylates and inactivates the retinoblastoma protein (Rb), which releases the transcription factor E2F to stimulate G1/S-Cdk and S-Cdk synthesis that is necessary for progression.
- **G1/S-Cdk and S-Cdk** also respond to DNA damage via the p53 pathway. On DNA damage, the transcription factor p53 is phosphorylated and stimulates transcription of the *p21* gene. p21 protein is an inhibitor of both G1/S-Cdk and S-Cdk. Both Rb and p53 are regulators of the restriction point. Loss of function of either disables aspects of the negative control pathways. *Rb* and *p53* are commonly mutated in cancer and both are therefore considered ‘tumour suppressor genes’ (see p. 119).

**G2/M checkpoint**

The G2/M checkpoint prevents entry into mitosis in the presence of DNA damage or non-replicated DNA. M-Cdk (cyclin B with Cdk1) accumulates towards the end of G2 but is inactive. Activation of M-Cdk is complex and includes dephosphorylation of M-Cdk by the phosphatase Cdc25. Activated M-Cdk has three roles at the G2/M checkpoint:
• to initiate chromosome condensation
• to promote breakdown of the nuclear membrane
• to initiate assembly of the mitotic spindle.

To achieve this, M-Cdk phosphorylates a number of proteins at this checkpoint. The phosphorylation of condensin is required to coil the DNA and initiate chromosome condensation; phosphorylation of nuclear pore and lamina proteins initiates breakdown of the nuclear membrane; and phosphorylation of microtubule-associated proteins and catastrophe factors are both required for assembly of the mitotic spindle. DNA damage and the presence of non-replicated DNA negatively regulate M-Cdk and prevent entry into mitosis. The kinases that phosphorylate p53 in response to DNA damage and block progression through the restriction point can also phosphorylate and inhibit Cdc25, inactivating M-Cdk. Thus DNA damage also blocks cell cycle progression at this checkpoint.

**Met/Ana checkpoint**

The metaphase to anaphase checkpoint is regulated by protein degradation. The anaphase-promoting complex APC/C, which is activated by Cdc20, is a ubiquitin ligase that transfers a small protein, ubiquitin, to other proteins, marking them for degradation. The primary targets are securin, and the S- and M-cyclins of the cyclin-Cdks present at the start of mitosis.

Securin is an inhibitor of a protease called ‘separase’, which, on release, digests the cohesin that holds the two sister chromatids together, allowing them to be pulled apart by the mitotic spindle. APC/C activity is tightly controlled but the complete mechanism remains obscure. It includes a negative feedback loop involving M-Cdk, which phosphorylates APC/C and increases its affinity for Cdc20. Thus M-Cdk induces its own inactivation by activating the ligase that ensures degradation of its own cyclin. APC/C is also negatively regulated via an unknown pathway by kinetochores that remain unattached to the mitotic spindle; thus chromatid separation is inhibited until all 46 duplicated chromosomes are on the spindle.

**Protein synthesis and secretion**

**Protein translation**

The mature mRNA is transported through the nuclear pore into the cytoplasm for translation into protein by ribosomes (see Fig. 7.15).

• The two subunits of ribosomes (the 40S and 60S) are formed in the nucleolus from multiple proteins and several rRNAs, before transport to the cytoplasm.

• In the cytoplasm, the two subunits interact on an mRNA molecule, usually via ribosome binding sites encoded in the untranslated 5′ region of the message. The mRNA is then pulled through the ribosome until a translation initiation codon is encountered (usually an AUG coding for methionine).

• As the mRNA is pulled through the ribosome in the 5′ to 3′ direction, codons 3′ to the AUG are recognized by complementary sequences, or anticodons, in tRNA molecules that dock on
the ribosome.

- Each tRNA molecule carries an amino acid specific to the anticodon. The amino acids are transferred from tRNA molecules and sequentially linked to the carboxy-terminus of the growing polypeptide by the peptidyl transferase activity of the ribosome.

- The poly-A tail of the mRNA is not translated (3’ untranslated region) and is preceded by a translational stop codon: UAA, UAG or UGA.

Translation of secreted or integral membrane proteins is different. Typically, the first few amino acids of the amino terminus of the nascent polypeptide exit the ribosome and are recognized by a signal recognition particle (SRP) that stops translation until the complex is docked on to the ER via the SRP receptor. Translation then continues and the protein is translocated into or through the ER membrane via the Sec61 translocation complex as it is being synthesized (co-translational transport).

**Protein structure**

The amino acid sequence of a polypeptide chain (its **primary structure**) ultimately determines its shape. The weak bonds (hydrogen bonds, electrostatic and van der Waals interactions) formed between the side-chains of the different amino acids and/or the peptide backbone provide the **secondary structure** (α-helices, β-strands, loops). These are in turn folded into a three-dimensional, **tertiary structure** to provide functional protein domains of 40–350 amino acids. The modular nature of domains allows their functionality to be combined in protein complexes of different proteins. This final level of organization is the **quaternary structure**.

The folding of polypeptides into fully functional proteins is facilitated by an assortment of molecular chaperones, e.g. heat shock proteins (HSP), which bind to partially folded polypeptides and prevent the formation of inappropriate bonds.

**Lipid synthesis**

Fatty acids, molecules with a hydrocarbon chain of 4–28 carbons, are central to cellular life and human metabolism. They form the hydrophobic moiety of membrane lipids (see p. 87); they are precursors for short-lived, near-acting lipid paracrines such as leukotrienes and prostaglandins; and they are energy stores, particularly in the form of triglycerides.

**Fatty acids as an energy store**

Long-chain fatty acids can be incorporated into triglycerides, which are relatively inert, lipophilic compounds that can be stored as fat droplets in cells (particularly adipocytes). When blood glucose is low, these triglycerides are hydrolysed, secreted into the bloodstream as free fatty acids, and distributed as an energy source for the cells of the body. In the recipient cell, fatty acids are metabolized in the mitochondrion to produce acetyl-CoA for the Krebs cycle (see pp. 103–104). This is a particularly efficient storage system as, gram for gram, triglyceride produces six times the amount of energy than glycogen and occupies less volume in the cell.
Essential fatty acids

Unsaturated fatty acids (UFAs) have carbon–carbon double bonds that are introduced by desaturase enzymes by removal of the hydrogens. The remaining hydrogens on either side of the double bond can be on the same side of the chain (cis) or on opposite sides (trans). The acyl chain of cis UFAs is kinked, which influences the packing of membrane lipids and the function of the membrane barrier. Humans have desaturases that can introduce some double bonds but lack a desaturase required to make linoleic acid or alpha-linolenic acid. These fatty acids have double bonds 6 and 3 carbons from their respective omega ends (the methyl end of the chain). Omega-6 and omega-3 UFAs are essential fatty acids that must be obtained from the diet (see pp. 186–187). They are precursors of arachidonic acid and eicosapentaenoic acid, respectively, from which cyclo-oxygenase 1 and 2 (COX-1 and 2) (see Fig. 24.30) produce the paracrines that play roles in inflammation, pain, fever and airway constriction.

Intracellular trafficking, exocytosis (secretion) and endocytosis

The molecular composition, the lipids and proteins of each type of organelle membrane, is different and distinct from that of the plasma membrane, yet there is a continuous flux of material between many of the different compartments. Much of this flow is via vesicles that carry cargo and bud from one compartment to fuse with another. The process is regulated by an array of lipids and membrane proteins (coat proteins, adaptors, signalling molecules and fusion proteins).

• Budding of vesicles involves recruitment of coat proteins and adaptors to the membrane. Thus, a receptor, on binding to its ligand, may stimulate a kinase to phosphorylate phosphatidylinositol, or activate a small GTPase like Arf or Sar1, increasing their affinities for a coat protein or adaptor. The coat protein (clathrin at the plasma membrane, COPI at the Golgi, and COPII in the ER) forms a mesh around the developing vesicle (see Fig. 7.4). Fully-formed vesicles normally shed their coat (often triggered by GTP hydrolysis by the GTPase), leaving the adaptor/receptor/lipid combination to identify the vesicle.

• Targeting and trafficking are mediated by a different family of GTPases (Rab proteins) that recognize the combination of vesicle surface markers and target them appropriately. Once activated by GTP, the Rab proteins are lipid-anchored to the vesicle, where they engage with a diverse pool of Rab effectors. These can be motor proteins that traffic the vesicle along the microfilament and microtubule fibres of the cytoskeleton, or tethering proteins on the target membrane.

• Fusion is accomplished by membrane-fusion SNARES (see Fig. 7.4). The v-SNARE protein on the vesicle (often associated with the Rab effector) interacts with the t-SNARE on the target membrane to facilitate fusion of the two compartments (distinct combinations of v-SNARE and t-SNARE specify particular pathways).

Vesicles that fuse with the plasma membrane replenish membrane lipids and proteins, and also release cargo extracellularly (exocytosis; see Fig. 7.4). Clathrin-coated vesicles are also used to recycle protein from the plasma membrane, and import extracellular cargo to internal...
compartments called endosomes in a process called endocytosis. From endosomes, the receptors may be recycled back to the membrane, while the cargo is sent for degradation in the lysosome.

Pinocytosis and phagocytosis (see p. 89) are forms of endocytosis. Endocytosis can also occur via plasma membrane microdomains or lipid rafts called caveolae, which pinch in to form uncoated vesicles that fuse with endosomes. Endocytosed vesicles can also be transported across the cell in a process called transcytosis. For example, cargo can be endocytosed at the apical surface of an epithelial cell and exocytosed across the basolateral membrane.

Energy production
As food is catabolized, cells temporarily store the energy released in carrier molecules. These include reduced nicotinamide adenine dinucleotide (NADH) and reduced nicotinamide adenine dinucleotide phosphate (NADPH), which release energy as they are oxidized to NAD$^+$ and NADP$^+$. The molar ratio of NAD$^+$ to NADH is typically high in a cell because NAD$^+$ is used as an oxidizing agent in catabolic pathways. In contrast, the molar ratio of NADP$^+$ to NADPH is typically low because NAPH is used as a reducing agent in anabolic reactions. The most versatile carrier is adenosine triphosphate (ATP). ATP can be hydrolysed to ADP and phosphate (Pi) and the release of energy used to power less favourable reactions.

Lipids and polysaccharides provide most energy in a human diet, although protein can also be used. Enzymes secreted into the gut break down these polymers to their respective building blocks of fatty acids and sugars, which are absorbed by the apical membrane of the gut epithelium (the transporters involved in the transcellular transport of glucose across the enterocyte are described in Fig. 13.30). Fatty acids and sugars are catabolized by the cell to produce an array of activated carrier molecules.

Glycolysis
The six-carbon glucose is primarily catabolized in ten steps by enzymes of the glycolytic pathway (see Fig. 16.22) to produce two three-carbon molecules of the carboxylic acid, pyruvate. Glycolysis occurs in the cytosol and the first three steps actually consume energy ($2\times$ATP), but the remaining steps generate $4\times$ATP and $2\times$NADH, giving a net return of $2\times$ATP and $2\times$NADH.

Pyruvate is central to metabolism. It can be catabolized as fuel for the Krebs cycle and oxidative phosphorylation. It can regulate the cellular redox state by dehydration to lactate and regeneration of NADH. It can be a precursor for anabolism of fuels (glucose, glycogen and fatty acids), or amino acids via conversion to alanine. The fate of pyruvate depends on the environmental conditions and needs of the cell.

Under anaerobic conditions (e.g. in skeletal muscle following prolonged exercise), NAD$^+$ must be regenerated (because it is needed as an oxidizing reagent in the catabolism of glucose), and pyruvate is reduced to lactate as NADH is oxidized to NAD$^+$ in a ‘redox’ reaction catalysed by lactate dehydrogenase. This allows the muscle to continue to catabolize glucose
to generate ATP under conditions in which metabolic oxygen is limiting. The lactate is secreted into the bloodstream and is ultimately metabolized by the liver back into glucose by gluconeogenesis, consuming 6×ATP in the process. This cycle of anaerobic respiration that produces lactate in muscle, which is released into the bloodstream to be taken up by the liver for reconversion to glucose, is known as the Cori cycle (see Fig. 14.3).

Krebs cycle

Under aerobic conditions, the fate of pyruvate is different. It is transported into the mitochondrion, where it is decarboxylated to acetyl-CoA and NADH, with CO₂ released as a waste product. The acetyl-CoA formed from pyruvate (or from catabolism of amino acids or β-oxidation of fatty acids) enters the Krebs cycle in the matrix of the mitochondrion, where it is condensed with the four-carbon oxaloacetate to form the six-carbon citric acid. Citric acid has three carboxylate groups, providing the alternative names for the Krebs cycle (the citric acid or tricarboxylic acid cycle). In eight reactions, the Krebs cycle oxidizes two of the six carbons of citric acid to 2×CO₂, regenerates oxaloacetate to enter the next cycle, and in the process, provides enough energy to produce 1×GTP, 3×NADH and 1×reduced flavin adenine dinucleotide (FADH₂, a carrier of electrons much like NADH). The latter two products feed their electrons into the electron transport chain, where they are used to make ATP from ADP and Pi, a process known as oxidative phosphorylation.

In addition to energy production, glycolysis and the Krebs cycle provide precursors for the anabolism of amino acids, cholesterol, fatty acids, nucleotides, amino sugars and lipids.

Oxidative phosphorylation

The activated carriers NADH and FADH₂ carry high-energy electrons as hydride (a proton H⁺ and two electrons), which are donated to complexes of the electron transport chain, in the process regenerating NAD⁺ and FAD as oxidizing agents for continued oxidative metabolism. The electrons are passed down the series of inner membrane proteins of the mitochondrion, moving to a lower-energy state at each step until they are finally transferred to oxygen to produce water (hence the requirement for molecular oxygen). The energy released by the electrons is used to efflux protons (H⁺) into the inter-membrane space, setting up an H⁺ electrochemical gradient, which the ATP synthase (or F₀F₁ ATPase), another integral membrane protein, uses to drive the formation of ATP from ADP and Pi. Oxidative phosphorylation produces the bulk of the cellular ATP. A single molecule of glucose is able to produce a net yield of approximately 30×ATP. Only two of these come from glycolysis directly.

Cellular degradation and death

Cell dynamics

Cell components are continually being formed and degraded. Most of the degradation steps
involve ATP-dependent multi-enzyme complexes. Old cellular proteins are identified and modified by ‘ubiquitin’, a small 8.5 kDa protein present in all living cells. ‘Ubiquitination’ can deactivate a protein and trigger its internalization from the membrane (both of which are reversible), or it can target the protein for degradation by the lysosome or proteosome (a large proteolytic multi-enzyme complex). Failure to remove dysfunctional or misfolded proteins can result in the development of chronic debilitating disorders. For example, Alzheimer's and frontotemporal dementias are associated with the accumulation of proteins that are resistant to ubiquitin-mediated proteolysis. Similar proteolytic-resistant ubiquitinated proteins give rise to the inclusion bodies found in myositis and myopathies. This resistance can be due to point mutation in the target protein itself (e.g. mutant p53 in cancer; see p. 119) or can result from an external factor that alters the conformation of the normal protein to create a proteolytic-resistant shape, as in the prion protein of variant Creutzfeldt–Jakob disease (vCJD). Other conditions include von Hippel–Lindau syndrome (see p. 791) and Liddle syndrome (see p. 166).

**Free radicals**

A free radical is any atom or molecule that contains one or more unpaired electrons, making it more reactive than the native species. The major free radical species produced in the human body are the hydroxyl radical (OH), the superoxide radical (O$_2^-$) and nitric oxide (NO).

Free radicals are implicated in a large number of human diseases. The hydroxyl radical is by far the most reactive species but the others can generate more reactive species as breakdown products. When a free radical reacts with a non-radical, a chain reaction ensues, which results in direct tissue damage by membrane lipid peroxidation. Furthermore, hydroxyl radicals can cause genetic mutations by attacking purines and pyrimidines. Superoxide dismutase (SOD) converts superoxide to hydrogen peroxide and is thus an inherent protective antioxidant mechanism. Patients with dominant familial forms of amyotrophic lateral sclerosis (motor neurone disease; see pp. 879–880) have mutations in the gene for Cu-Zn SOD-1 catalase. Glutathione peroxidases are enzymes that remove hydrogen peroxide generated by SOD in the cell cytosol and mitochondria.

Free radical scavengers bind reactive oxygen species. Alpha-tocopherol, urate, ascorbate and glutathione remove free radicals non-catalytically by direct interaction. Severe deficiency of α-tocopherol (vitamin E deficiency) causes neurodegeneration. There is some evidence that cardiovascular disease and cancer can be prevented by a diet rich in substances that diminish oxidative damage (see p. 201). The principal dietary antioxidants are vitamin E, vitamin C, β-carotene and flavonoids.

**Heat shock proteins**

The heat shock response is a highly conserved and ancient response to tissue stress (chemical and physical) that is mediated by activation of specific genes, leading to the production of specific heat shock proteins (HSPs). The diverse functions of HSPs include the transport of proteins in and out of specific cell organelles, acting as molecular chaperones (the catalysis of
protein folding and unfolding) and the degradation of proteins (often by ubiquitination pathways). As well as heat, cytotoxic chemicals and free radicals can trigger HSP expression. The unifying feature, which leads to the activation of HSPs, is the accumulation of damaged intracellular protein. Tumours have an abnormal thermotolerance, which is the basis for the observation of the enhanced cytotoxic effect of chemotherapeutic agents in hyperthermic subjects. HSPs are expressed in a wide range of human cancers and are implicated in tumour cell proliferation, differentiation, invasion, metastasis, cell death and immune response.

**Autophagy**

Cells continually recycle material. For example, cellular proteins are degraded by the proteasome (see p. 104), and mRNA can be de-tailed and degraded by the exosome or decapping complex. Cells respond to stresses like starvation by degrading much of their cytoplasmic contents in order to recycle components and survive.

Cells achieve this by autophagy, during which everything from sugars, lipids, protein aggregates, ribosomal particles and organelles are enclosed in a double membrane (a vesicle that forms a cup shape and extends around the material to be degraded; see Fig. 7.6). The new autophagosome then fuses with a lysosome to degrade the contents by acid hydrolysis. Autophagic induction is complex and still not completely understood, but it has roles in tumour growth and elimination of intracellular microorganisms and toxic misfolded proteins, such as those that give rise to neurodegenerative disorders. Autophagy can suppress apoptotic cell death induced by chemotherapy, while excessive autophagy in response to starvation can lead to autophagic cell death.

**Necrotic cell death**

In necrotic cell death, external factors (e.g. hypoxia, chemical toxins, injury) damage the cell irreversibly. Necrotic cell death is associated with ischaemia and stroke, cardiac failure, neurodegeneration and pathogen infection, and occurs in the centre of tumours deprived of a blood supply. Characteristically, there is an influx of water and ions, after which the cell and its organelles swell and rupture. Lysosomal proteases released into the cytosol cause widespread degradation. There is a rise in cytosolic calcium, increased reactive oxygen species production, intracellular acidification and ATP depletion. Necrosis is regulated and is sometimes referred to as necroptosis; the cellular processes and activated pathways are still being investigated. Necrotic cell lysis induces acute inflammatory responses owing to the release of lysosomal enzymes into the extracellular environment.

**Apoptotic cell death**

Most terminally differentiated cells can no longer replicate and eventually die by apoptosis, a type of programmed cell death. Apoptosis occurs through the deliberate activation of cellular pathways, which causes cell suicide. In contrast to necrosis, apoptosis is orderly. Cells are destroyed and their remains phagocytosed by adjacent cells and macrophages without inducing inflammation. Apoptosis is essential for many life processes, including tissue maintenance in
the adult, tissue formation in embryogenesis, and normal metabolic processes such as the autodestruction of thickened endometrium leading to menstruation in a non-conception cycle. Cells that have accumulated irreparable DNA damage from toxins or ultraviolet radiation also trigger apoptosis via p53 to prevent replication of mutations or progression to cancer. Many chemotherapy and radiotherapy regimens work by triggering apoptotic pathways in the tumour cell.

Apoptosis has characteristic features:

• shrinkage of the cell and its nucleus
• chromatin aggregation into membrane-bound vesicles called apoptotic bodies
• cell ‘blebs’ (which are intact membrane vesicles) and exposure of phosphatidylserine on the cell surface
• absence of inflammatory response.

Apoptosis requires proteases called caspases, whose action is very tightly regulated. Caspases not only destroy cell organelles, but also cleave nuclear lamin, causing collapse of the nuclear envelope, and activate, through cleavage, nucleases that degrade DNA. Caspase activation can be achieved by:

• signals from outside the cell (the extrinsic apoptotic pathway or the death receptor pathway)
• internal signals, such as DNA damage (the intrinsic apoptotic pathway or the mitochondrial pathway) (Fig. 7.18).
**Extrinsic pathway**

The extrinsic pathway is required for tissue remodelling and induction of immune self-tolerance. Cells ubiquitously express a member of the tumour necrosis factor (TNF) death receptor family, such as Fas, on their cell surface. Ligand binding (e.g. by Fas ligand expressed on lymphocytes) causes assembly of a death-inducing signalling complex that produces a cascade of caspase activation. The extrinsic pathway can be amplified by induction of the intrinsic pathway.

**Intrinsic pathway**

In the intrinsic pathway, increased mitochondrial permeability releases pro-apoptotic proteins like cytochrome C. Cellular stresses, such as growth factor withdrawal, p53-dependent cell cycle arrest, DNA damage and intracellular reactive oxygen species accumulation, induce
expression of pro-apoptotic Bcl-2 proteins, Bax and Bak. These enter the outer mitochondrial membrane, forming pores that release cytochrome C, which forms a complex (the apoptosome) with other proteins. The apoptosome activates a caspase cascade.

**Stem Cells**

Following fertilization, the newly formed fertilized cell (the zygote) and those following the first few divisions are totipotent, meaning that they can differentiate into any cell type in the adult body. At the blastula stage of embryonic development, these cells undergo a primary differentiation event to become either the trophectoderm or the inner cell mass (ICM). The trophectoderm gives rise to the fetal cells of the placenta, while the ICM cells are pluripotent and give rise to all other cell types of the body (except those of the placenta); they are more commonly called embryonic stem (ES) cells. Stem cells have two properties:

- **self-renewal**: the ability to divide indefinitely without differentiating
- **pluripotency** or **totipotency**: the capability to differentiate, given the appropriate signals, into any cell type (except fetal placental cells).

As they begin to differentiate, their ability to self-renew and their potency are reduced but adult progenitor cells (sometimes erroneously referred to as stem cells) remain; these have a limited ability to self-renew and can differentiate into multiple related lineages (multipotent, like haemopoietic ‘progenitor cells’) or single lineages (unipotent, like muscle satellite cells). The body uses these partially differentiated progenitor cells to replace or repair damaged cells and tissues continually.

Stem cells have great therapeutic potential and can be obtained from blood from the umbilical cord, which contains embryo-like stem cells (which are not as primitive as ES cells but can differentiate into many more cells types than adult progenitor cells). Alternatively, adult cells can be reprogrammed to regain stem-like properties (induced pluripotent stem cells, IPSC).

**Cancer ‘stem cells’**

Only a very small proportion (<1%) of the individual cells from a cancer can form a cancer in a recipient immunodeficient mouse. These cells equate with the population that exclude the fluorescent drug Hoechst 33342 due to presence of a primary active (ABC) drug transporter on their cell surface. They have the characteristics of adult progenitor cells. The high relapse rate
of many cancers may well be due to the persistence of these cancer ‘stem cells’, and new therapies are required to target these in the initial treatment regimen.

**Human Genetics**

In 2003, the Human Genome Project was completed, with all $3.2 \times 10^9$ bp of DNA sequenced. Over 99% of the DNA sequence is identical between individuals, but still millions of different base-pair variations occur (variants that occur at a frequency $>1\%$ are called polymorphisms; pathological polymorphisms are called mutations; single nucleotide polymorphisms are called SNPs, pronounced ‘snips’). In addition, the genome contains segmental, duplication-rich regions, where the number of duplications varies between people. These are called copy number variations (CNVs). These variations underlie most human differences, and confer genetic disease and susceptibility to many common diseases. To understand this variation, the 1000 Genomes Project was undertaken and completed in 2015. It involved the sequencing of many genomes from people of Asian, West African and European ancestry. This has now been extended and over 90 000 exomes (protein coding regions of the genome) have been sequenced via the Exome Aggregation Consortium (ExAC).

Genomic DNA encodes approximately 21 000 genes. However, these protein-encoding genes (the exome) comprise only about 1.5% of the human genome. About 90% of the remaining genome is not ‘junk’ DNA but can be transcribed to form RNA molecules, which are not translated into protein (non-coding RNA, ncRNA). Some of these RNAs have known regulatory roles including microRNAs that can repress gene expression. The remaining DNA also contains evolutionarily conserved non-coding regions, some with known enhancer functions, moderately repeated elements (transposons) with probable viral origin, and microsatellites consisting of short, simple sequence (1–6 nucleotide) repeats. About 10% of the genome is highly repetitive or ‘satellite’ DNA, consisting of long arrays of tandem repeats. The function of non-protein coding DNA is being intensively investigated, for example, within the ENCODE (Encyclopedia of DNA Elements) project.
Tools for Human Genetic Analysis

The polymerase chain reaction (PCR)

This technique revolutionized genetic research because minute amounts of DNA – for example, from buccal cell scrapings, blood spots or single embryonic cells – can be amplified over a million times within a few hours. The DNA is amplified between two short (generally 17–25 bases) single-stranded DNA fragments (‘oligonucleotide primers’) that are complementary to the sequences on different strands at each end of the DNA of interest (Fig. 7.19).
Polymerase chain reaction. The technique is based on thermal cycling and has three basic steps. (a) The double-stranded genomic DNA is heat-denatured into single-stranded DNA. (b) The sample is cooled to favour annealing of the primers to their target DNA. (c) A thermostable DNA polymerase extends the primers over the target DNA. After one cycle, there are two copies of double-stranded DNA, after two cycles there are four copies, and so on.

Hybridization arrays

A fundamental property of DNA is that when two strands are separated – for example, by heating – they will always re-associate and stick together again because of their complementary base sequences. Therefore, the presence or position of a particular gene can be identified using a gene ‘probe’ consisting of DNA or RNA, with a base sequence that is complementary to that of the sequence of interest. A DNA probe is thus a piece of single-stranded DNA that can locate and bind to its complementary sequence. Hybridization is utilized in array-based platforms, where thousands and thousands of probes can be analysed in one experiment to investigate global gene expression, large-scale genotyping, gene methylation status and/or to seek chromosomal aberrations, including small chromosomal deletion/insertion events or copy number changes (Fig. 7.20).
DNA sequencing

A chemical process known as dideoxy-sequencing, or Sanger sequencing (after its inventor), allows identification of the exact nucleotide sequence of a piece of DNA. As in PCR, an oligonucleotide primer is annealed adjacent to the region of interest. This primer acts as the starting point for a DNA polymerase to build a new DNA chain that is complementary to the sequence under investigation. Chain extension can be prematurely interrupted when a dideoxynucleotide becomes incorporated (because it lacks the necessary 3′-hydroxyl group). As the dideoxynucleotides are present at a low concentration, not all the chains in a reaction tube will incorporate a dideoxynucleotide in the same place; so the tubes contain sequences of different lengths but which all terminate with a particular dideoxynucleotide. Each base dideoxynucleotide (G, C, T, A) has a different fluorochrome attached, and thus each termination base can be identified by its fluorescent colour. As each strand can be separated efficiently by capillary electrophoresis according to its size/length, simply monitoring the fluorescence as the reaction products elute from the capillary will give the gene sequence (Fig. 7.21).
Sequencing technology has developed dramatically to the extent that it is now cost-effective and quick to sequence an individual's whole genome in one experiment. This has massive implications in disease gene discovery but also can raise serious ethical considerations. There are a number of different platforms to perform this high-throughput sequencing (or ‘next generation sequencing’) and new faster and cheaper ones are being developed. For under £500 (2016 price), it is possible to sequence all the coding genes in an individual's human genome (termed the ‘exome’) to catalogue all possible disease-associated and non-disease-associated variants in every human gene. As well as sequencing genomic DNA, the technology can be used to sequence RNA (termed RNAseq) to assess gene expression levels accurately, in addition to determining all splice variations and allelic copy number. This can also be used to assess the effect of epigenetic modifications on gene expression.

Identification of gene function
Following sequencing of the genome, the challenge is to understand the function of the protein-coding genes. Most tools rely on the comparison of a cell or animal's phenotype in the presence or absence of the gene in question. Each tool has different merits and faults.

Cell culture
Human cells can be grown in culture flasks in the laboratory and their behaviour (growth rate, morphology, motility, gene expression profile and biochemistry) characterized. A specific gene can then be introduced in a small plasmid (a circle of DNA from which the gene of interest can be expressed) or incorporated into a virus, and the change in cell behaviour assessed to provide an indication of gene function. Alternatively, if the cell line in question already expresses the gene of interest, its expression can be knocked down by RNA interference.

RNA interference (RNAi)
RNAi takes advantage of the cellular machinery that allows microRNAs encoded by the genome to regulate the expression of many genes at the level of messenger RNA stability and translation (see ‘Control of gene expression’, pp. 98–99). This phenomenon has been exploited
in the laboratory to study the function of a gene of interest or, on a much larger scale, the function of each gene in the genome. In such an RNAi screen, a small interfering (si) RNA specific for each gene in the genome is introduced into cells grown in vitro, in effect knocking down expression of each gene in approximately 20,000 separate experiments. The phenotype of the cells in each experiment is then monitored to test the effect of loss of gene expression.

**Animal models**

The effect of a gene at organism level can also be tested by mis-expression/over-expression or knockout of a particular gene in a model animal. Nematode worms (*Caenorhabditis*), fruit flies (*Drosophila*), zebrafish and rodents have all been genetically engineered to identify the function of a gene of interest. Knockout models of the higher organisms can be particularly helpful for medical research to provide a model of disease for exploration of therapeutic intervention. Large-scale mutagenesis programmes are knocking out every gene or regulatory element in the mouse genome. However, it should be noted that the physiology of rodents and humans can differ.

**Genetic polymorphisms and linkage studies**

Techniques have been developed to identify and quantitate genetic polymorphisms such as single nucleotide polymorphisms (SNPs; see p. 106), microsatellites and copy number variants (CNVs). For example, SNPs consist usually of two nucleotides at a particular site and vary between populations and ethnic groups. They must occur in at least 1% of the population to be a SNP. SNPs can be in coding or non-coding regions of the genes or be between genes, and thus may not change the amino acid sequence of the protein.

**Linkage disequilibrium**

Polymorphisms that are closer together are more likely to have alleles that move together in a block than those further apart. This phenomenon is called ‘linkage disequilibrium’ and enables, for example, one SNP variant (tag SNP) in this block to act as a marker for the presence of other SNP variants. Linkage analysis has provided many breakthroughs in mapping the positions of genes that cause genetic diseases, such as the gene for cystic fibrosis, which was found to be tightly linked to a marker on chromosome 7.

**The International Hapmap Project**

As SNPs close together are inherited in blocks (haplotypes), tag SNPs for each haplotype block are typed and can then be correlated with a specific phenotype. An International Hapmap Project was developed. The Wellcome Trust Case Control Consortium was set up to analyse thousands of DNA samples from patients with different diseases in which there is thought to be a genetic component. Utilizing the Hapmap data and high-density SNP hybridization arrays, genetic risk-associated sequence variants have been found in many diseases and traits, including diabetes, cancer, hypertension, Crohn's disease, height and metabolism.
The ‘lod score’

The likelihood of recombination between the marker under study and the disease allele must be taken into account. This degree of likelihood is known as the ‘lod score’ (the logarithm of the odds) and is a measure of the statistical significance of the observed co-segregation of the marker and the disease gene, compared with what would be expected by chance alone.

• Positive lod scores make linkage more likely.
• Negative lod scores make linkage less likely.

By convention, a lod score of +3 is taken to be definite evidence of linkage because this indicates 1000:1 odds that the co-segregation of the DNA marker and the disease did not occur by chance alone.

Genome databases

Information arising from human genome sequencing is publicly available, providing biological information on every gene in the human genome. Information on any gene describing its protein product, function, tissue specific expression, disease association and sequence variation/mutation can all be easily obtained by searching and manipulating computer-based databases.

The Biology of Chromosomes

**Human chromosomes**

The nucleus of each diploid cell contains $6 \times 10^9$ bp of DNA in long molecules called *chromosomes* (see Fig. 7.14). Chromosomes are massive structures containing one linear molecule of DNA that is wound around histone proteins into small units called nucleosomes, and these are further wound to make up the structure of the chromosome itself.

Diploid human cells have 46 chromosomes, 23 inherited from each parent; thus there are 23 ‘homologous’ pairs of chromosomes (22 pairs of *autosomes* and two *sex chromosomes*). The sex chromosomes, called X and Y, are not homologous but are different in size and shape. Males have an X and a Y chromosome; females have two X chromosomes. (Primary male sexual characteristics are determined by the SRY gene – sex-determining region, Y chromosome.)
The chromosomes are classified according to their size and shape, the largest being chromosome 1. The constriction in the chromosome is the centromere, which can be in the middle of the chromosome (metacentric) or at one extreme end (acrocentric). The centromere divides the chromosome into a short arm and a long arm, referred to as the p arm and the q arm, respectively (Fig. 7.14D).

Chromosomes can be stained when they are in the metaphase stage of the cell cycle and are very condensed. The stain gives a different pattern of light and dark bands that is diagnostic for each chromosome. Each band is given a number, and gene-mapping techniques allow genes to be positioned within a band within an arm of a chromosome. For example, the CFTR gene (in which a defect gives rise to cystic fibrosis) maps to 7q21: that is, on chromosome 7 in the long arm in band 21.

During cell division (mitosis), each chromosome divides into two so that each daughter nucleus has the same number of chromosomes as its parent cell. During gametogenesis, however, the number of chromosomes is halved by meiosis, so that, after conception, the number of chromosomes remains the same and is not doubled. In the female, each ovum contains one or other X chromosome, but in the male, the sperm bears either an X or a Y chromosome.

Chromosomes can only be seen easily in actively dividing cells. Typically, lymphocytes from the peripheral blood are stimulated to divide and are processed to allow the chromosomes to be examined. Cells from other tissues can also be used for chromosomal analysis: for example, amniotic fluid, placental cells from chorionic villus sampling, bone marrow and skin (Box 7.1).

### Box 7.1

**Indications for chromosomal analysis**

Chromosome studies may be indicated in the following circumstances:

**Antenatal**
- Pregnancies in women over 35 years
- Positive maternal serum screening test for aneuploid pregnancy
- Ultrasound features consistent with an aneuploid fetus
- Severe fetal growth retardation
- Sexing of fetus in X-linked disorders

**In the neonate**
- Congenital malformations
- Suspicion of trisomy or monosomy
- Ambiguous genitalia
In the adolescent
• Primary amenorrhoea or failure of pubertal development
• Growth retardation

In the adult
• Screening of parents of a child with a chromosomal abnormality for further genetic counselling
• Infertility or recurrent miscarriages
• Learning difficulties
• Certain malignant disorders (e.g. leukaemias and Wilms' tumour)

The X chromosome and inactivation
Although females have two X chromosomes (XX), they do not have two doses of X-linked genes (compared with just one dose for a male XY) because of the phenomenon of X inactivation or Lyonization (after its discoverer, Dr Mary Lyon). In this process, one of the two X chromosomes in the cells of females is epigenetically (see p. 99) silenced through the action of a regulatory ncRNA, so the cell has only one dose of the X-linked genes. Inactivation is random and can affect either X chromosome.

Telomeres and immortality
The ends of chromosomes, telomeres (see Fig. 7.14D, p. 99), do not contain genes but many repeats of a hexameric sequence, TTAGGG. Replication of linear chromosomes starts at coding sites (origins of replication) within the main body of chromosomes and not at the two extreme ends. The extreme ends are therefore susceptible to single-stranded DNA degradation back to double-stranded DNA. Thus, cellular ageing can be measured as a genetic consequence of multiple rounds of replication, with consequential telomere shortening. This leads to chromosome instability and cell death.

Stem cells have longer telomeres than their terminally differentiated daughters. However, germ cells replicate without shortening of their telomeres. This is because they express an enzyme called telomerase, which protects against telomere shortening by acting as a template primer at the extreme ends of the chromosomes. Most somatic cells (unlike germ and embryonic cells) switch off the activity of telomerase after birth and die as a result of apoptosis. Many cancer cells, however, reactivate telomerase, contributing to their immortality. Conversely, cells from patients with progeria (premature ageing syndrome) have extremely short telomeres. Transient expression of telomerase in various stem and daughter cells is part of their normal biology.

The mitochondrial chromosome
In addition to the 23 pairs of chromosomes in the nucleus of every diploid cell, the
mitochondria in the cytoplasm of the cell also have their own genome. The mitochondrial chromosome is a circular DNA (mtDNA) molecule of approximately 16,500 bp, and every base-pair makes up part of the coding sequence. These genes principally encode proteins or RNA molecules involved in mitochondrial function. These proteins are components of the mitochondrial respiratory chain involved in oxidative phosphorylation, producing ATP. They also have a critical role in apoptotic cell death. Every cell contains several hundred mitochondria, and therefore several hundred mitochondrial chromosomes. Virtually all mitochondria are inherited from the mother, as the sperm head contains no (or very few) mitochondria. Disorders mapped to the mitochondrial chromosome are shown in Figure 7.22 and discussed on pages 111–112.
Genetic Disorders

The spectrum of inherited or congenital genetic disorders can be classified as the chromosomal disorders, including mitochondrial chromosome disorders, the Mendelian and sex-linked single-gene disorders, a variety of non-Mendelian disorders, and the multifactorial and polygenic disorders (Boxes 7.2 and 7.3). All are a result of a mutation in the genetic code. This may be a change of a single base-pair of a gene, resulting in functional change in the product protein (e.g. thalassaemia) or gross rearrangement of the gene within a genome (e.g. chronic myeloid leukaemia). These mutations can be congenital (inherited at birth) or somatic (arising during a person's life).

Box 7.2

Prevalence of genetic disease

Genetic disease

- 0.5% of all newborns have a chromosomal abnormality
- 7% of all stillborns have a chromosomal abnormality
- 20–30% of all infant deaths are due to genetic disorders
- 11% of paediatric hospital admissions are for children with genetic disorders
- 12% of adult hospital admissions are for genetic causes
- 15% of all cancers have an inherited susceptibility
- 10% of chronic diseases of the adult population (heart, diabetes, arthritis) have a significant genetic component

Congenital malformation

- 3–5% of all births result in congenital malformations
- 30–50% of post-neonatal deaths are due to congenital malformations
- 18% of paediatric hospital admissions are for children with congenital malformations

European incidences per 1000 births

Single-gene disorders: 10
  Dominant: 7.0
  Recessive: 1.66
  X-linked: 1.33

Chromosomal disorders: 3.5
  Autosomes: 1.69
  Sex chromosomes: 1.80

Congenital malformations: 31
Genetically determined: 0.6
Multifactorial: 30
Non-genetic: ~0.4

*Although individual genetic diseases are rare, regional variation is enormous; the incidence of Down syndrome varies from 1/1000 to 1/100 worldwide. Single-gene diseases collectively comprise over 15,500 recognized genetic disorders. The global prevalence of all single-gene diseases at birth is approximately 10/1000.

Box 7.3

Genetic disorders

Mendelian
- Inherited or new mutation
- Mutant allele or pair of mutant alleles at single locus
- Clear pattern of inheritance (autosomal or sex-linked) dominant or recessive
- High risk to relatives

Chromosomal
- Loss, gain or abnormal rearrangement of one or more of 46 chromosomes in diploid cells
- No clear pattern of inheritance
- Low risk to relatives

Multifactorial
- Common
- Interaction between genes and environmental factors
- Low risk to relatives

Mitochondrial
- Due to mutations in mitochondrial genome
- Transmitted through maternal line
- Different pattern of inheritance from Mendelian disorders

Somatic cell
- Mutations in somatic cells
- Somatic event is not inherited
- Often give rise to tumours

Chromosomal disorders
Chromosomal abnormalities are much more common than is generally appreciated. Over half of spontaneous abortions have chromosomal abnormalities, compared with only 4–6 abnormalities per 1000 live births. Specific chromosomal abnormalities can lead to well-recognized and severe clinical syndromes, although autosomal aneuploidy (a differing from the normal diploid number) is usually more severe than the sex-chromosome aneuploidies. Abnormalities may occur in either the number or the structure of the chromosomes.

**Abnormal chromosome numbers**

If a chromosome or chromatids fail to separate (‘non-disjunction’) in either meiosis or mitosis, one daughter cell will receive two copies of that chromosome and one daughter cell will receive no copies of the chromosome. If this non-disjunction occurs during meiosis, it can lead to an ovum or sperm having:

- **either an extra chromosome**, so resulting in a fetus that is ‘trisomic’ and has three instead of two copies of the chromosome
- **or no chromosome**, so the fetus is ‘monosomic’ and has one instead of two copies of the chromosome.

Non-disjunction can occur with autosomes or sex chromosomes. However, only individuals with trisomy 13, 18 and 21 survive to birth, and most children with trisomy 13 and trisomy 18 die in early childhood. **Trisomy 21 (Down syndrome)** is observed with a frequency of 1 in 650 live births, regardless of geography or ethnic background. This should be reduced with widespread screening (see p. 116). Full **autosomal monosomies** are extremely rare and very deleterious. **Sex-chromosome trisomies** (e.g. Klinefelter syndrome, XXY) are relatively common. The **sex-chromosome monosomy** in which the individual has an X chromosome only and no second X or Y chromosome (i.e. X0) is known as **Turner's syndrome** and is estimated to occur in 1 in 2500 live-born girls.

Occasionally, non-disjunction can occur during mitosis shortly after two gametes have fused. It will then result in the formation of two cell lines, each with a different chromosome complement; the person is termed a ‘mosaic’ individual.

Very rarely, the entire chromosome set will be present in more than two copies, so the individual may be triploid rather than diploid and have a chromosome number of 69. Triploidy and tetraploidy (four sets) result in spontaneous abortion.

**Abnormal chromosome structures**

As well as abnormal numbers of chromosomes, chromosomes can have abnormal structures, and the disruption to the DNA and gene sequences may give rise to a genetic disease.

- **Deletions** of a portion of a chromosome may give rise to a disease syndrome if two copies of the genes in the deleted region are necessary, and the individual will not be normal with just the one normal copy remaining on the non-deleted homologous chromosome. Many deletion syndromes have been well described. For example, **Prader–Willi syndrome** is the result of cytogenetic events resulting in deletion of part of the long arm of chromosome 15; **Wilms'**
tumour is characterized by deletion of part of the short arm of chromosome 11; and microdeletions in the long arm of chromosome 22 give rise to DiGeorge syndrome (see p. 140)

- **Duplications** occur when a portion of the chromosome is present on the chromosome in two copies, so the genes in that chromosome portion are present in an extra dose. A form of neuropathy, Charcot–Marie–Tooth disease (see p. 886), is due to a small duplication of a region of chromosome 17.

- **Inversions** involve an end-to-end reversal of a segment within a chromosome: for example, ‘abcdefg’ becomes ‘abcfedg’, as in haemophilia (see pp. 571–573).

- **Translocations** occur if two chromosome regions join together, when they would not do so normally. Chromosome translocations in somatic cells may be associated with tumorigenesis (see p. 607 and Fig. 17.21).

  Translocations can be very complex, involving more than two chromosomes, but most are simple and fall into one of two categories:

  - **Reciprocal translocations** occur when any two non-homologous chromosomes break simultaneously and rejoin, swapping ends. In this case, the cell still has 46 chromosomes but two of them are rearranged. Someone with a balanced translocation is likely to be normal (unless a translocation breakpoint interrupts a gene); however, at meiosis, when the chromosomes separate into different daughter cells, the translocated chromosomes will enter the gametes and any resulting fetus may inherit one abnormal chromosome and have an unbalanced translocation, with physical manifestations.

  - **Robertsonian translocations** occur when two acrocentric chromosomes join and the short arm is lost, leaving only 45 chromosomes. This translocation is balanced, as no genetic material is lost and the individual is healthy. However, any offspring have a risk of inheriting an unbalanced arrangement. This risk depends on which acrocentric chromosome is involved. The 14/21 Robertsonian translocation is clinically relevant. A woman with this karyotype has a 1 in 8 risk of having a baby with Down syndrome (a male carrier has a 1 in 50 risk). However, they have a 50% risk of producing a carrier like themselves; hence the necessity for genetic family studies. Relatives should be alerted to the increased risk of Down syndrome in their offspring, and should have their chromosomes checked.

  Box 7.4 shows some of the syndromes resulting from chromosomal abnormalities.

### Mitochondrial chromosome disorders

The mitochondrial chromosome (see Fig. 7.22) carries its genetic information in a very compact form; for example, there are no introns in the genes. Therefore, any mutation has a high chance of having an effect. However, as every cell contains hundreds of mitochondria, a single altered mitochondrial genome will not be noticed. As mitochondria divide, there is a
statistical likelihood that there will be more mutated mitochondria and, at some point, this will give rise to a mitochondrial disease.

Most mitochondrial diseases are myopathies and neuropathies with a maternal pattern of inheritance. Other abnormalities include retinal degeneration, diabetes mellitus and hearing loss. Many syndromes have been described.

**Myopathies** include chronic progressive external ophthalmoplegia (CPEO); encephalomyopathies include myoclonic epilepsy with ragged-red fibres (MERRF) and mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes (MELAS) (see p. 892).

**Kearns–Sayre syndrome** includes ophthalmoplegia, heart block, cerebellar ataxia, deafness and mental deficiency due to long deletions and rearrangements.

**Leber's hereditary optic neuropathy** (LHON) is the most common cause of blindness in young men, with bilateral loss of central vision and cardiac arrhythmias, and is an example of a mitochondrial disease caused by a point mutation in one gene.

**Multisystem disorders** include **Pearson syndrome** (sideroblastic anaemia, pancytopenia, exocrine pancreatic failure, subtotal villous atrophy, diabetes mellitus and renal tubular dysfunction). In some families, hearing loss is the only symptom, and one of the mitochondrial genes implicated may predispose patients to aminoglycoside cytotoxicity.

**Analysis of chromosome disorders**

The cell cycle can be arrested at mitosis with colchicine and, following staining, the chromosomes with their characteristic banding can be seen and any abnormalities identified (**Fig. 7.23**). This is an automated process with computer scanning software searching for metaphase spreads and then automatic binning of each chromosome to allow easy scoring of chromosome number and banding patterns. Another approach utilizes genome-wide array-based platforms (comparative genomic hybridization (CGH) or chromosomal microarray analysis (CMA)) to identify changes in chromosome copy number and can identify very small interstitial deletions and insertions (<1 Mb in size).
Large region-specific probes are labelled with fluorescently tagged nucleotides and used to allow rapid identification of metaphase chromosomes. This approach allows easy identification of chromosomal translocations (Fig. 7.24). Whole genome sequencing is becoming a common method for identifying deletions, insertions and translocation breakpoints.

Gene defects

Mendelian and sex-linked single-gene disorders are the result of mutations in coding sequences and their control elements. These mutations can have various effects on the expression of the gene, as explained below, but all cause a dysfunction of the protein product.

Mutations

Although DNA replication is a very accurate process, occasionally mistakes occur and produce changes or mutations. These changes can also occur because of other factors such as radiation, ultraviolet light or chemicals. Mutations in gene sequences or in the sequences that regulate gene expression (transcription and translation) may alter the amino acid sequence in the protein encoded by that gene. In some cases, protein function will be maintained; in other cases, it will change or cease, perhaps producing a clinical disorder. Many different types of mutation occur.

Point mutation

This is the simplest type of change and involves the substitution of one nucleotide for another, so changing the codon in a coding sequence and leading to an amino acid substitution (non-synonymous). For example, in sickle cell disease, a mutation within the globin gene changes one codon from GAG to GTG so that, instead of glutamic acid, valine is incorporated into the polypeptide chain, which radically alters its properties. However, substitutions may have no effect on the function or stability of the proteins produced, as several codons code for the same amino acid (synonymous).

Insertion or deletion
Insertion or deletion of one or more bases is a more serious change, particularly if the inserted or deleted DNA is not a multiple of three bases, as this will cause the following sequence to be out of frame.

**Splicing mutations**
If the DNA sequences that direct the splicing of introns from mRNA are mutated, then abnormal splicing may occur. In this case, the processed mRNA that is translated into protein by the ribosomes may carry intron sequences or miss exons, so altering amino acid composition.

**Nonsense mutations**
A nonsense mutation is a point mutation in a sequence of DNA that results in a premature stop codon.

**Single-gene disease**
Monogenetic disorders involving single genes can be inherited as dominant, recessive or sex-linked characteristics. Although classically divided into autosomal dominant, recessive or X-linked disorders, many syndromes show multiple forms of inheritance pattern. For example, in **Ehlers–Danlos syndrome**, we find autosomal dominant, recessive and X-linked inheritance. In addition, there is a spectrum between autosomal recessive and autosomal dominance, in that having just one defective allele gives a mild form of the disease (semi-dominant), while having both alleles with the mutation results in a more severe form of the syndrome. In some cases, such as **factor V Leiden disease**, the boundary between dominant and recessive forms is very blurred.

Some monogenetic disorders show a racial or geographical prevalence. For example, **thalassaemia** (see pp. 535–538) is seen mainly in Greeks, South-east Asians and Italians; **porphyria variegata** in the South African white population; and **Tay–Sachs disease** (see p. 1287) in Ashkenazi Jewish people. Thus, although the prevalence of some single-gene diseases is very low worldwide, it is much higher in specific populations.

**Autosomal dominant disorders**
Each diploid cell contains two copies of all the autosomes. An autosomal dominant disorder (**Fig. 7.25A**) occurs when one of the two copies has a mutation and the protein produced by the normal form of the gene cannot compensate. In this case, a heterozygous individual who has two different forms (or alleles) of the same gene will manifest the disease. The offspring of heterozygotes have a 50% chance of inheriting the chromosome carrying the disease allele, and therefore also of having the disease. However, estimation of risk to offspring for counselling families can be difficult because of three factors:

- Some disorders have a great variability in their manifestation. ‘Incomplete penetrance’ may occur if patients have a dominant disorder but it does not manifest itself clinically in them. This gives the appearance of the gene having ‘skipped’ a generation.
- Dominant traits are extremely variable in severity (variable expression) and a mildly affected
parent may have a severely affected child.

• New cases in a previously unaffected family may be the result of a new mutation. In this case, the risk of a further affected child is negligible. Most cases of achondroplasia, for example, are due to new mutations.
Autosomal recessive disorders

These disorders (Fig. 7.25B) manifest themselves only when an individual is homozygous or a compound heterozygote for the disease allele: that is, both chromosomes carry the same gene
mutation (homozygous) or two different mutations in the same gene (compound heterozygote). The parents are unaffected carriers (heterozygous for the disease allele). If carriers marry, the offspring have a 1 in 4 chance of carrying both mutant copies of the gene and being affected, a 1 in 2 chance of being a carrier, and a 1 in 4 chance of being genetically normal. Consanguinity increases the risk.

**Sex-linked disorders**

Genes carried on the X chromosome are said to be ‘X-linked’, and can be dominant or recessive in the same way as autosomal genes (*Fig. 7.25C and D*).

**X-linked dominant disorders**

These are rare. Females who are heterozygous for the mutant gene and males who have one copy of the mutant gene on their single X chromosome will manifest the disease. Half the male or female offspring of an affected mother and all the female offspring of an affected man will have the disease. Affected males tend to have the disease more severely than the heterozygous female.

**X-linked recessive disorders**

These disorders present in males and present only in homozygous females (usually rare). X-linked recessive diseases are transmitted by healthy female carriers or affected males if they survive to reproduce. An example of an X-linked recessive disorder is haemophilia A (see pp. 571–573), which is caused by a mutation in the X-linked gene for factor VIII. It has been shown that in 50% of cases there is an intrachromosomal rearrangement (inversion) of the tip of the long arm of the X chromosome (one breakpoint being within intron 22 of the factor VIII gene).

Of the offspring from a carrier female and a normal male:

- 50% of the girls will be carriers, as they inherit a mutant allele from their mother and the normal allele from their father; the other 50% of the girls inherit two normal alleles and are themselves normal
- 50% of the boys will have haemophilia, as they inherit the mutant allele from their mother (and the Y chromosome from their father); the other 50% of the boys will be normal, as they inherit the normal allele from their mother (and the Y chromosome from their father).

The male offspring of a male with haemophilia and a normal female will not have the disease, as they do not inherit his X chromosome. However, all the female offspring will be carriers, as they all inherit his X chromosome.

**Other single-gene disorders**

These are disorders that may be due to mutations in single genes but which do not manifest as simple monogenic disorders. They can arise from a variety of mechanisms, including the following:
**Triplet repeat mutations**

In the gene responsible for myotonic dystrophy (see p. 891), the mutated allele was found to have an expanded 3’UTR region in which three nucleotides, CTG, were repeated up to about 200 times. In families with myotonic dystrophy, people with the late-onset form of the disease had 20–40 copies of the repeat, but their children and grandchildren who presented with the disease from birth had vast increases in the number of repeats, up to 2000 copies. It is thought that some mechanism during meiosis causes this ‘triplet repeat expansion’ so that the offspring inherit an increased number of triplets. The number of triplets affects mRNA and protein function (Box 7.5). See also page 116 for the phenomenon of ‘anticipation’.

AD, autosomal dominant; AR, autosomal recessive.

**Mitochondrial disease**

As discussed on pages 111–112, various mitochondrial gene mutations can give rise to complex disease syndromes with incomplete penetrance maternal inheritance (see Fig. 7.22).
**Imprinting**

It is known that normal humans need a diploid number of chromosomes of 46. However, the maternal and paternal contributions can be different. The mechanism that regulates the differential expression of two alleles of the same gene is termed *genetic imprinting*.

Imprinting is relevant to human genetic disease because different phenotypes may result, depending on whether the mutant chromosome is maternally or paternally inherited. A deletion of part of the long arm of chromosome 15 (15q11-q13) will give rise to the **Prader–Willi syndrome** (PWS), if it is paternally inherited. A deletion of a similar region of the chromosome gives rise to **Angelman syndrome** (AS) if it is maternally inherited. The affected gene has been identified as ubiquitin (*UBE3A*).

**Complex traits: multifactorial and polygenic inheritance**

Characteristics resulting from a combination of genetic and environmental factors are said to be multifactorial; those involving multiple genes are said to be polygenic. There has been an explosion of genetic discovery about these complex traits with the development of high-throughput genome-wide SNP arrays, which has allowed cost-effective and unbiased screening of large case–control cohorts (in excess of 1000 cases). This has permitted unequivocal identification of SNPs associated with a variety of traits and diseases. For example, over 30 SNPs in immune-related gene loci have been associated with coeliac disease, with over half also associated with other immune-mediated or inflammatory diseases. This indicates that there are many low-risk genetic risk factors associated with complex traits, and common pathways are implicated in different diseases.

Most human diseases, such as heart disease, diabetes and common mental disorders, are multifactorial traits *(Box 7.6)*.

---

**Box 7.6**

**Examples of disorders that may have a polygenic inheritance**
Population Genetics

The genetic constitution of a population depends on many factors. The **Hardy–Weinberg equilibrium** is a concept, based on a mathematical equation, that describes the outcome of random mating within populations. It states that ‘in the absence of mutation, non-random mating, selection and genetic drift, the genetic constitution of the population remains the same from one generation to the next’.

This genetic principle has clinical significance in terms of the number of abnormal genes in the total gene pool of a population. The Hardy–Weinberg equation states that:

\[ p^2 + 2pq + q^2 = 1 \]

where \( p \) is the frequency of the normal gene in the population, \( q \) is the frequency of the abnormal gene, \( p^2 \) is the frequency of the normal homozygote, \( q^2 \) is the frequency of the affected abnormal homozygote, \( 2pq \) is the carrier frequency, and \( p + q = 1 \)

**Example:** The equation can be used, for example, to find the frequency of heterozygous carriers in cystic fibrosis. The incidence of cystic fibrosis is 1 in 2000 live births. Thus \( q^2 = 1/2000 \), and therefore \( q = 1/44 \). Since \( p = 1 - q \), then \( p = 43/44 \). The carrier frequency is represented by \( 2pq \), which in this case is \( 1/22 \). Thus 1 in 22 individuals in the whole population is a heterozygous carrier for cystic fibrosis.

**Further reading**

Clinical Genetics and Genetic Counselling

Genetic disorders pose considerable health and economic problems because often there is no
effective therapy. In any pregnancy, the risk of a serious developmental abnormality is approximately 1 in 50 pregnancies; approximately 15% of paediatric inpatients have a multifactorial disorder with a predominantly genetic element. In addition, 50% of clinical genetics referrals are adults with late-onset disease, including neurological, endocrine, gastrointestinal or cancer.

People with a history of a congenital abnormality in a member of their family often seek advice as to why it happened and about the risks of producing further abnormal offspring. Interviews must be conducted with great sensitivity and psychological insight, as parents may feel a sense of guilt and blame themselves for the abnormality in their child.

Genetic counselling should have the following aims:

• **Obtaining a full history.** The pregnancy history, drug and alcohol ingestion during pregnancy, and maternal illnesses (e.g. diabetes) should be detailed.

• **Establishing an accurate diagnosis.** Examination of the child may help in diagnosing a genetically abnormal child with characteristic features (e.g. trisomy 21) or ascertaining whether a genetically normal fetus was damaged *in utero*.

• **Drawing a family tree.** This is essential. Questions should be asked about abortions, stillbirths, deaths, marriages, consanguinity, and medical history of family members. Diagnoses may need verification from other hospital reports.

• **Estimating the risk of a future pregnancy being affected or carrying a disorder.** Estimation of risk should be based on the pattern of inheritance. Mendelian disorders (see p. 113) carry a high risk; chromosomal abnormalities other than translocations typically carry a low risk. Empirical risks may be obtained from population or family studies.

• **Information giving.** Information on prognosis and management should be supplied, with adequate time allowed for it to be discussed openly and freely, and repeated as necessary.

• **Continued support and follow-up.** Explanation should be provided of the implications for other siblings and family members.

• **Genetic screening.** This includes prenatal diagnosis or pre-implantation genetic diagnosis (*in vitro* fertilization followed by testing of embryos before implantation) if requested, carrier detection and data storage in genetic registers. A large number of molecular genetic tests are available.

• **The near future?** With the development of cheap, high-throughput sequencing, couples could be tested for all genetic variations in their genome (termed ‘exome’ sequencing for all coding genes, or whole-genome sequencing for all coding *and* non-coding genomic DNA), prior to starting a family, to assess whether they are carriers of recessive mutations in the same disease-associated gene. This information could then be used in prenatal diagnosis.

Genetic counselling should be non-directive, with the couple making their own decisions on the basis of an accurate presentation of the facts and risks in a way they can understand.

**Genetic anticipation**
It has been noted that successive generations of people with, for example, dystrophia myotonica or Huntington's chorea, present earlier and with progressively worse symptoms. This ‘anticipation’ is due to unstable mutations occurring within the disease gene. Trinucleotide repeats, such as CTG (dystrophia myotonica) and CAG (Huntington's chorea), expand within the disease gene with each generation, and somatic expansion with cellular replication is also observed. This type of genetic mutation can occur within the translated region or untranslated (and presumably regulatory) regions of the target genes. This genetic distinction has been used to subclassify a number of genetic diseases that have now been shown to be caused by trinucleotide repeat expansion and display phenotypic ‘anticipation’ (see Box 7.5).

**Prenatal diagnosis for chromosomal disorders**

This should be offered to all pregnant women. Practice and uptake vary in different maternity units, with some offering screening only to high-risk mothers. The risks of Down syndrome increase disproportionately and rapidly for children born to mothers older than 35 years. Infants born to mothers with a history or family history of other conditions due to chromosomal abnormalities may be at increased risk.

**Personal choice**

There should be a detailed discussion with all mothers as to the possible consequences of each screening test before they are offered it. In particular, they should have an understanding of the failure rates, the detection rates, and the false positive and the false negative rates of each test so that they can properly exercise choice.

**Investigations**

The choice of investigation depends on gestational age:

**7–11 weeks (vaginal ultrasound)**

Ultrasound is used to confirm viability, fetal number and gestation by crown–rump measurement.

**11–13 weeks and 6 days (combined test)**

The combined test comprises:

- ultrasound for nuchal translucency measurement (normal fold <6 mm) to attempt to detect major chromosomal abnormalities (e.g. trisomies and Turner syndrome)
- testing of maternal serum for pregnancy-associated plasma protein-A (PAPP-A from the syncytial trophoblast) and β-human chorionic gonadotrophin for trisomy 21.

All serum marker measurements are corrected for gestational ages, a multiple of the mean (MOM) value for the appropriate week of gestation. If abnormalities are detected, it is necessary to continue to discuss whether further investigation is desired or not. Chorionic
villus sampling (CVS) at 11–13 weeks under ultrasound control to sample the placental site, or amniocentesis at 15 weeks to sample amniotic fluid and obtain the fetal cells necessary for cytogenetic testing, is the next option. The combined test is more accurate than the triple test alone at 16 weeks (see below).

14–20 weeks (serum triple or quadruple test)
A serum triple or quadruple test is done if the pregnancy is too advanced for the earlier tests or if the combined test was not offered.

The triple test for chromosomal abnormalities consists of testing maternal serum for:
- α-fetoprotein (low)
- unconjugated oestradiol (low)
- human chorionic gonadotrophin (high) for Down syndrome and for neural tube defects.
  
The α-fetoprotein is high for neural tube defects.
  The quadruple test also measures inhibin A – high in Down syndrome.

14–22 weeks
Ultrasound detects structural abnormalities (e.g. neural tube defects; the gestation period for detection depends on severity). The best time to detect congenital heart defects is 18–22 weeks.

Reported detection rates for all congenital defects vary: for example, from 14–61% for hypoplastic ventricle to 97–100% for anencephaly.

In time, some of these tests are likely to be superseded by salvage of fetal cells from the maternal blood or cervical secretions, or by retrieval of maternal plasma cell free fetal DNA. Other conditions, such as myotonic dystrophy and Huntington's chorea, may be detected from fetal circulating nucleic acids.

Genomic Medicine
Gene therapy
Some genetic disorders, such as phenylketonuria or haemophilia, can be managed by diet or
replacement therapy, but most have no effective treatment. One approach to managing inherited genetic disease entails placing a normal copy of a gene into the cells of a patient who has a defective copy of the gene; this is termed gene therapy.

There are many technical problems to overcome in gene therapy, particularly in finding delivery systems to introduce DNA into a mammalian cell. Very careful control and supervision of gene manipulation will be necessary because of its potential hazards and the ethical issues.

Two major factors are involved in gene therapy:
• the introduction of the functional gene sequence into target cells
• the expression and permanent integration of the transfected gene into the host cell genome.

**Cystic fibrosis**

CFTR, the cystic fibrosis transmembrane regulator (see also p. 1088), is an unusual ABC transporter in that it does not function as a primary active transporter but as a ligand-gated chloride channel *(Fig. 7.26)*. The common CF mutation is a 3 bp deletion in exon 10 that results in the removal of a codon specifying phenylalanine (F508del). In this mutation, the CFTR protein is misfolded, thereby causing ineffective biosynthesis and consequently disrupting the delivery of the protein to the cell surface. In the mutation G551 D-CFTR, glycine in position 551 is replaced by aspartate; the CFTR channel reaches the cell surface but fails to open. This has introduced a new era of treatment. VX-770, a potentiating agent that can be given orally, has been developed. It increases the fraction of time for which the phosphorylated G551 D-CFTR channel is open, allowing bicarbonate and chloride flow across the membrane. Early clinical results are encouraging.

---

**FIGURE 7.26** Model of cystic fibrosis transmembrane regulator (CFTR). This is an integral membrane glycoprotein, consisting of two repeated elements. The cylindrical structures represent six membrane-spanning helices in each half of the molecule. The nucleotide-binding folds (NBFs) are in the cytoplasm. The regulatory (R) domain links the two halves and contains charged individual amino acids and protein kinase phosphorylation sites (black triangles). N and C are the amino and carboxy termini of the protein, respectively. The branched structure top right represents potential glycosylation sites.

There are also over 1000 different mutations of the *CFTR* gene, many of which map to the ATP-binding domains. Two other routes of gene therapy have been tried, placing the wild-type
CFTR complementary DNA (cDNA) either into an adenovirus vector to allow infection of human cells, or into a plasmid (an engineered circle of DNA) that is then encapsulated into a liposome to allow transfection of human cells. The latter can be conveyed via an aerosol spray to the lung, where the liposome fuses with the cell membrane to deliver the CFTR cDNA into the cell. However, neither of these methods is a treatment option yet. An alternative method is to suppress premature termination codons and thus permit translation to continue; topical nasal gentamicin (an aminoglycoside antibiotic) has been shown to result in the expression of functional CFTR channels.

**Adenosine deaminase (ADA) deficiency**

Successful gene therapy for this rare immunodeficiency disease has entailed introducing a normal human ADA gene into the patient's lymphocytes to reconstitute the function of the cellular and humoral immune system in severe combined immunodeficiency (SCID).

**Pharmacogenomics**

This is the study of individual SNPs that determine drug behaviour to explain why some patients give a variable response to the particular drug. The potential of pharmacogenomic approaches is usually related to single-gene traits that affect drug metabolism: for example, SNPs in the gene encoding thiopurine-S-methyl-transferase (TPMT), which metabolizes immunosuppressant drugs (e.g. azathioprine). Patient-specific therapies based on their genetic profile will lead to the development of drugs (or drug combinations).

**Stem cell therapy**

Stem cell therapy has the potential to change the treatment of human disease radically (see pp. 105–106). A number of adult stem cell therapies already exist, particularly bone marrow transplants. It is currently anticipated that technologies derived from stem cell research can be used to treat a wider variety of diseases in which replacement of destroyed specialist tissues is required, such as in Parkinson's disease, spinal cord injuries and muscle damage.

**Ethical considerations**

Ethical considerations must be taken into account in any discussion of clinical genetics. For example, prenatal diagnosis with the option of termination may be unacceptable on moral or religious grounds. With diseases for which there is no cure and currently no treatment (e.g. Huntington's chorea), genetic tests can accurately predict which family members will be affected; however, many people would rather not have this information. One very serious outcome of the new genetic information is that disease susceptibility may be predictable – for example, in Alzheimer's disease – so the medical insurance companies can decline to issue policies for individuals at high risk. Society has not decided who should have access to an individual's genetic information and to what extent privacy should be preserved.

**Further reading**
Cancers are genetic diseases and involve changes to the normal function of cellular genes. However, multiple genes interact during oncogenesis and an almost stepwise progression of defects leads from an over-proliferation of a particular cell to the breakdown of control mechanisms such as apoptosis (programmed cell death). This would be triggered if a cell were to attempt to survive in an organ other than its tissue of origin. For the vast majority of cancer cases (especially those in older people), the multiple genetic changes that occur are somatic. For some cancers, however (where the cancer normally occurs at an earlier age), a dominant inherited single-gene defect can give rise to an almost Mendelian trend with lifetime risks of nearly 90%.

### Autosomal dominant inheritance

The following are examples of cancer syndromes (see Box 17.2, p. 588) that exhibit dominant inheritance:

- **Retinoblastoma.** This is an eye tumour found in young children. It occurs in both hereditary (40%) and non-hereditary (60%) forms. In the hereditary form, there is a germline mutation in the retinoblastoma gene (RB1) and people are also at risk for developing other tumours, particularly osteosarcoma.

- **Breast and ovarian cancer.** Two major genes have been identified – BRCA1 and BRCA2. A strong family history along with germline mutation of these genes accounts for most cases of familial breast cancer and over half of familial ovarian cancers. BRCA1 and 2 proteins bind to the DNA repair enzyme Rad51 to make it functional in repairing DNA breaks. Mutations in the BRCA genes will lead to accumulation of unrepaired mutations in tumour suppressor genes and crucial oncogenes.

- **Neurofibromatosis.** Inactivation of the NF1 gene will lead to constitutive activation of Ras proteins.

- **Multiple endocrine adenomatosis syndromes** (see pp. 1239–1240). Multiple endocrine neoplasia type 1 is associated with the MEN1 gene, and type 2 (MEN2) is associated with mutations in the RET proto-oncogene on chromosome 10; as such, these diseases are the exception to all the other syndromes that involve tumour suppressor genes.
Autosomal recessive inheritance

Some relatively rare autosomal recessive diseases associated with abnormalities of DNA repair predispose to the development of cancer:

- **Xeroderma pigmentosum.** There is an inability to repair DNA damage caused by ultraviolet light and by some chemicals, leading to a high incidence of skin cancer.

- **Ataxia telangiectasia.** Mutation results in an increased sensitivity to ionizing radiation and an increased incidence of lymphoid tumours.

- **Bloom syndrome and Fanconi’s anaemia.** An increased susceptibility to lymphoid malignancy is seen.

Oncogenes

The genes coding for growth factors, growth factor receptors, secondary messengers or even DNA-binding proteins would act as promoters of abnormal cell growth if mutated. This concept was verified when viruses were found to carry genes that, when integrated into the host cell, promoted oncogenesis. These were originally termed viral or ‘v-oncogenes’; later, their normal cellular counterparts, c-oncogenes, were found. Thus, oncogenes encode proteins that are known to participate in the regulation of normal cellular proliferation: for example, erb-A on chromosome 17q11-q12 encodes for the thyroid hormone receptor.

Activation of oncogenes

Non-activated oncogenes, which are functioning normally, have been referred to as ‘proto-oncogenes’ *(Box 7.7)*. Their transformation to oncogenes can occur by three routes: mutation, chromosomal translocation and viral stimulation.

---

### Box 7.7
Examples of acquired/somatic mutations and proto-oncogenes

#### Point mutation
- **K-RAS:** Colorectal and pancreatic cancer
- **B-RAF:** Melanoma, thyroid
- **ALK:** Lung cancer

#### DNA amplification
- **MYC:** Neuroblastoma
- **HER2-neu:** Breast cancer

#### Chromosome translocation
- **BCR/ABL:** Chronic myeloid leukaemia, acute lymphoblastic leukaemia
• **PML/RARA**: Acute promyelocytic leukaemia  
• **BCL2/IGH**: Follicular lymphoma  
• **IGH/CCND1**: Mantle cell lymphoma  
• **MYC/IgH**: Burkitt's lymphoma

**Mutation**

Carcinogens, such as those found in cigarette smoke, ionizing radiation and ultraviolet light, can cause point mutations in genomic DNA encoding tumour suppressor genes or oncogenes.

**Chromosomal translocation**

If an error occurs during cell division and two chromosomes translocate, so that a portion swaps over, the translocation breakpoint may occur in the middle of two genes. If this happens, then the end of one gene is translocated on to the beginning of another gene, giving rise to a ‘fusion gene’. Therefore, sequences of one part of the fusion gene are inappropriately expressed because they are under the control of the other part of the gene.

An example of such a fusion gene (the Philadelphia chromosome) occurs in **chronic myeloid leukaemia** (see pp. 612–613). Similarly in **Burkitt's lymphoma** (see p. 623), a translocation causes the regulatory segment of the **myc** oncogene to be replaced by a regulatory segment of an unrelated immunoglobulin.

**Viral stimulation**

When viral RNA is transcribed by reverse transcriptase into viral cDNA and in turn is spliced into the cellular DNA, the viral DNA may integrate within an oncogene and activate it. Alternatively, the virus may pick up cellular oncogene DNA and incorporate it into its own viral genome. Subsequent infection of another host cell might result in expression of this viral oncogene. For example, the Rous sarcoma virus of chickens was found to induce cancer because it carried the **ras** oncogene.

After the initial activation event, other changes occur within the DNA. A striking example of this is amplification of gene sequences, which can affect the **myc** gene, for example. Instead of the normal two copies of a gene, multiple copies of the gene appear either within the chromosomes (these can be seen on stained chromosomes as homogeneously staining regions) or as extrachromosomal particles (double minutes). **N-myC** sequences are amplified in neuroblastomas, as are **N-myC** or **L-myC** in some lung small-cell carcinomas.

**Tumour suppressor genes**

These genes restrict undue cell proliferation (in contrast to oncogenes), and induce the repair or self-destruction (apoptosis) of cells containing damaged DNA. Therefore, mutations in these genes, which disable their function, lead to uncontrolled cell growth in cells with active oncogenes. An example is the germline mutations in genes found in non-polyposis colorectal cancer, which are responsible for repairing DNA mismatches (see p. 422).
The **RB gene** was the first tumour suppressor gene to be described (see p. 588). In the familial variety, the first mutation is inherited and, by chance, a second somatic mutation occurs with the formation of a tumour. In the sporadic variety, by chance, both mutations occur in both of the RB genes in a single cell.

Since the finding of RB, other tumour suppressor genes have been described, including the **gene p53**. Mutations in p53 have been found in almost all human tumours, including sporadic colorectal carcinomas, carcinomas of breast and lung, brain tumours, osteosarcomas and leukaemias. The protein encoded by p53 is a cellular 53 kDa nuclear phosphoprotein that plays a role in DNA repair and synthesis, in the control of the cell cycle, cell differentiation and programmed cell death – apoptosis. p53 is a DNA-binding protein that activates many gene expression pathways but it is normally only short-lived. In many tumours, mutations that disable p53 function also prevent its cellular catabolism. Although in some cancers there is a loss of p53 from both chromosomes, in most cancers (particularly colorectal carcinomas; see Fig. 17.2) such long-lived mutant p53 alleles can disrupt the normal alleles' protein. As a DNA-binding protein, p53 is likely to act as a tetramer.

Thus, a mutation in a single copy of the gene can promote tumour formation because a hetero-tetramer of mutated and normal p53 subunits would still be dysfunctional. p53 and RB are involved in normal regulation of the cell cycle. Other cancer-associated genes are also intimately involved in control of the cell cycle (see Fig. 7.16).

Anatomy and Principles of the Immune System

Immunity can be defined as protection from infection, whether bacterial, viral, fungal or due to multicellular parasites. The immune system is composed of cells and molecules organized into specialized tissues (Fig. 8.1).
Lymphocytes are generated as precursors in the bone marrow and differentiate into T (thymus) or B (bone marrow) lymphocytes in the primary lymphoid tissue. Once differentiated, 98% of lymphocytes reside in the secondary lymphoid tissue where the adaptive immune response takes place.

The primary lymphoid organs (thymus and bone marrow) are where the cells originate. Cells and molecules of the immune system circulate in the blood; immune responses do not take place there but are at the site of infection (typically the mucosa or skin). They are then propagated and refined in the secondary lymphoid organs (e.g. lymph nodes). Following resolution of the infection, immunological memory specific for the pathogen is generated and resides in cells (lymphocytes) in the spleen and lymph nodes, as well as being widely secreted in a molecular form (antibodies). Secondary lymphoid organs also include adenoids, tonsils, spleen, Peyer's patches in the small intestine, lymphoids (cervical, axillary, inguinal) and thoracic duct.

Cells involved in immune responses: origin and function

All immune cells derive from pluripotent stem cells generated in the bone marrow. They have diverse functions (Box 8.1). T lymphocytes undergo ‘education’ in the thymus to avoid self-
recognition, and populate the peripheral lymphoid tissue, where B lymphocytes also reside. Both sets of lymphocytes undergo activation in the peripheral tissue, to become mature effector cells. B lymphocytes may further differentiate into antibody-secreting plasma cells. Lymphoid tissue is frequently found at mucosal surfaces in non-encapsulated patches, termed **mucosa-associated lymphoid tissue** (MALT).

### The immune system

Cells and molecules involved in immune responses are classified into innate and adaptive systems:

- **The innate immune system** is inborn and operates throughout life (pp. 123–128).
- **The adaptive immune system** changes in response to the pathogens it encounters (pp. 128–132).

There are also non-immunological barriers that are involved in host protection, and lowering of these may allow a pathogen to gain a foothold (**Box 8.2**).
The immune system is immensely powerful, in terms of its ability to inflame, damage and kill, and it has a capacity to recognize a myriad of molecular patterns in the microbial world. However, immune responses are not always beneficial. They can give rise to a range of autoimmune and inflammatory diseases, known as **immunopathologies**. Conversely, the immune system may fail, giving rise to immune deficiency states. These conditions are grouped under the umbrella of clinical immunology.

A major feature of the immune system is the complexity of its surface-bound, intracellular and soluble mediators. In particular, it is necessary to be aware of the clusters of differentiation (CD) classification (Box 8.3) and the functions of cytokines and chemokines. The CD classification is the ultimate way of defining a cell.

### Box 8.3

**The CD classification**

- Immune cells are distinguished by the surface receptors and proteins that they express in order to mediate their particular range of immunological functions, e.g. cell–cell signalling, cell activation.
- The surfaces are covered with such proteins and indicate the cell lineage or differentiation pathway. The discovery of monoclonal antibodies (proteins tailor-made to bind to a specific target) made this feasible.
- Surface molecules defining the origin and function of selected groups of cells are known as clusters of differentiation (CD). Over 360 CD numbers exist.
- A clinical example is the number of peripheral blood lymphocytes expressing CD4 (‘the
CD4 count’), which is used to monitor human immunodeficiency virus (HIV) infection (see p. 339)
An updated listing is available at: http://www.hcdm.org/.

Cytokines

These are small polypeptides released by a cell in order to change the function of the same or another cell. These chemical messengers are found in many organ systems, but especially the immune system. Cytokines have become markers in the investigation of disease pathogenesis; they are also therapeutic agents in their own right, and the targets of therapeutic agents (see pp. 146–147). The key features of a cytokine are:

• **pleiotropy**: has different effects on different cells
• **autocrine function**: modulates the cell secreting it
• **paracrine function**: modulates adjacent cells
• **endocrine effects**: modulates cells and organs at remote sites
• **synergistic activity**: acts in concert with other cytokines to achieve effects greater than the summation of their individual actions.

The main immune cytokines are the **interferons** (IFNs) and the **interleukins** (ILs). The IFNs are limited to a few major types (α, β and γ), whereas there are 38 interleukins.

Chemokines

The defining feature of chemokines is their function as chemotactic molecules: that is, they attract cells along a gradient of low to high chemical concentration, particularly from the blood into the tissues, and tissues into lymphatics. They also have the ability to activate immune cells. All chemokines have a similar structure relating to the configuration of cysteine residues, which gives rise to four families *(Box 8.4)*.

R, receptor.

Cell-surface receptors for chemokines are denoted by ‘R’. CCR5 is a co-receptor for human immunodeficiency virus (HIV; see pp. 333–334) and drugs to block this and other chemokine receptors are under active development to combat inflammation and cancer (by promoting migration of immune cells into tumours).

**Innate Immune System**

**Innate immunity** provides immediate, first-line host defence. The key features of this system (as well as the adaptive system, p. 128) are shown in *Box 8.5*. It is present at birth and remains operative at comparable intensity into old age. Innate immunity is mediated by a variety of cells and molecules (*Box 8.6*). Activation of innate immune responses is mediated through interaction between the:

- pathogen side, comprising a relatively limited array of molecules (pathogen-associated molecular patterns, PAMPs)
- host side, a limited portfolio of receptors (pattern recognition receptors, PRRs).

\(^a\)Opsonize = coat bacteria to enhance phagocytosis by granulocytes and monocytes/macrophages.

\(^b\)C-reactive protein (CRP) is an acute phase protein. Blood level rises 10–100-fold within hours of the start of an infective or inflammatory process, making it extremely useful in monitoring infective or inflammatory diseases, and their response to treatment.

Activation of certain cells in the innate immune system leads to activation of the adaptive immune response (see p. 128).

The dendritic cell is especially involved in this process, and forms a bridge between innate and adaptive systems.

Complement

Complement proteins are produced in the liver and circulate in an inactive form. When triggered, complement molecules become enzymatically active and trigger several molecules of the next stage in a series. This complement cascade is initiated via three distinct pathways: alternative, classical and mannose-binding lectin (Fig. 8.2). Each pathway culminates in the cleavage of C3 and C5. Cleavage of C3 has a number of biological consequences; breakdown of C5 achieves the same and, in addition, provides the triggering stimulus to the final common (‘membrane attack’) pathway, which provides most of the biological activity (Fig. 8.2).
The main functions of complement activation are to:

- promote inflammation (e.g. through the actions of the anaphylatoxins C3a, C4a and C5a)
- recruit cells (e.g. through chemoattractants)
- kill targeted cells, such as bacteria
- solubilize antigen–antibody (‘immune’) complexes and remove them from the circulation.

During an immune response, removal of immune complexes protects unaffected tissues from the deposition of these large, insoluble composites, which could result in unwanted inflammation. Failure of this protective mechanism can result in immunopathology: for example, in the joints, kidney and eye.

**Neutrophils**

Neutrophils (see pp. 562–563) phagocytose and kill microorganisms by releasing antimicrobial compounds (e.g. defensins). They are derived from the bone marrow, which can produce between $10^{11}$ (healthy state) and $10^{12}$ (during infection) new cells per day. In health, neutrophils are rarely seen in the tissues.
Neutrophil phagocytosis is activated by interaction with bacteria, either directly or after bacteria have been coated (opsonized) to make them more ingestible (Fig. 8.3). The contents of neutrophil granules are released both intracellularly (predominantly azurophilic granules) and extracellularly (specific granules) following fusion with the plasma membrane. Approximately 100 different molecules in neutrophil granules (Box 8.7) kill and digest microorganisms, for example:

- **Myeloperoxidase and cytochrome b<sub>558</sub>** are key components of major oxygen-dependent bactericidal systems.
- **Cathepsins, proteinase-3 and elastase** are deadly to Gram-positive and Gram-negative organisms, as well as some *Candida* species.
- **Defensins** are naturally occurring cysteine-rich antibacterial and antifungal polypeptides (29–35 amino acids).
- **Collagenase and elastase** break down fibrous structures in the extracellular matrix, facilitating progress of the neutrophil through the tissues.
FIGURE 8.3 Opsonization. Bacteria are coated with a variety of soluble factors from the innate immune system (opsonins), which enhance phagocytosis. This leads to engulfment of the bacteria into phagosomes and fusion with granules to release antibacterial agents.

Box 8.7
Contents and function of key neutrophil granules
Granule release is initiated by the products of bacterial cell walls, certain complement proteins, leukotrienes (LTB₄) and chemokines (e.g. CXCL8), and cytokines such as tumour necrosis factor-alpha (TNF-α).

Eosinophils

Eosinophils release pro-inflammatory mediators to provide immunity against parasites. In contrast to neutrophils, several hundred times more eosinophils are present in the tissues than in the blood, particularly at epithelial surfaces, where they survive for several weeks. The main role of eosinophils is protection against multicellular parasites such as worms (helminths). This is achieved by the release of pro-inflammatory mediators, which are toxic, cationic proteins. In populations and societies in which such parasites are rare, eosinophils contribute mainly to allergic disease, particularly asthma (see p. 1094). Eosinophils have two types of granules:

- **Specific granules** (95%) contain the cationic proteins, of which there are four main types: *major basic protein (MBP), eosinophil cationic protein (ECP)* and *eosinophil neurotoxin*, which are all potently toxic to helminths, and *eosinophil peroxidase*, similar to neutrophil myeloperoxidase.

- **Primary granules** (5%) synthesize and release *leukotrienes C₄ and D₄* and *platelet-activating factor* (PAF), which alter airway smooth muscle and vasculature (see p. 1095).

Eosinophils are activated and recruited by a variety of mediators via specific surface receptors, including complement factors and LTB₄. In addition, the chemokines eotaxin-1 (CCL11) and eotaxin-2 (CCL24) are highly selective in eosinophil recruitment. There are surface receptors for the cytokines IL-3 and IL-5, which promote the development and differentiation of eosinophils.

Mast cells and basophils

Mast cells release pro-inflammatory and vasoactive mediators, and have a role in allergy.
Mast cells and basophils share features in common, especially in containing:
- histamine-containing granules
- high-affinity receptors for immunoglobulin E (IgE, an antibody type that is involved in allergic disease; see pp. 142–144).

Mast cells are found in tissues (especially skin and mucosae) and basophils in the blood. Both mast cells and basophils release pro-inflammatory mediators, which are either pre-formed or synthesized de novo (Box 8.8).

**Histamine** is a low-molecular-weight amine (111 Da) with a blood half-life of less than 5 minutes; it constitutes 10% of the mast cell's weight. When injected into the skin, histamine induces the typical ‘weal and flare’ or ‘triple’ response: reddening (erythema) due to increased blood flow, swelling (weal) due to increased vascular permeability, and distal vascular changes (flare) due to effects on local axons.

The *complement-derived anaphylatoxins* C3a, C4a and C5a activate basophils and mast cells, as does IgE. The mast cell also has a role in the early response to bacteria through release of TNF-α, in cell recruitment to inflammatory sites such as arthritic joints, in promotion of tumour growth by enhancing neovascularization and in allograft tolerance.

### Monocytes and macrophages

Monocytes (in blood) and macrophages (in tissue) ingest and kill bacteria, release pro-inflammatory molecules, present antigen to T lymphocytes, and are necessary in immunity to
intracellular pathogens such as mycobacteria.

Cells of the monocyte/macrophage lineage are highly sophisticated phagocytes. *Monocytes* are the blood form of a cell that spends a few days in the circulation before entering into the tissues to differentiate into *macrophages*, and possibly some types of dendritic cells.

**Blood monocytes**

Blood monocytes can be divided into subsets according to expression of CD14 (a receptor for lipopolysaccharide, a bacterial cell wall component) and CD16 (a receptor for IgG antibodies). *In vitro*, monocytes have the potential to differentiate into myeloid dendritic cells (after culture with IL-4 and granulocyte-monocyte colony stimulating factor, GM-CSF) and into macrophages, which may exist in specialized forms (e.g. alveolar and gut macrophages and osteoclasts).

**Tissue macrophages**

A key role of tissue macrophages is the maintenance of tissue homeostasis, through clearance of cellular debris, especially following infection or inflammation. They are responsive to a range of pro-inflammatory stimuli, using their pattern recognition receptors (PRRs) to recognize pathogen-associated molecular patterns (PAMPs). Once activated, they engulf and kill microorganisms, especially bacteria and fungi. In doing so, they release a range of pro-inflammatory cytokines and have the capacity to present fragments of the microorganisms to T lymphocytes (see below) in a process called *antigen presentation*. Evidence suggests that evolutionarily conserved molecular patterns in mitochondria (organelles that originally were derived from bacteria) can also activate monocytes. These damage-associated molecular patterns (DAMPs) could play a major role in the systemic inflammatory response that follows extensive tissue damage (e.g. following ischaemic injury).

It has been observed that some PAMPs induce the cytoplasmic assembly of large oligomeric structures of PRRs termed *inflammasomes*. There are numerous examples: members of the Nod-like receptor (NLR) family can be activated by stimuli such as viruses, bacterial toxins and, interestingly, crystallized endogenous molecules, including urate. Inflammasomes have potent effects in activating caspases, leading to processing and secretion of pro-inflammatory cytokines such as IL-1β and IL-18.

Macrophages have pro-inflammatory and microbicidal capabilities similar to those of neutrophils. Under activation conditions, antigen presentation (see p. 135) is enhanced and a range of cytokines secreted, notably TNF-α, IL-1 and IFN-γ. These are necessary for the removal of certain pathogens that live within mononuclear phagocytes (e.g. mycobacteria). Macrophages and related cells may also undergo a process termed *autophagy* (see p. 104). This self-cannibalization is a critical property of many cell types under starvation conditions, but is used by the immune system to destroy intracellular pathogens such as *Mycobacterium tuberculosis*, which otherwise persist within cells and block normal antibacterial processes. Autophagy is also a means of enhancing antigen presentation pathways. Dysregulation of the autophagic pathway has been associated with a number of diseases including cancer,
inflammatory disease and infections.

Tissue macrophages involved in chronic inflammatory foci may undergo terminal differentiation into multinucleated giant cells, typically found at the site of the granulomata characteristic of tuberculosis and sarcoidosis (see pp. 1118–1120).

**Dendritic cells**

The major function of dendritic cells (DCs) is activation of naive T lymphocytes to initiate adaptive immune responses (see p. 127); they are the only cells capable of this. The definition of a dendritic cell is one that has:

• dendritic morphology *(Fig. 8.4)*

![Figure 8.4](image)

**FIGURE 8.4** Mature dendritic cell. The cell ingests pathogens, migrates to lymph nodes and presents pathogen-derived antigen to T lymphocytes to enable adaptive immunity.

• machinery for sensing pathogens

• the ability to process and present antigens to CD4 and CD8 T lymphocytes, coupled with the ability to activate these T lymphocytes from a naive state

• the ability to dictate the T lymphocyte's future function and differentiation.

This is a powerful cell type that functions as a critical bridge between the innate and adaptive immune systems.

**Types of dendritic cell**

The major types are the **myeloid DC (mDC)**, the **plasmacytoid DC (pDC)** and a variety of specialized DCs found in tissues that resemble mDCs (e.g. the Langerhans cell in the skin; see **Fig. 31.1**). DCs have several distinctive cell surface molecules, some of which have pathogen-sensing activity (e.g. the antigen uptake receptor DEC205 on mDCs) whilst others are involved in interaction with T lymphocytes *(Box 8.9)*. Immature mDCs and pDCs are present in the blood, but at very low levels (<0.5% of lymphocyte/monocyte cells).

Pathogen sensing is a key component of the function of immature DCs, as well as monocytes/macrophages, and is achieved through expression of a limited array of specialized PRR molecules capable of binding to structures common to pathogens, aided by long cell dendrites and pinocytosis (constant ingestion of soluble material).

PRRs include:

- **Mannose-binding lectin**, which initiates complement activity, inducing opsonization (see p. 124).
- **Signalling receptors**, such as the PRR known as toll-like receptor 4 (TLR4), which binds lipopolysaccharide, a molecular pattern found in the cell walls of many Gram-negative bacteria (*Box 8.10*). Other TLRs bind double-stranded and single-stranded RNA from viruses and other non-self antigens. Innate immunity critically depends on toll-like receptor signalling. These receptors act through a key adaptor molecule, myeloid differentiation factor 88 (MyD88), to regulate the activity of nuclear factor kappa B (NF-κB) pathways. Some anti-inflammatory pathways (such as transforming growth factor-beta, TGF-β) specifically inhibit MyD88 to limit immune-mediated damage.

mDC, myeloid dendritic cell; pDC, plasmacytoid dendritic cell.

- **Endocytic pattern recognition receptors**, which act by enhancing antigen presentation on
macrophages, by recognizing microorganisms with mannose-rich carbohydrates on their surface, or by binding to bacterial cell walls and scavenging bacteria from the circulation. All lead to *phagocytosis*.

- **TREM-1** (triggering receptor expressed on myeloid cells), a cell surface receptor, which, when bound to its ligand, triggers secretion of pro-inflammatory cytokines. It is upregulated by bacterial lipopolysaccharides but not in non-infective disorders. Interestingly, rare variants in the gene encoding the related protein TREM-2 confer a significant risk of Alzheimer's disease, implying a role for immune cells in preventing the buildup of amyloid plaque (see p. 878).

The key principle at play here is that the immune system has devised a means of identifying most types of invading microorganisms by using a limited number of PRRs recognizing common molecular patterns, or PAMPs. This recognition event has been termed a ‘danger signal’; it alerts the immune system to the presence of a pathogen. Sensing danger is a key role of the DC and a key first step towards activation of the adaptive immune system.

**Dendritic cells and T cell activation**

In a sequence of events that spans 1–2 days, immature DCs are activated by PAMPs or DAMPs in the tissues binding to a PRR on DCs. The immature pDC is a small, rounded cell that develops dendrites upon activation and secretes enormous quantities of IFN-α, a potent antiviral and pro-inflammatory cytokine. On activation, the DC migrates to the local lymph node with the engulfed pathogen. During migration, the DC matures, changing its shape, gene and molecular profile and function within a matter of hours to take on a mature form, with altered functions (*Box 8.11, Fig. 8.5*), in particular upregulating machinery required to activate T lymphocytes. Once in the lymph node, the mature DC interacts with naive T lymphocytes (antigen presentation), resulting in two key outcomes:

1. activation of T cells with the ability to recognize peptide fragments (termed epitopes) of the pathogen
2. polarization of the T cell towards a functional phenotype (see below) that is tailored to the particular pathogen.

---

**Box 8.11**

**Myeloid dendritic cell (mDC) maturation**
Immature mDC | Mature mDC
---|---
Is highly pinocytotic | Ceases pinocytosis
Has low-level expression of molecules required for T lymphocyte activation | Upregulates CD80, CD86 and HLA molecules
Has low-level expression of machinery required to process and present microbial antigens | Begins to process microbial antigens (break down into small peptides) in readiness to present them to T lymphocytes (using HLA molecules)
Is generally localized and sedentary | Begins active migration to local lymph node
Minimally secretes cytokines | Actively secretes cytokines in readiness to stimulate T lymphocytes, in particular IL-12

CD, cluster of differentiation; HLA, human leucocyte antigen; IL-12, interleukin 12.

**FIGURE 8.5** Dendritic cell activation of T lymphocytes. (a) Immature dendritic cells (DCs) in the tissues are activated by pathogens through pathogen-associated molecular pattern–pattern recognition receptor (PAMP–PRR) interaction. (b) Multiple rapid changes in gene expression lead to migration to the lymph node as the DC takes on the mature phenotype. During migration, there is synthesis of the machinery required for activation of T lymphocytes, shown here in response to signals 1–3. CD, cluster of differentiation; HLA, human leucocyte antigen; IL-12, interleukin 12; TCR, T cell receptor.

The mature DC provides three major signals to naive T cells (*Fig. 8.5*):

- **signal 1** = presentation of peptide fragments from the pathogen bound to surface human leucocyte antigen (HLA) molecules
- **signal 2** = co-stimulation through CD80 and CD86 interacting with CD28 on T cells
- **signal 3** = secretion of cytokines, notably IL-12.

**Natural killer cells**

Natural killer (NK) cells are described on page 132.

**Further reading**
Adaptive Immune System

The information gained by DCs that interact with a pathogen is passed on, in the form of signals 1–3 (see Fig. 8.5b). These activate T lymphocytes in the adaptive immune system, which recognize the same pathogen. T lymphocytes may be involved in pathogen removal directly (e.g. by killing) or indirectly (e.g. by recruiting B lymphocytes to make specific antibody). Lymphocytes orchestrate immune responses via cell-to-cell interactions and cytokine release.

Antigen receptors on T and B lymphocytes

One of the key features of the adaptive immune system is specificity for antigen. For example, if you are immunized against the measles virus, you do not have immunity to hepatitis B, and vice versa. Specificity is conferred by two types of receptor: the T cell receptor (TCR) on T lymphocytes and an equivalent on B lymphocytes, the BCR. BCRs are also termed surface immunoglobulin (sIg) and differ from TCRs in also being secreted in large quantities by end-stage B lymphocytes (plasma cells) as soluble immunoglobulins, also known as antibodies.

To maintain protection against the multiplicity of pathogens in our environment, each of us generates great diversity amongst TCRs and antibodies. This is achieved through a mechanism shared by both TCR and antibody, in which distinct families of genes are encoded in the germline, each family (called constant, variable, diversity and joining) contributing a sequence to part of the receptor. Recombination between randomly selected members of each family ensures diversity in the end product. Recombination frequently involves base deletions and additions, adding to the diversity. In the case of antibodies, the result is a potential capacity of more than $10^{14}$ different antibody molecules; for TCRs, it may be as high as $10^{18}$.

Immunoglobulins

In structural terms, antibodies have four chains: two identical heavy and two identical light
chains (Fig. 8.6). Each chain contains both highly variable and essentially constant regions. The variable parts of the heavy and light chains pair to form the potentially diverse part of the antibody molecule that binds antigen. The constant region of the heavy chain dictates the function of the antibody, and belongs to one of the classes M, G1–4, A1–2, D and E, giving rise to antibodies called IgM, IgG1–4, IgA1–2, IgD and IgE. The characteristics of these different isotypes are shown in Box 8.12.

![Image of Immunoglobulin structure](image)

**FIGURE 8.6** Immunoglobulin structure. (a) Basic subunit consisting of two heavy and two light chains. (b) Genes on the Fab and Fc regions of an immunoglobulin. The chain is made up of a V (variable) gene, which is translocated to the J (joining) chain. The VJ segment is then spliced to the C (constant) gene. Heavy chains have an additional D (diversity) segment, which forms the VDJ segment that bears the antigen-binding site determinants.

**Antibody production**

Essential points about antibody production are as follows:

- IgM is the first isotype to be made in a primary immune response and thus measurement of pathogen-specific IgM is a useful diagnostic test for recent infection.
- IgG dominates in the second exposure to antigen.
- IgG and IgM are the most efficient complement activators when bound to antigen in an immune complex.
- IgG antibodies cross the placenta, and can carry both immunity and disease to the unborn fetus.
- IgA antibodies are present in secretions (tears, saliva, gastrointestinal tract) to give protection to the mucosae.
- As it matures, and under the instruction of T lymphocytes, a B lymphocyte may change the class (class switching), but never the specificity, of the antibody it makes.
- As B lymphocytes mature and are stimulated to undergo further division, minor changes in antibody gene sequence can take place (somatic mutation), potentially allowing antibodies with higher affinity to arise and be selected for the effector response (affinity maturation).

**Antibody function**
Essential points about antibody function are as follows:

• In host defence, antibodies target, neutralize and remove infectious organisms and toxins from the circulation and tissues, often through recruitment of innate host effector mechanisms such as complement, phagocytes and mast cells (by binding to specific surface receptors on these cells).

• In clinical medicine, specific anti-pathogen antibody levels are used in diagnosing/monitoring infectious disease, and may also be administered as serum pools to provide host protection passively.

• Antibodies can be raised in animals to generate monoclonal antibodies, which are commonly used in diagnostic immunology tests and increasingly employed as therapeutics (e.g. to target cancer cells), often after ‘humanization’ (see below).

**T cell receptor genes and receptor diversity**

The genomic organization of T cell receptor (TCR) genes and principles of generation of receptor diversity are similar to those of immunoglobulin genes. The TCR exists as a heterodimer, with a similar overall structure to the antibody molecule. There are two TCR types:

- α and β chains (αβ TCR; expressed on all CD4 T lymphocytes and approximately 90% of CD8 T lymphocytes; play a role in adaptive immune responses)
- γ and δ chains (γδ TCR; fewer in number, mainly on intraepithelial lymphocytes; involved in epithelial defence).

The chains of each type of TCR are divided into variable and constant domains, each domain being encoded by separate gene pools. Like the B lymphocyte producing a single clone of immunoglobulin molecules, the T lymphocyte expresses only one form of TCR once the genes have been rearranged. Unlike antibodies, TCRs do not undergo somatic hypermutation and are not secreted.

**T lymphocyte development and activation**

T lymphocytes are generated from precursors in the bone marrow, which migrate to the thymus (*Fig. 8.7*). Only 1% of the cells that enter the thymus will leave it as naive T lymphocytes to populate the lymph nodes. This process (termed thymic selection) leads to a cohort of cells (*Box 8.13*) with:

- functionally rearranged genes allowing surface expression of a receptor for antigen (the TCR) alongside the CD3 accessory molecule involved in transducing the antigen-specific signal
- selection of a co-receptor, either CD4 or CD8, to stabilize the interaction between TCR and peptide-HLA:
  - CD4 T cell responses require presentation of peptide antigens by *self* HLA class II molecules
– CD8 T cell responses require presentation of peptide antigens by self HLA class I molecules

• a reduced or absent tendency of the selected TCR to recognize self antigens (thus avoiding autoimmunity).

MHC, major histocompatibility complex.

Thus, during thymic education, most TCRs are rejected for further use (negative selection), either because they are unable to bind self HLA molecules, or because they bind with too strong an affinity, which would run the risk of self-reactivity and autoimmune disease. The chosen TCRs (positive selection) have low/intermediate affinity for self HLA molecules. During post-thymic activation of T lymphocytes in the lymph node, TCR interaction with HLA has to be bolstered by additional signals (co-stimulation) provided by dendritic cells. This ensures that T lymphocytes are activated only when the checkpoint of DC maturation has been passed, which will happen only in the presence of pathogens.

Co-stimulation of T cells is a competitive process, ensuring that when the activation requirements of T cells have been reduced and the original stimulus (e.g. infection) has been dealt with, the immune response can be switched off. The competition may be provided by alternative ligands for the same molecule with an opposing action. For example, CTLA-4 competes with CD80 and CD86 for CD28, and provides a negative signal, reducing T cell activation. Alternatively, different pairs of molecules, such as programmed cell death protein-1 (PD-1) and its ligand (PD-L1), may be expressed and trigger cell deactivation or death. These pathways can be exploited in therapies for inflammatory diseases: for example, blocking the interaction between CD80/86 and CD28 (via a drug called abatacept) is a highly successful treatment for rheumatoid arthritis. Co-stimulation is also at the centre of a revolution in cancer immunotherapy. Monoclonal antibodies (see pp. 146–147), designed to promote co-stimulation and prevent deactivation, are having dramatic effects on several solid tumours such as melanoma and renal cell carcinoma.

Most naive T lymphocytes are resident in the lymph nodes or spleen, whilst 2% are present in the blood, representing a recirculating pool. Naive T lymphocytes are activated for the first time in the lymph node by antigens presented to their TCRs as short peptides bound to major histocompatibility complex (MHC) molecules on the surface of DCs (see Fig. 8.5). Provision of signals 1–3 (see p. 127) sets off an intracellular cascade of signalling molecule activation, leading to induction of gene transcription in T lymphocytes.

Nuclear factor kappa B (NF-κB) is a pivotal transcription factor in chronic inflammatory diseases and malignancy (see Fig. 7.12). It is found in the cytoplasm bound to an inhibitor, IκB, which prevents it from entering the nucleus. It is released from IκB on stimulation of the cell and passes into the nucleus, where it binds to promoter regions of target genes involved in inflammation. It is stimulated by, for example, cytokines, protein C activators and viruses. The
outcome is T lymphocyte activation, cell division and functional polarization, which is the acquired ability to promote a selected type of adaptive immune response. These processes take several days to achieve. The best-described polarities of T cell responses (Box 8.14) are:

- CD4⁺ pro-inflammatory T lymphocytes; Th1, Th2 and Th17
- CD8⁺ cytotoxic T lymphocytes (CTLs) (Box 8.15)
- CD4⁺ regulatory responses (Treg).

Through cell division, a proportion of the T lymphocytes that are activated in response to a pathogen undertake these effector or regulatory functions, whilst a proportion is assigned to a memory pool. Once established, effector and memory T lymphocytes have lesser requirements for subsequent activation, which can be mediated by monocytes, macrophages and B lymphocytes.

**CD4 T lymphocyte functions**

As the pivotal cell in immune responses, the CD4 T lymphocyte influences most aspects of immunity, either through the release of cytokines, or via direct cell–cell interaction, a process often termed ‘licensing’. Licensing critically involves the pairing of CD40 on the antigen presenting cell and CD40 ligand (CD154) on the CD4 T lymphocyte; defects in this process result in antibody deficiency (see below).

Major functions of CD4 T lymphocytes are:

- **licensing of DCs** during antigen presentation to activate CD8 T lymphocytes and generate cytotoxic cells
- **licensing of B lymphocytes** to initiate and mature antibody responses, leading to class switching, affinity maturation of antibodies, and generation of plasma cells or memory cells
- **secretion of cytokines** responsible for growth and differentiation of a range of cell types, especially other T lymphocytes, macrophages and eosinophils
- **regulation of immune reactions**.

**T helper 1 cells**

T helper 1 cells (Th1) are the main effector subtype of CD4 T lymphocytes. In physiology, they drive activation of monocytes/macrophages and CTLs. In pathology, they have a key role in protection against intracellular pathogens such as viruses and mycobacteria. Th1 cells are recognized by their secretion of the pro-inflammatory cytokines IFN-γ and TNF-α (*Box 8.15*).
In physiology, Th2 cells drive antibody responses, especially IgE, and also promote eosinophil granulocyte functions. In pathology, they have a key role in protection from extracellular parasites (helminths) and also in the immune responses that underlie allergic disease. Th2 cells are recognized by secretion of IL-4, IL-5 and IL-13.

**T helper 17 cells**

In physiology, Th17 cells drive inflammatory responses, especially via recruitment of neutrophil granulocytes. In pathology, they are necessary for protection from fungal infections, and are increasingly recognized as having a role in chronic inflammatory diseases such as multiple sclerosis, rheumatoid arthritis and inflammatory bowel disease. They are recognized by secretion of IL-17.

**Regulatory T lymphocytes**

The generation of B and T lymphocytes provides a potentially vast array of rearranged antigen receptors. Although there are selection processes to remove lymphocytes with ‘dangerous’ avidity for ‘self’, these are not foolproof and the potential for autoreactivity remains. The fact that there is no self-destruction in the vast majority of people implies that the norm is a state of immunological self-tolerance: the controlled inability to respond to self. Several mechanisms operate to maintain this state, including CD4 T lymphocytes that respond to antigenic stimulation by suppressing ongoing immune responses. At least two different types of regulatory T lymphocytes (Treg) are recognized:

- **CD4+ CD25hi Tregs.** These express high levels of CD25, the receptor for IL-2; regulate other T lymphocytes by cell–cell contact, and also secrete the immune-suppressive cytokines IL-10 and TGF-β; and can be generated in the thymus or post-thymically in the periphery. Their key feature is high expression of the transcription factor Foxp3.

- **Tr1 Tregs.** These are generated naturally or induced (e.g. by repeated antigen injection); they regulate through production of IL-10.

Evidence that Tregs are clinically relevant is given by the example of immune deficiency states in which they are defective. For example, genetic defects in the Foxp3 gene give rise to IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome). Patients with this rare syndrome have defective Tregs and develop a range of conditions soon after birth, including organ-specific autoimmune disease such as type 1 diabetes. Much research effort is directed at harnessing this natural regulatory potential, for example to control organ graft rejection and autoimmune disease.

**CD8 T lymphocyte functions**

Cytotoxic CD8 T lymphocytes (CTLs) are involved in defence against viruses. CTLs kill virus-infected cells following recognition of viral peptide-HLA class I complexes. CTLs must be activated first in the lymph node by a DC cross-presenting the same viral peptide, and licensed by a CD4 T lymphocyte recognizing viral peptide-HLA class II complexes. The same
defence mechanism may also apply in tumour surveillance. This is a checkpoint that ensures that CTL responses, which have great destructive power, are only activated against a target for which there is also a CD4 T cell response. CTLs kill via three mechanisms:

• cytotoxic granule proteins (cytolysins such as perforin, granzyme B)
• toxic cytokines (e.g. IFN-γ, TNF-α)
• death-inducing surface molecules (e.g. Fas ligand binds Fas on target cells mediating apoptosis via caspase activation; see Fig. 7.18).

**Natural killer cells**

Natural killer (NK) cells are bone marrow-derived, present in the blood and lymph nodes, and represent 5–10% of lymphoid cells. The name reflects two features. Unlike B and T lymphocytes, NK cells are able to:

• Mediate their effector function *spontaneously* (i.e. killing of target cells through release of perforin, a pore-forming protein) in the absence of previous known sensitization to that target.
• Achieve this with a very limited repertoire of germline-encoded receptors that do not undergo somatic recombination.

Despite their close resemblance to T and B lymphocytes in morphology, the lack of requirement for sensitization and the absence of gene rearrangement to derive receptors for target cells mean that NK cells are also categorized as a part of the innate immune system. For identification purposes, the main surface molecules associated with NK cells are CD16 (see below) and CD56 (note that NK cells are CD3- and TCR-negative).

The role of NK cells is to kill ‘abnormal’ host cells, typically cells that are virus-infected, or tumour cells. Killing is achieved in similar ways to CTLs. NK cells also secrete copious amounts of IFN-γ and TNF-α, through which they can mediate cytotoxic effects and activate other components of the innate and adaptive immune system. To become activated, NK cells integrate the signal from a potential target cell through a series of receptor–ligand pairings (Box 8.16). These pairings provide activating and inhibitory signals, and it is the overall balance of these that determines the outcome for the NK cell. The balance can be abnormal on a virus-infected or tumour cell, which might have altered expression of HLA molecules, for example, that mark them out for NK cytotoxicity.

**Box 8.16**

### Cell Migration

Immune cells are mobile. They can migrate into the lymph node to participate in an evolving immune response (e.g. a pathogen-loaded DC from the skin, or a recirculating naive T lymphocyte), or can migrate from the lymph node, via the blood, to the site of a specific
infection in the tissues. Such migration takes place along blood and lymphatic vessels, and is a highly regulated process.

To take the example of a DC migrating into the lymph node from the tissues via the lymphatics (Fig. 8.8), this is highly dependent upon expression of the chemokine receptor CCR7 by the migrating cell and of its ligand (CCL21) by the target tissue. Likewise, circulating naive lymphocytes are CCR7$^+$ and migrate with ease into the lymph nodes from the blood or via tissue recirculation. In addition, naive lymphocytes express L-selectin, which binds a glycoprotein cell adhesion molecule (GlyCAM-1) found on the high endothelial venules of lymph nodes. This system can be upregulated in an inflamed lymph node, leading to an influx of naive lymphocytes and the typical symptom of a swollen node.
Migration into inflamed tissue requires that:

- an affected organ or tissue signals that there is a focus of injury/infection and
- responding immune cells bind and adhere specifically to that tissue.

This process is highly organized and has a similar basis for all immune cells, involving three basic steps: rolling, adhesion and trans-migration. Each of these is dependent on specialized adhesion molecules, as shown in Figure 8.9.
Neutrophil migration. Neutrophils arrive at the site of inflammation, attracted by various chemoattractants. (1) They roll along the blood vessel wall through interaction between L-selectin, on their surface, binding to a carbohydrate structure (e.g. sialyl-LewisX) on the endothelium. E-selectin on the endothelium mediates a similar effect. P-, E- and L-selectin (platelet, endothelium and leucocyte, respectively) are named after the predominant cell type that expresses them and bind to carbohydrate moieties such as sialyl-LewisX (CD15s) on immune cells, inducing them to slow and roll along the vessel lumen. (2) Firm adhesion is then mediated via interaction between integrins on the neutrophil and intercellular and vascular cell adhesion molecules (ICAM-1 and VCAM-1) on the endothelium. The best-known integrin is the heterodimer of CD11a/CD18 (leucocyte function associated antigen-1 – LFA-1), which binds ICAM-1. (3) Trans-migration (diapedesis) then occurs: this is a complex process that involves platelet-endothelial cell adhesion molecule-1 (PECAM-1) and junctional adhesion molecules (JAMs). Following trans-migration (diapedesis), mediators such as interleukin-8 (IL-8), macrophage-chemotactic factor and tumour necrosis factor alpha (TNF-α) attract and activate the neutrophil to the infected tissue, where it phagocytoses and destroys the C3b-coated bacteria. IFNs, interferons; LTB4, leukotriene B4; MCP-1, monocyte chemoattractant protein-1 (CCL2); PAF, platelet-activating factor.

The expression of these molecules (e.g. LFA-1) is upregulated on T lymphocytes after activation in the lymph node. ICAM-1 expression on tissue endothelium is sensitive to numerous pro-inflammatory molecules and allows immune cells to be guided from the blood into the tissues. Once there, cells move along a gradient of increasing concentration of mediators such as chemokines in the process of chemotaxis.

HLA Molecules and Antigen Presentation

On the short arm of chromosome 6 is a collection of genes termed the major histocompatibility complex (MHC; known as the human leucocyte antigens, or HLA, in humans), which plays a critical role in immune function. MHC genes code for proteins expressed on the surface of a variety of cell types that are involved in antigen recognition by T lymphocytes. The T lymphocyte receptor for antigen recognizes its ligand as a short antigenic peptide embedded within a physical groove at the extremity of the HLA molecule (Fig. 8.10).
The HLA genes are particularly interesting for clinicians and biologists. First, differences in HLA molecules between individuals are responsible for tissue and organ graft rejection (hence the name ‘histo’ (tissue)-compatibility). Second, possession of certain HLA genes is linked to susceptibility to particular diseases (Box 8.17).

The human major histocompatibility complex

The human MHC comprises three major classes (I, II and III) of genes involved in the immune response (*Fig. 8.11*).
FIGURE 8.11 The HLA system in humans. On chromosome 6 are three major HLA regions (classes I–III) including genes that encode the HLA class I and II molecules, complement genes, the cytokine tumour necrosis factor (TNF) and other genes involved in antigen presentation (HLA-DO, HLA-DM; transporter associated with processing, TAP; proteasome subunit beta, PSMB; and the non-classical HLA class Ic molecule, MICA).

**HLA classes**

**Classical HLA class I genes**

Classical HLA class I genes (also termed Ia) are designated HLA-A, HLA-B and HLA-C. Each encodes a class I α chain, which combines with a β chain to form the class I HLA molecule (see Fig. 8.10). While there are several types of α chain, there is only one type of β chain, β2 microglobulin. The HLA class I molecule has the role of presenting short (8–10 amino acids) antigenic peptides to the T cell receptor on the subset of T lymphocytes that bear the co-receptor CD8. As an example of HLA polymorphism, there are nearly 200 allelic forms at the A gene locus. Class I HLA molecules are expressed on all nucleated cells.

**Non-classical HLA class I genes**

Non-classical HLA class I genes are less polymorphic, have a more restricted expression on specialized cell types, and present a restricted type of peptide or none at all. These are the HLA-E, F and G (Iib genes) and MHC class I-related (MIC, or class Ic) genes, A and B. The products of these genes are predominantly found on epithelial cells, signal cellular stress and interact with lymphoid cells, especially natural killer cells (see p. 132).

**HLA class II genes**

The class II genes have three major subregions: DP, DQ and DR. In these subregions are genes encoding A and B genes that combine to form dimeric αβ molecules that present short (12–15 amino acid) peptides to T lymphocytes that bear the CD4 co-receptor. Class II HLA genes (apart from DRA) are highly polymorphic. Other genes in this region encode proteins with key roles in antigen presentation (e.g. TAP, HLA-DM, HLA-DO, proteasome subunits; see below). Class II HLA genes are expressed on a restricted cohort of cells that go by the general term of antigen presenting cells (APCs; DCs, monocyte/macrophages, B lymphocytes).
HLA class III genes

HLA class III genes encode proteins that can regulate/modify immune responses, e.g. tumour necrosis factor (TNF), heat shock protein (HSP) and complement protein (C2, C4).

HLA genotypes and the range of their protein products

HLA genotype is denoted first by the letters that designate the locus (e.g. HLA-A, HLA-DR, HLA-DQ). For class I alleles, this is followed by an asterisk and then a 2- to 4-digit number defining the allelic variant at that locus, often called the HLA type (e.g. HLA-A*02 is the 02 variant of the HLA-A gene). The class II nomenclature is the same, except that both A and B genes are named (although HLA-DR molecules only require the name of the B gene because the A gene is the same in all of us).

Some general principles apply to the HLA genes and their protein products:

• The presence of multiple genes on each chromosome, and the fact that both maternal and paternal genes are co-dominantly expressed, allow considerable breadth in the number of HLA molecules that an individual expresses.

• The existence of polymorphisms at each locus provides great breadth in the number of HLA molecules expressed at a population level. The polymorphic forms of HLA molecules differ predominantly in the peptide-binding groove (see Fig. 8.10).

Overall, then, each human can bind a range of peptide epitopes from pathogens to enhance individual protection; similarly, the population has an even greater range of protection, to ensure population survival.

Antigen presentation

HLA molecules bind short peptide fragments that are processed (‘chopped up’) from larger proteins (antigens) derived from pathogens. The peptide–HLA complex is presented on antigen presenting cells (APCs) for recognition by T cell receptors (TCRs) on T lymphocytes. There are three major routes to antigen processing and presentation:

• The endogenous route (Fig. 8.12) is a property of all nucleated cells; the internal milieu is sampled to generate peptide–HLA class I complexes for display (‘presentation’) on the cell surface. In a healthy cell, the peptides are derived from self proteins in the cytoplasm (Fig. 8.12) and are ignored by the immune system. In a virus-infected cell, viral proteins are processed and presented. The resulting viral peptide–HLA class I complex is presented to CD8 T lymphocytes that have cytotoxic (killer) function. In an immune response against a virus infection, CD8 T lymphocytes recognizing viral peptide–HLA complexes on the surface of an infected cell will kill it as a means to limit and eradicate infection.
The endogenous route of antigen presentation. Antigen is presented to CD8 T lymphocytes. Cytosolic proteins derived from self (resting cells) or viruses (virus-infected cells) are broken down by the proteasome (a sort of ‘protein recycler’) into fragments 2–25 amino acids long. Some of these are taken into the endoplasmic reticulum (ER) by a transporter (TAP), trimmed, and loaded into empty HLA class I molecules. These are exported to the surface membrane for presentation to CD8 T lymphocytes.

The exogenous route (Fig. 8.13) is a property of APCs; the external milieu is sampled. Antigens are internalized, either in the process of phagocytosis of a pathogen, through pinocytosis, or through specialized surface receptors (e.g. for antigen/antibody/complement complexes). The antigen is broken down by a combination of low pH and proteolytic enzymes for ‘loading’ into HLA class II molecules. At the APC surface, the pathogen peptide–HLA class II complex is presented to, and able to interact with, CD4 T lymphocytes. Presentation by DCs can initiate an adaptive immune response by activating a naive, pathogen-specific CD4 T lymphocyte. Presentation by monocyte/macrophages and B lymphocytes can maintain and enhance this response by activating effector and memory pathogen-specific CD4 T lymphocytes.
The exogenous route of antigen presentation and cross-presentation. External material (e.g., virus particles) is taken into an antigen presenting cell and broken down into specialized compartments by a combination of low pH and proteolysis. Peptides are then loaded into HLA class II molecules for presentation to CD4 T lymphocytes. Material may also be transferred across the cell so that it is loaded on to HLA class I molecules for presentation to CD8 T lymphocytes. This process of cross-presentation is restricted to specialized antigen presenting cells such as dendritic cells.

Cross-presentation refers to the ability of some APCs (mainly DCs) to internalize exogenous antigens and process them through the endogenous route (see Fig. 8.12). This is an essential component in the activation of CD8 cytotoxic T cell responses against a virus.

The Immune System in Concert

Acute inflammation: events and symptoms

This is the early and rapid host response to tissue injury. To take a bacterial infection as the classic example:
• Local expansion of pathogen numbers leads to direct activation of complement in the tissues, with ensuing degranulation of mast cells.

• Inflammatory mediators (from mast cells and complement) change the blood flow and attract and activate granulocytes (neutrophils).

• Concomitantly, there are the local symptoms of heat, pain, swelling and redness, and perhaps more systemic symptoms such as fever due to the effect of circulating cytokines (IL-1, IL-6, TNF-α) on the hypothalamus. Indeed, gene mutations that lead to excessive actions of IL-1 (e.g. mutation of the \textit{IL1RN} gene, which encodes a natural IL-1 antagonist) give rise to rare disease with just these symptoms, as well as bone erosion and skin rashes, which are treatable with IL-1 blockade using soluble IL-1 receptor antagonist (anakinra) or monoclonal anti-IL-1β antibody.

• Systemically active mediators (especially IL-6) also initiate the production of C-reactive protein (CRP) in the liver.

• Bacterial lysis follows through the actions of complement and neutrophils, leading to formation of fluid in the tissue space containing dead and dying bacteria and host granulocytes (‘pus’).

• At the site of pathogen entry, there is often relative tissue hypoxia. The low oxygen tension has the effect of amplifying the responses of innate immune cells and suppressing the response of adaptive immune cells. This is probably an effective means of preventing excessive immune activation, which can result in collateral damage (\textit{Fig. 8.14}).
The inflammation may become organized and walled off through local fibrin deposition to protect the host.

- Antigens from the pathogen travel via the lymphatics (which may become visible as red tracks in the superficial tissues – lymphangitis) in soluble form or are carried by DCs to establish an adaptive immune response, which, at the first host–pathogen encounter, takes approximately 7–14 days. DCs are activated via the PRR–PAMP system (see Fig. 8.5).

- The adaptive immune response leads to activation of pathogen-specific T lymphocytes and of B lymphocytes, and production of pathogen-specific antibody, initially of the IgM class and of low–moderate affinity, and subsequently of the IgG class (or IgA if the infection is mucosal) and of high affinity.

- Resolution of the infection is aided by the scavenging activity of tissue macrophages.

**Chronic inflammation: events and symptoms**

Inflammation arising in response to immunological insults that cannot be resolved in days/weeks gives rise to chronic inflammation. Examples include infectious agents (viruses that cause chronic infections such as hepatitis B and C, or intracellular bacteria such as mycobacteria) and environmental toxins (such as asbestos and silicon). At the intracellular level, key processes of inflammasome generation (see p. 126) and autophagy (see p. 104) serve to enhance the chronic inflammatory process. Chronic inflammation is also a hallmark of some forms of allergic disease, autoimmune disease and organ graft rejection.
Mycobacterial disease

The common feature of these pathological processes is that the inciting stimulus is not easy to remove. For example, some viruses and mycobacteria remain hidden intracellularly. In many ways, the pathology that results is thus inadvertent; the immune system is caught between the repercussions of not dealing with the infection/insult and the tissue damage that is caused by chronic activation of lymphoid and mononuclear cells.

• Mycobacterium leprae. In Mycobacterium leprae infection (leprosy; see p. 285) this is well demonstrated. With the same infecting organism, two very different forms of disease are seen: lepromatous or tuberculous. In the tuberculous form, there is a good immune response to chronic infection but the immune response causes nerve damage and numb patches of skin. In the lepromatous form, Th1 responses are less pronounced and infection is widespread but there is less nerve damage.

In both of these forms of mycobacterial disease, the chronic inflammation may lead to permanent organ damage or impaired vascular function, and can be fatal. If the inciting stimulus is removed, inflammation resolves. With leprosy, this is achieved with antibiotics. However, inflammation can return rapidly (24–48 hours) on re-exposure. This rapid recall response is the basis for patch testing to identify the cause of contact dermatitis, another form of chronic inflammation, and also for the Mantoux (skin) or the interferon gamma release (IGRA) blood test of tuberculosis immunity.

The main immunological event is the presence of a pro-inflammatory focus comprising T and B lymphocytes and APCs, especially macrophages. If antigen persists, inflammation becomes chronic and the macrophages in the lesion fuse to form giant cells and epithelioid cells. Both Th1 and Th2 reactivity is recognized but specific syndromes may be polarized towards one or the other (e.g. chronic mycobacterial or viral infection initiates Th1 responses, chronic allergic inflammation Th2).

When the inflammation is sufficiently chronic, it may take on the appearance of organized lymphoid tissue resembling a lymph node germinal centre (e.g. in the joints in rheumatoid arthritis; see pp. 672–674). There is massive cytokine production by T lymphocytes and APCs, which contributes to local tissue damage. Granulomata, which ‘wall off’ the inciting stimulus, may also arise and result in fibrosis and calcification. Symptoms typically relate to the site of the inflammation and the type of pathology, but there may also be systemic effects such as fever and weight loss.

• Crohn's disease. Chronic inflammation is a hallmark of several immune-mediated and autoimmune diseases but it is often unclear what kick-starts or maintains the inflammatory process. Large-scale studies that identify the genetic basis for these disorders (genome-wide association studies, GWAS) are beginning to provide some clues. A good example is Crohn's disease (CD). Several of the polymorphisms associated with CD reside in genes known to be involved in inflammasome induction, such as NOD2. Cytokine regulation has also emerged as a critical disease pathway in GWAS studies on CD: most notably, IL-23R (the IL-23 receptor gene), which influences Th17 cell differentiation. Clues like these point to patients with CD having impaired ability to control or terminate inflammasome activity, as well as a
predisposition to make polarized pro-inflammatory cytokine responses. This information can now be exploited to devise novel therapeutic approaches, such as monoclonal antibodies that target the key cytokines.

**Laboratory Investigations of the Immune System**

In the clinical immunology laboratory, proteins and cells can be measured to ascertain the status of the immune system. The results may indicate an undiagnosed inflammatory or infectious disease (e.g. through high CRP level); a state of immune deficiency (e.g. low concentration of IgG); or a state of immune pathology (e.g. the presence of autoantibodies or allergen-specific IgE).

Examples of the more common tests and their interpretation are shown in *Box 8.18*.

**Box 8.18**

*Examining the immune system in the clinical immunology laboratory*
### Measurement | Interpretation
---|---
**Proteins** |  
C-reactive protein | Raised levels indicate infection or inflammation  
Total immunoglobulins | Low levels indicate antibody deficiency, usually a result of underlying disease or primary immunodeficiency. High levels, e.g. ↑ IgM, are seen in acute viral infection (e.g. hepatitis A)  
IgG subclasses | Specific reductions in IgG subclasses (1–4) may indicate immune deficiency. High levels of IgG4 are observed in IgG4 disease  
Complement level and function | Low levels indicate consumption of complement in immune complex disease or primary complement deficiency, which can be confirmed with testing of the alternate or classical pathway function  
IgE | Raised levels are seen in allergy; allergen-specific IgE is useful to pinpoint the inciting stimulus (e.g. pollen, grass), component allergens may be useful in assessing anaphylaxis risk or cross-reactivity between allergens  
**Cells** |  
Neutrophils | High levels are seen in bacterial infection; low levels in secondary immune deficiency  
Eosinophils | High levels are seen in allergic or parasitic disease  
CD4 T lymphocytes | Low levels are seen in HIV infection  
**Function** |  
Neutrophil respiratory burst | Absent in immune deficiency chronic granulomatous disease  
T lymphocyte proliferation | Abnormally low in primary T cell immune deficiency disease  
**Autoantibodies** (see also Box 8.25 and Box 18.37) |  
Rheumatoid factor, anti-citrullinated peptide antibodies (ACPA) | Rheumatoid arthritis  
Double-stranded DNA autoantibodies | Systemic lupus erythematosus  
Acetylcholine receptor antibodies | Myasthenia gravis  
Anti-neutrophil cytoplasmic antibodies (ANCA) | Vasculitis  
Mitochondrial | Primary biliary cholangitis

---

**Clinical Immunodeficiency**

**Secondary (acquired) versus primary immunodeficiency**

Most forms of immunodeficiency are secondary to infection (mainly HIV) or therapy (e.g. corticosteroids, anti-TNF-α monoclonal antibody therapy, cytotoxic anticancer drugs, bone marrow ablation pre-transplant). Examples of other secondary immunodeficiencies are:

- **Acquired neutropenias**, which are common (e.g. due to myelosuppression by disease or drugs, or the increased rate of destruction in hypersplenism or autoimmune neutropenia) and carry a high risk of infection once the neutrophil count falls below $0.5 \times 10^9/L$.
- **Acquired reductions in levels of immunoglobulins** (hypogammaglobulinaemia), which are seen in patients with myeloma and chronic lymphocytic leukaemia or lymphoma.
• Impairment of defence against capsulated bacteria, especially pneumococcus, following splenectomy; such patients should receive pneumococcal, meningococcal and Hib vaccinations as a matter of course (see Box 16.20).

Primary immunodeficiency is rare and arises at birth as the congenital effect of a developmental defect or as a result of genetic abnormalities (Box 8.19). Gene defects may not become manifest until later in infancy or childhood, and some forms of immunodeficiency typically present in adolescence or adulthood.

*aApart from AIDS, all diseases shown here are primary immunodeficiencies.*

### Clinical features of immunodeficiency

The infections associated with immunodeficiency have several typical features:

- They are often chronic, severe or recurrent.
- They resolve only partially with antibiotic therapy or return soon after cessation of therapy.
• The organisms involved are often unusual (‘opportunistic’ or ‘atypical’).

The pattern of infection, in terms of the type of organism involved, is indicative (Box 8.20):
• **Opportunistic** organisms are of low virulence but become invasive in immunodeficient states, e.g. atypical mycobacteria, *Pneumocystis jiroveci, Staphylococcus epidermidis*.
• **Phagocyte defects** cause deep skin infections, abscesses and osteomyelitis, for example.
• **Defective antibody** producers experience infections with pyogenic (‘pus-forming’) bacteria.
• **T lymphocyte deficiency** causes infection with fungi, protozoa and intracellular microorganisms.
• **Congenital deficiencies** of antibody production are not revealed for several months after birth, due to the 28-day half-life of maternal IgG.

- *Ureaplasma* spp.
• Echovirus
• *Pseudomonas* spp.

**Complement lytic pathway defects (C5–9)**
• Meningococcus
• Gonococcus (disseminated)

**Defect in T cell or T cell–APC responses**
• *Listeria monocytogenes*
• *Legionella pneumophila*
• *Salmonella* spp. (non-typhi)
• *Nocardia asteroides*
• *Mycobacterium tuberculosis*
• Atypical mycobacteria, especially *M. avium-intracellulare*
• *Candida* spp. (mucocutaneous)
• *Cryptococcus neoformans*
• *Histoplasma capsulatum*
• *Pneumocystis jiroveci*
• *Toxoplasma gondii*
• Herpes simplex
• Herpes zoster
• Cytomegalovirus
• Epstein–Barr virus

The family history may reveal unexplained sibling death, the fact that only males of the family are affected (X-linked), or consanguinity; each of these makes a primary genetic syndrome more likely. Graft-versus-host disease (GVHD) may arise as a complication of primary or secondary T lymphocyte immunodeficiency. For GVHD to arise, there must be impaired T lymphocyte function in the recipient and the transfer of immunocompetent T lymphocytes from an HLA non-identical donor (see below). GVHD usually arises from therapeutic interventions such as transfusions or transplantation.

**Primary immunodeficiency**

**T lymphocyte deficiency**

**DiGeorge syndrome**
This is due to T lymphocyte deficiency. The third and fourth pharyngeal arches, which
normally give rise to the parathyroid glands, aortic arch and the thymus, fail to develop. DiGeorge syndrome arises in 1–5 per 100,000 of the population and presents at birth with dysmorphic facies, hypoparathyroidism and cardiac defects, followed by infections (fungi, protozoa) in later months.

This combination of cardiac abnormalities, abnormal facies, thymic dysfunction, cleft deformities, hypocalcaemia/ hypoparathyroidism and mutations on chromosome 22 is remembered by the acronym CATCH-22. The lack of a location for T lymphocyte development – that is, the thymus – means that affected children have reduced/absent T lymphocyte number and proliferation responses. Apart from calcium supplementation, correction of cardiac abnormalities and prophylactic antibiotics, cure has been reported with thymic transplantation using fetal tissue or stem cell transplant (SCT) from HLA identical siblings.

**Other T lymphocyte deficiencies**

Other T lymphocyte deficiencies caused by single-gene defects have been characterized and typically present from the age of 3 months with candidal infections of the mouth and skin, protracted diarrhoea, fever and failure to thrive. Examples include deficiency of CD3 itself; defects in signal transduction pathways; and deficiency of IL-2. These disorders are similar in presentation and management to the combined (T and B lymphocyte) immune deficiencies.

**T and B lymphocyte deficiency**

**Severe combined immunodeficiencies**

Severe combined immunodeficiencies (SCID) are a heterogeneous group of rare (1–2 live births per 100,000), genetically determined disorders resulting from impaired T, NK and B lymphocyte immunity. The most common form of SCID is an X-linked defect in the IL-2 receptor γ chain, interfering with the function of not just IL-2 but also IL-4, IL-7, IL-9 and IL-15, which share this component in their receptors. Clinical features are similar to those of pure T lymphocyte deficiency and, in the blood, T and NK cells are lacking whilst B lymphocyte numbers may be normal. The most successful treatment for all forms of SCID is SCT, preferably from HLA-identical donors such as siblings. For a few disorders such as γ chain SCID, gene therapy is possible if no appropriate HLA-matched donor can be found.

**Hyper-IgM syndrome**

This is a mixed deficiency, which may not be diagnosed until later in life. It results from an X-linked defect in the gene encoding CD40 ligand (CD40L, also called CD154). Signalling between CD40 on B lymphocytes and CD40L on T lymphocytes is necessary for the generation of class-switched B lymphocytes bearing high-affinity immunoglobulin, as well as for the maturation of the T cell response. In CD40L deficiency, B lymphocytes are to class switch, producing only IgM. Levels of other types of immunoglobulin IgG and IgA are absent/low and there are mild defects in T cell function.

Opportunistic infections occur: for example, with *Pneumocystis*, *Cryptosporidium*,

---

*Pneumocystis*, *Cryptosporidium*,
Candida, Cryptococcus and herpes viral infections.

Wiskott–Aldrich syndrome
This is an X-linked defect (at Xp11–23) in a gene involved in signal transduction and cytoskeletal function with associated eczema and thrombocytopenia; a mainly cell-mediated defect with falling immunoglobulins is seen, and autoimmune manifestations and lymphoreticular malignancy may develop. Activating mutations in the same gene have been described that cause severe congenital neutropenia, highlighting the key role of Wiskott–Aldrich serine protease (WASP) in immune regulation.

Ataxia telangiectasia
Patients with this disease have defective DNA repair mechanisms and have cell-mediated defects with low IgA and IgG₂; lymphoid malignancy is again common and a shortened life expectancy often results from the neurological disease.

X-linked lymphoproliferative disease (Epstein–Barr virus)-associated immunodeficiency (Duncan syndrome)
Apparently normal but genetically predisposed (usually X-linked) individuals develop overwhelming Epstein–Barr virus (EBV) infection, polyclonal EBV-driven lymphoproliferation, combined immunodeficiency, aplastic anaemia and lymphoid malignancy. EBV appears to act as a trigger for the expression of a hitherto silent immunodeficiency. Two genetically distinct forms (X-linked lymphoproliferative disease 1 and 2, XLP1 and XLP2) are described, which have defects in the SH2D1A and XIAP gene, respectively.

B lymphocyte deficiency

X-linked agammaglobulinaemia
X-linked agammaglobulinaemia (XLA) presents soon after maternal IgG protection falls, with recurrent infections of the upper and lower respiratory tract involving pyogenic organisms, enteritis and malabsorption. Morbidity and mortality are high if the condition is untreated, mainly due to chronic lung disease and central nervous system infections with enteroviruses. IgG levels are usually much less than 2.0 g/L (a 1–2-year-old child will usually have an IgG level of 3.5–14 g/L) and all five classes of immunoglobulins are affected, with total levels of less than 2.5 g/L (typically >4 g/L at age 1–2 years). B lymphocyte development is arrested at the pre-B stage, and B lymphocytes are absent in the blood. The cause is a loss-of-function mutation on chromosome Xq22 that affects the gene for a tyrosine kinase involved in cell activation and maturation.

Treatment
Treatment is with replacement immunoglobulins (intravenous or subcutaneous, IVIg or SCIg) to a level that controls infections. Trough IgG concentrations should remain well within normal
limits (i.e. >5–6 g/L). Prognosis has improved in recent years as more patients survive into adulthood, but chronic lung disease and lymphomas are life-threatening complications.

**Selective IgA deficiency**

Selective IgA deficiency (IgAD; serum IgA <0.05 g/L), with normal levels of IgG and IgM, is found in approximately 1/600 Northern Europeans, making it the most common primary immunodeficiency, although the underlying defect is unknown. Most individuals are asymptomatic but patients may present at any age with recurrent infections caused by pyogenic organisms and affecting mucosal sites.

**Treatment**

When required, this comprises antibiotics. Some IgAD patients produce anti-IgA antibodies of the IgG and IgE classes. Infusion of exogenous IgA (e.g. during a blood transfusion) could therefore result in anaphylaxis. Thus IgAD patients should be screened for anti-IgA antibodies if there is a history of transfusion reaction, and transfused if necessary with washed red cells, blood from an IgAD donor or stored aliquots of their own blood.

**Common variable immunodeficiency**

Common variable immunodeficiency (CVID) is a heterogeneous disease affecting 1/50 000 and arising during late childhood and early adulthood, with IgG levels <0.5 g/L. It is the most common profound immune deficiency. Presentation with recurrent upper and lower respiratory tract infections is typical and may progress to chronic bronchiectatic lung disease, malabsorption and diarrhoea. There may be additional features of T lymphocyte deficiency, and autoimmunity and granulomatous disease are found in up to 15% of cases. Genetic defects underlying the condition have revealed mutations in multiple genes including *ICOSLG* (ligand for inducible co-stimulator) on activated T lymphocytes in some cases. In most patients, the underlying defect is not known and IVIg or subcutaneous Ig (SCIg) and antibiotics are the treatments of choice.

**Defects in antigen presenting cell function**

A series of rare genetic defects have been uncovered in which APCs demonstrate an inability to mount protective responses to intracellular bacteria, particularly low-virulence mycobacteria and salmonella. The axis affected is the interplay between CD4 T lymphocytes and APCs that drives Th1 responses, and therefore in turn activates mononuclear cells such as macrophages to kill and eradicate intracellular pathogens. Defective genes so far identified include those encoding a component chain of IL-12; a component chain of the IL-12 receptor; and IFN-γ receptor chains 1 or 2 or the intracellular signalling pathway (STAT 1).

**Neutrophil defects**

**Chronic granulomatous disease**
Chronic granulomatous disease (CGD) is a rare (1/250 000) immunodeficiency due to a defect in neutrophil killing and characterized by deep-seated infections. The functional defect is an inability to generate antibacterial metabolites through the respiratory burst (see Box 8.7). Typical onset is at toddler age. Neutrophil numbers are normal or increased. A simple respiratory burst test of neutrophil function is diagnostic. The inability to clear infection and frustrated apoptosis adequately by dysfunctional neutrophils leads to granulomatous inflammation.

**Treatment**

Treatment of infections and prophylactic antibiotic and antifungal therapy are required. Immunotherapy with interferons may have a role in patients with intractable infections, and in some cases SCT is necessary.

**Leucocyte adhesion deficiency**

Leucocyte adhesion deficiency (LAD) results from defects in integrins (see p. 94). Numerous underlying defects in the genes encoding one of the component chains, CD18, have been described in LAD-1. LAD-1 has an autosomal recessive inheritance presenting almost immediately after birth, with delayed umbilical cord separation. In later life, there is a characteristic failure to lose primary dentition and severe gingivitis. Recurrent infections similar to those in chronic granulomatous disease appear during the first decade of life. Blood neutrophil levels are high but cells are absent from the sites of infection, which require aggressive antimicrobial and antifungal treatment, and SCT for cure.

**Hyper-IgE syndrome (Job syndrome)**

This is an autosomal dominant (occasionally sporadic) immune disorder with high serum IgE levels, dermatitis, boils, pneumonias with cyst formation, and bone and dental abnormalities. Mutations in STAT3 and DOCK8 have been found.

**Schwachman–Diamond syndrome**

This can resemble cystic fibrosis clinically, with exocrine pancreatic insufficiency and pyogenic infections. A mild neutropenia is associated with a defect of neutrophil migration.

**Chédiak–Higashi syndrome**

This is a rare, recessive disorder due to a mutation in the lysosomal trafficking regulator gene (LYST) on chromosome 1q42–45. There are defects in neutrophil function with defective phagolysosome fusion, and large lysosome vesicles are seen in phagocytes. Patients have recurrent infections, neutropenia, anaemia and hepatomegaly. As with Schwachman–Diamond syndrome, tissue infiltration with histiocytes is usually seen, including bone marrow, and Chédiak–Higashi syndrome is one of several genetic causes of primary haemophagocytic lymphohistiocytosis (HLH). Similar genetic abnormalities in melanocytes cause partial oculocutaneous albinism.
Complement deficiency

The consequences of deficiency of complement proteins can be predicted from their functions (see Fig. 8.2):

• Failures in innate response components (e.g. the alternative pathway) lead to impaired non-specific immunity with an increase in bacterial infections.

• Genetically determined low levels of mannose-binding lectin (MBL) are associated with a number of inflammatory and infectious diseases.

• Failure of the classical pathway results in a tendency towards infection and also towards diseases in which immune complex deposition causes inflammation, such as systemic lupus erythematosus (SLE; e.g. C1 and C4 deficiency), vasculitis and glomerulonephritis.

An unexpected finding is that neisserial infections (e.g. meningitis due to *N. meningitidis*) are often encountered in patients with complement defects of the membrane attack complex (C6–9).

Complement regulatory proteins

Deficiency of C1 inhibitor (*C1 esterase deficiency*; see also pp. 1356–1357) is relatively rare. Since this enzyme is involved in regulation of several plasma enzyme systems (e.g. the kinin system) and is continuously consumed, a single parental chromosome enzyme defect resulting in 50% of normal production barely copes with the demand and fails under stress (hence has an autosomal dominant effect). As a result, uncontrolled activation of complement and the kinins may occur, leading to oedema of the deep tissues affecting the face, trunk, viscera and airway, explaining the alternative name of hereditary angio-oedema (HAE). Treatment is with C1 inhibitor concentrate or a selective bradykinin-2 receptor antagonist (icatibant). Steroids and antihistamines are not useful in this form of angio-oedema. A rarer acquired form (AAE) may be seen in lymphoproliferative disease or complicating autoimmunity. The treatment is largely as for HAE.

**Further reading**

Type I (Immediate) Hypersensitivity and Allergic Disease

Normally, host defence can cope with potentially harmful cells and molecules. Under some circumstances, a harmless molecule can initiate an immune response that can lead to tissue
damage and death. Such exaggerated, inappropriate responses are termed hypersensitivity reactions or allergic disease.

In **allergic hypersensitivity**, the binding of an antigen to specific IgE bound to its high-affinity receptor on a mast cell surface results in massive and rapid cell degranulation and the inflammatory response outlined on page 125. The antigens involved are typically inert molecules present in the environment (these are termed allergens; see pp. 1091–1092).

The immediate effects of allergen exposure are often very florid (**early phase response**). Allergic disorders also have a second phase, occurring a few hours after exposure and lasting up to several days. These ‘**late phase responses**’ (LPRs) are mediated by Th2 cells recognizing peptide epitopes of the allergen. Recruitment of eosinophils is often a prominent feature.

From a pathological and therapeutic viewpoint, the LPR gives rise to chronic inflammation, which is difficult to control. In **asthma**, the LPR causes prolonged wheezing, which can be fatal. Immediate hypersensitivity is usually responsive to antihistamines but the LPR is not, requiring powerful immune modulators such as corticosteroids.

In immunopathological terms, in the LPR:

- Neutrophils and eosinophils are prominent in the first 6–18 hours and may persist for 2–3 days.
- Th2 cells accumulate around small blood vessels and persist for 1–2 days.
- Mediators responsible for the cellular infiltrate include platelet-activating factor and leukotrienes (**Box 8.21**).

<table>
<thead>
<tr>
<th>Box 8.21</th>
</tr>
</thead>
</table>

**Mediators involved in the allergic response**

**Pre-formed mediators**

- Histamine and serotonin:
  - Bronchoconstriction
  - Increased vascular permeability
- Neutrophil chemotactic factor (NCF) and eosinophil chemotactic factor (ECF):
  - Induction of inflammatory cell infiltration

**Newly formed mediators (membrane-derived)**

- Leukotriene (LT) B₄:
  - Chemoattractant
- LTC₄, LTD₄, LTE₄ (slow-reacting substance of anaphylaxis, SRS-A):
  - Sustained bronchoconstriction and oedema
- Prostaglandins and thromboxanes:
Platelet-activating factor (PAF)

– Prolonged airway hyperactivity

• Th2 cytokines IL-4 and IL-5 and chemokines such as eotaxin act as growth and activation stimuli for eosinophils, which are capable of extensive tissue damage. Th2 cytokines are also responsible for the class switch of Ig production towards IgE, maintaining the cycle of immediate and late responses.

**What makes an allergen so powerful?**

Several allergens are proteolytic enzymes, allowing them to cross skin and mucosal barriers. They are often contained within small, aerodynamic particles (e.g. pollen grains) that gain access to nasal and bronchial mucosa.

**Why do some people react and others not?**

The tendency to develop allergic responses (known as atopy) shows strong heritability. Between 20% and 30% of the UK population is atopic and two, one or no atopic parents pass on the atopic trait to their children with a risk of 75%, 50% and 15%, respectively. In developing nations, the tendency to allergy is estimated at one-tenth of the rate in industrialized countries. Amongst the predisposing genes are those encoding the β chain of the high-affinity receptor for IgE and IL-4, both strongly associated with Th2 pathways. The presence of Th2 cells recognizing allergens is the pathological hallmark of allergy.

**What environmental factors are involved?**

Early exposure to allergens (even in utero) may be a factor in developing atopy. Over-zealous attention to cleanliness (the hygiene hypothesis) in developed societies (use of antibiotics, reduced exposure to pathogens that might favour a Th1-like environment) may favour a reduction in Treg activity. This environmental factor is shown by the rapid increase of allergy in the eastern part of Germany following reunification in 1990.

In clinical terms, approximately two-thirds of atopic individuals (who can be identified as those with circulating allergen-specific IgE) have **clinical allergic disease** (equating to 15–20% of the UK population). Allergy accounts for up to one-third of school absences because of chronic illness. Allergic disorders include allergic rhinitis (hay fever), allergic eczema, bee and wasp venom allergy, some forms of food allergy, urticaria and angio-oedema.

**Diagnosis.**

Diagnosis of allergic disease is usually made on the history and backed up by skin-prick testing (insertion of a tiny quantity of allergen under the skin and measurement of the size of the weal) and/or measurement of serum allergen-specific IgE. Mast cell tryptase serum levels peak 1–2 hours after an event, remaining high for 24 hours.

**Treatment.**
Avoidance is the first line of therapy. Other measures are as follows:

- **Antihistamines** are effective for many immediate hypersensitivity reactions (but have no role in the treatment of asthma).

- **Corticosteroids** have several well-identified modifying actions in the allergic process: production of prostaglandin and leukotriene mediators is suppressed, inflammatory cell recruitment and migration are inhibited, and vasoconstriction leads to reduced cell and fluid leakage from the vasculature.

- **Cysteinyl leukotriene receptor antagonists (LTRAs)** inhibit leukotrienes (LTs) by blocking the type I receptor (e.g. montelukast, used in asthma, particularly the aspirin-induced type).

- **Omalizumab** is a monoclonal antibody that binds IgE. It is used in severe asthma (see p. 1099) that cannot be controlled with a corticosteroid plus a long-acting β₂ agonist. Treatment must be initiated in a specialist centre where staff have experience of treating severe, persistent asthma.

- **Desensitization (allergen immunotherapy)** can be used. It works on the principle that allergy can be prevented by inoculation if the allergen is given in a controlled way. Desensitization is indicated for disorders in which the hypersensitivity is IgE-mediated: for example, life-threatening allergy to insect stings, drug allergy and allergic rhinitis. An induction course of subcutaneous injections of increasing doses of the allergen extract, given once every 1–2 weeks, is followed by maintenance injections monthly for 2–3 years. A systematic review of 51 published randomized, placebo-controlled clinical trials, enrolling a total of nearly 3000 participants, showed a low risk of adverse events with consistent clinical benefit. From an immunological viewpoint, desensitization seems capable of modifying the allergic response at several levels (Box 8.22). Sublingual allergen immunotherapy (using grass pollen extract tablets of Phl p 5 from timothy grass; see p. 1077) is used in hay fever that has not responded to anti-allergic drugs (the first dose is given under medical supervision).

---

**Box 8.22**

**Mechanism of action of desensitization for allergy**
### Anaphylaxis

Anaphylaxis is a serious allergic reaction that is rapid in onset and may cause death. It arises as an acute, generalized IgE-mediated immune reaction involving specific antigen, mast cells and basophils. The reaction requires priming by the allergen, followed by re-exposure. To provoke anaphylaxis, the allergen must be systemically absorbed, after either ingestion or parenteral injection. A range of allergens that provoke anaphylaxis has been identified ([Box 8.23](#)).

### Box 8.23

**Sources of allergens known to provoke anaphylaxis**

#### Foods
- Nuts: peanuts (*protein-arachis hypogaea Ara h 2*), Brazil, cashew
- Shellfish: shrimp (*allergen Met e 1*), lobster
- Dairy products
- Egg
- More rarely: citrus fruits, mango, strawberry, tomato

#### Venoms
- Wasps, bees, yellow-jackets, hornets

#### Medications
- Antisera (tetanus, diphtheria), dextran, latex, some antibiotics

Anaphylaxis is rare, and the symptom/sign constellation ranges from widespread urticaria to cardiovascular collapse, laryngeal oedema, airway obstruction and respiratory arrest leading to death:

<tbody>
<tr>
<td>IgG blocking antibodies</td>
<td>During repeated exposure to desensitizing allergen, IgG class antibodies develop (especially IgG4 subclass); these compete with the pathogenic IgE for allergen binding and/or prevent IgE–allergen complexes binding to mast cell high-affinity IgE receptors</td>
</tr>
<tr>
<td>Regulation</td>
<td>Exposure to repeated desensitizing allergen induces Treg cells, which recognize allergen but invoke regulatory immune responses, dampening down migration, infiltration and inflammation</td>
</tr>
<tr>
<td>Immune deviation</td>
<td>A shift away from Th2- to Th1-producing CD4 cells results in the generation of cytokines (e.g. IFN-γ) that are inhibitory to IgE production</td>
</tr>
</tbody>
</table>
• Fatal reactions to penicillin occur once every 7.5 million injections.

• Between 1 in 250 and 1 in 125 individuals have severe reactions to bee and wasp stings, and a death takes place every 6.5 million stings, with 60–80 deaths per year in North America and 5–10 in the UK.

Central to the pathogenesis of anaphylaxis is the activation of mast cells and basophils, with systemic release of some mediators and generation of others. The initial symptoms may appear innocuous: tingling, warmth and itchiness. The ensuing effects on the vasculature give vasodilatation and oedema. The consequence of these may be no more than a generalized flush, with urticaria and angio-oedema. More serious sequelae are hypotension, bronchospasm, laryngeal oedema and cardiac arrhythmia or infarction. Death may occur within minutes.

Serum platelet-activating factor (PAF) levels correlate directly with the severity of anaphylaxis, whereas PAF acetylhydrolase (the enzyme that inactivates PAF) correlates inversely and is significantly lower in peanut-sensitive patients with fatal anaphylactic reactions.

### Management

Early recognition and treatment are essential *(Box 8.24)*.

#### Box 8.24

**Treatment of acute anaphylaxis**

**Clinical features**

• Bronchospasm
• Facial and laryngeal oedema
• Hypotension
• Nausea, vomiting and diarrhoea

**Management**

• ABCDE (airway, breathing, circulation, disability, exposure)
• Position the patient lying flat with feet raised
• Ensure the airway is free
• Give oxygen
• Monitor blood pressure
• Establish venous access
• Administer 0.5 mg *intramuscular* adrenaline (epinephrine) 0.5 mL of 1 : 1000 adrenaline, i.e. 1 mg/mL, and repeat after 5 min if shock persists. (Dose reduced for children or adults on beta-blockers)
• Administer intravenous antihistamine (e.g. 10–20 mg chlorphenamine) slowly
• Administer 100 mg intravenous hydrocortisone.
  – If hypotension persists, give 1–2 L of intravenous fluid
  – If hypoxia is severe, assisted ventilation may be required
  – Take blood for tryptase levels (aids diagnosis)

The best treatment is prevention. Avoidance of triggering foods, particularly nuts and shellfish, may require almost obsessive self-discipline. Patient education is necessary and many are instructed in the self-administration of adrenaline (epinephrine) and carry pre-loaded syringes. Desensitization has a well-established place in the management of this disorder, particularly if exposure is unavoidable or unpredictable, as in insect stings. In peanut allergy (see p. 216), it has been shown that early introduction of peanuts in children modulates the response in later life.

Autoimmune Disease
Autoimmunity is when the immune response turns against self, i.e. recognizes ‘self’ antigens. The vast array of possible T cell receptors (TCRs) and antibodies that can be generated by the host make it highly probable that at least a small proportion can recognize self (i.e. are autoreactive). Moreover, a degree of autoreactivity is physiological – the TCR is designed to interact both with the peptide epitope in the HLA molecule binding groove and with the HLA molecule itself.

The critical event in the development of autoimmune disease is when T and B lymphocytes bearing these receptors for ‘self’ become activated. The following are the major checkpoints that the immune system has in place to prevent this:

1. removal of TCRs with very strong affinity for ‘self’ in the thymus
2. the presence of naturally arising regulatory T lymphocytes (Tregs)
3. the requirement for a danger signal to license dendritic cells to activate CD4 T lymphocytes.

Autoimmune diseases affect 5% of the population at some stage of their life.

Failure of checkpoint 1, thymic education
During thymic education, TCRs with dangerously high affinity for self are deleted. It has become apparent that this process relies upon the thymic expression of self antigens. Situations that compromise the expression of a self protein would be expected to favour the development
of autoimmunity. Indeed, in a rare group of patients who develop multiple autoimmune disorders affecting the adrenal and parathyroid glands (autoimmune polyglandular syndrome type 1; see p. 1239), there is a defect in the autoimmune regulator (AIRE) gene, which controls thymic expression of a host of self genes. When the gene malfunctions, there is reduced expression of self proteins in the thymus and autoimmune disease is a consequence.

**Failure of checkpoint 2, regulatory T lymphocytes**

An example of Treg failure is the defect in the gene encoding Foxp3, a critical transcription factor in Tregs (see p. 132), which leads to IPEX (see p. 132). IPEX is very rare but it serves to indicate how Treg defects can lead to autoimmune disease. Laboratory studies in this area are revealing subtle Treg defects in several autoimmune diseases (e.g. type 1 diabetes, multiple sclerosis, rheumatoid arthritis). The role of FoxP3 in regulating peripheral immune responses highlights the control of immune expansion and regulation of immunological ‘space’. Another component of this process is the contraction of an immune response once the infection has been dealt with. Autoimmune lymphoproliferative syndrome (ALPS) is a disorder with defects in either Fas, its ligand (FasL or CD95) or the associated intracellular signalling pathway. Individuals develop multiple cytopenias, organ-specific autoimmunity, and lymphoproliferation that may mimic lymphoma. The common problem is the inability to ‘switch off’ activated T cells. Treatment is with haemopoietic stem cell transplantation if the disorder is severe. Many patients with multiple cytopenias, including Evans syndrome (autoimmune thrombocytopenia and haemolytic anaemia), are revealed to have ALPS defects when appropriately tested.

**Failure of checkpoint 3, CD4 T lymphocyte activation against an autoantigen (or its mimic)**

For an autoimmune disease to develop, there must be presentation of autoantigens to a naive, potentially autoreactive CD4 T lymphocyte by activated DCs. This could happen in one of two ways:

- Tissue damage due to infection leads to both the release of hidden self antigens and the provision of sufficient danger signals to activate DCs, which in turn activate autoreactive CD4 T lymphocytes, as well as the pathogen-specific ones. This is often termed ‘bystander activation’.

- A pathogen mimics a self antigen. In the process of making an entirely appropriate immune response against the pathogen, T or B lymphocytes are generated that also have the capacity to recognize self. This is termed molecular mimicry.

It is unlikely that, for the common autoimmune diseases (Box 8.25), there is a ‘single checkpoint’ explanation. Rather, it is likely that multiple subtle defects, at various checkpoints, are at play.

### Mechanisms of tissue damage in autoimmune disease

Figure 8.15 illustrates potential mechanisms of immune damage in autoimmune disease.
Tissue damage via chronic inflammation

In a number of autoimmune diseases (e.g. type 1 diabetes, multiple sclerosis), autoreactive T lymphocytes are likely to be the main drivers of disease and tissue damage. Th1 cells, CTLs and Th17 cells induce chronic inflammation and release cytokines that recruit other effector cells (macrophages) or are directly toxic (e.g. insulin-producing β-cells are susceptible to the combined effects of IL-1β, IFN-γ and IL-17 in type 1 diabetes).

IgG4 disease

IgG4 disease is a fibro-inflammatory condition with the formation of swellings at multiple sites infiltrated with IgG4-producing plasma cells and a tendency to high circulating levels of IgG4. Unlike many autoimmune disorders, IgG4-related disease is driven by Th2 T cells in association with high numbers of FoxP3⁺ T cells. The first recognized form of this disorder was autoimmune pancreatitis, but lesions in the biliary tree, salivary glands, periorbital tissues, kidneys, lungs, lymph nodes, meninges, aorta, breast, prostate, thyroid, pericardium and skin are recognized (Box 8.26). The current hypothesis is that Th2 cells drive the activation of macrophages and myofibroblasts, leading to fibrosis and IgG4 plasma cell proliferation.

**Tissue damage via autoantibodies**

Examples of damage through direct binding to a target cell or structure, with recruitment of complement and other destructive processes, include:

- **myasthenia gravis** (autoantibodies against the acetylcholine receptor cause damage to the neuromuscular junction)

- **autoimmune haemolytic anaemia** (autoantibody targets red blood cell autoantigens, leading to lysis)

- **Goodpasture syndrome** (anti-glomerular basement membrane autoantibodies damage glomerular integrity).

Autoantibodies can also bind their antigen in the circulation to form immune complexes. When these are deposited in the tissues, complement- and cell-mediated immune reactions are initiated. Immune complexes preferentially deposit in sites such as the kidney glomerulus, leading to chronic kidney disease. This is a feature of SLE, in which the autoantigen within the immune complexes is DNA.

Autoantibody binding may act by binding to surface receptors. In Graves' thyroiditis, for example, the anti-thyroid stimulating hormone receptor antibody stimulates follicular cells to produce thyroid hormones, leading to hyperthyroidism.

**Common autoimmune diseases**
There are now over 80 diseases classified as autoimmune. The autoimmune origin of some of these diseases is very clear-cut but that is not so for others, and both major and minor factors must be defined.

**Major criteria**

- There is evidence of autoreactivity (e.g. activated or memory autoreactive T lymphocytes or autoantibodies).
- A clinical response to immune suppression can be demonstrated.
- Passive transfer of the putative immune effector (e.g. autoreactive T lymphocyte or autoantibody) causes the disease (this is the hardest criterion to satisfy in humans but is the most stringent).

**Minor criteria**

- An animal model exists that resembles the human condition, and in which there is a similar loss of immunological tolerance to self.
- There is evidence that, in the animal model, passive transfer of the putative immune effectors reproduces the disease in a naive animal.
- There is an HLA association (a frequent indicator that a disease is autoimmune).

**Further reading**

**Organ Rejection in Clinical Transplantation**

The outcome of an allograft (i.e. a graft between genetically non-identical members of the same species) in the absence of adequate immunosuppressive therapy is **immunological rejection**. Histological analysis of rejected organs shows a range of immunological processes in action (*Box 8.27*). With modern tissue-matching approaches, hyperacute rejection is rare and acute rejection can usually be prevented or treated with immunosuppression. The process of chronic rejection typically takes place over several years and is the main reason for organ graft failure.

**Box 8.27**

The antigens recognized in acute and chronic graft responses are donor HLA molecules (alloantigens):

- In acute rejection, it is thought that the predominant response is against intact HLA molecules (direct allorecognition) and is mediated by CD4\(^+\) and CD8\(^+\) T lymphocytes.
- As the rejection process becomes more chronic, peptides from donor HLA molecules are processed and presented to T lymphocytes by host HLA molecules (indirect allorecognition).

**Immune-Based Therapies**

Manipulating the immune response in a therapeutic setting has seen many successes, as evidenced by the control of organ rejection in clinical transplantation through targeted
Monoclonal antibodies offer the opportunity to neutralize the unwanted effects of cytokines, or to direct immune responses, drugs, toxins or irradiation against a specific target, whether it be a tumour cell or an immune cell involved in a damaging autoimmune response. Natural antiviral mediators, such as the interferons, are already in the clinic as therapies for chronic viral infection, amongst other things.

### Monoclonal antibody therapy (targeted therapy)

The combined power of monoclonal antibody (MAb) and recombinant DNA technology has led to a series of ‘designer’ drugs, which have been engineered so that they:

- are exquisitely targeted
- have optimal effector function
- do not carry antigenic segments that may incite a neutralizing response in the host.

In general, this has meant a process of ‘humanizing’ antibodies of mouse origin and selecting an appropriate effector function. For example, a MAb designed to remove a subpopulation of lymphocytes from the patient should have good complement-fixing ability or bind well to receptors on phagocytes, whereas a MAb designed to ‘modulate’ a cell without depletion should have these functions removed. An example of the latter is an anti-CD3 MAb that has modified Fc regions and is designed to downregulate functionally, but not deplete, T lymphocytes. Many examples of MAbs in current use are described in individual chapters. Therapeutic MAbs are potent modifiers of essential components of immune responses and therefore carry both predictable and unpredictable risks. For example, anti-TNF therapies increase the risk of invasive viral and mycobacterial infection. The new inhibitors of integrins, such as natalizumab, have been associated with JC virus reactivation in patients, leading to progressive multifocal leukoencephalopathy (PML). Since integrins are essential for the migration of T cells into tissues, the blockade prevents egress into inflammatory sites, but also reduces immune surveillance of infection. Emerging therapies require an increasing vigilance for side-effects and appropriate counselling of patients.

### Immunosuppressive drugs

- **Glucocorticosteroids** (cortisone, hydrocortisone, prednisone and prednisolone) are the most commonly used steroids and have a variety of effects on immune function, including:

  - potent effects on monocyte production of the pro-inflammatory cytokines IL-1 and TNF-α
  - blockade of T lymphocyte production of IL-2 and IFN-γ
  - reduced activation and migration of a range of innate and adaptive immune cells.

- **Ciclosporin, tacrolimus and rapamycin** (sirolimus) have similar effects on T lymphocyte function. Ciclosporin and tacrolimus are calcineurin inhibitors and inhibit Ca\(^{2+}\)-dependent second messenger signals in T lymphocytes following activation via TCRs. By contrast, sirolimus achieves a similar effect but acts at the level of post-activation events in the
nucleus.

- **Purine analogues** such as azathioprine are also frequently used as anti-inflammatory drugs in conjunction with steroids and act by inhibiting DNA synthesis in dividing adaptive immune cells. Similar in mode of action, but more powerful, is mycophenolate mofetil (MMF).

- **Alkylating agents** that interfere with DNA synthesis, such as cyclophosphamide, are also used for immunosuppression.

- **Kinase inhibitors** have profoundly improved the treatment of some malignancies with previously very poor outcomes. Tyrosine kinases (TYK) are ubiquitous regulators of cell activation, promoting cell division and proliferation in response to growth factors and cytokines. Inhibition of the signalling pathways can lead to immune suppression. In immune cells, the relevant kinases include the Janus kinases (JAK) that signal through the STAT pathway. Inherited mutations in JAK-STAT pathway molecules can lead to immunodeficiency or, if the mutation causes constant (constitutive) activation, can cause uncontrolled cell division independent of growth factors: that is, cancer. Specific inhibitors of TYK have been developed for a range of cancers and as T and B cell immune suppressants.

### Cytokines and anticytokines

Cytokines are pleiotropic agents with powerful pro-inflammatory and immunosuppressive effects, and are attractive targets for therapies that inhibit or enhance their function. TNF-α targeting agents (cytokine modulators) have been tested in rheumatoid arthritis, as has the recombinant IL-1 receptor antagonist anakinra, although with much less success. None the less, the good safety profile of anakinra has prompted its use in other diseases, and a beneficial effect has been shown in type 2 diabetes, which may have an innate inflammatory component. IL-2 and its receptor (CD25) are also obvious candidates for immune therapies. Interferons are successfully used to boost pro-inflammatory immunity in chronic virus infection.

### Restoring tolerance in autoimmune diseases and allergy

One of the goals for immune-based therapies for autoimmune disease is not simply to achieve immunosuppression, but also to restore immunological tolerance against the relevant autoantigens. In animal models, an effective means of achieving this is to administer the autoantigen itself, or key peptide epitopes from it. This is known as antigen-specific or peptide immunotherapy and is under trial in several autoimmune diseases, where it appears to induce Tregs. The diseases that have the most advanced clinical data are in the field of allergy. For example, administration of cocktails of peptides of the cat allergen Fel d 1 has led to a reduction in detectable skin-prick responses and improved clinical scores.

### Intravenous immunoglobulin

Intravenous immunoglobulin (IVIg) is a preparation of polyspecific IgG chemically purified from the plasma of large numbers (>20,000) of healthy donors. IVIg is used as a replacement therapy in patients with primary and secondary antibody deficiencies. However, when used for
inflammatory conditions, there is also a therapeutic benefit, although randomized placebo-controlled studies are few. In the USA, IVIg is only recommended for a small number of diseases in addition to antibody deficiency. These include: immune-mediated thrombocytopenia, Kawasaki syndrome, chronic inflammatory demyelinating polyneuropathy and post-transfusion purpura.

The mechanism of action is not known, but may include:

- blockade of Fc receptors to prevent pathogenic antibodies binding to phagocytes
- inhibition of autoantibody synthesis by B lymphocytes
- modulation of dendritic cell function
- inhibition of complement activation
- inhibition of specific cytokines
- induction of T cell regulation.

## Water and Electrolytes

### Distribution and Composition of Body Water

In normal, healthy people, the total body water constitutes 50–60% of lean body weight in men and 45–50% in women. In a healthy 70 kg male, total body water is approximately 42 L. This is contained in three major compartments:

- intracellular fluid (28 L, about 35% of lean body weight)
- extracellular – the interstitial fluid that bathes the cells (9.4 L, about 12%)
• plasma (also extracellular) (4.6 L, about 4–5%).

In addition, small amounts of water are contained in bone, dense connective tissue and epithelial secretions, such as the digestive secretions and cerebrospinal fluid (CSF).

The intracellular and interstitial fluids are separated by the cell membrane; the interstitial fluid and plasma are separated by the capillary wall (Fig. 9.1). In the absence of solute, water molecules move randomly and in equal numbers in either direction across a semi-permeable membrane. However, if solutes are added to one side of the membrane, the intermolecular cohesive forces reduce the activity of the water molecules. As a result, water tends to stay in the solute-containing compartment because there is less free diffusion across the membrane. This ability to hold water in the compartment can be measured as the osmotic pressure.

![FIGURE 9.1 Distribution of water between the vascular and extravascular (interstitial) spaces. This is determined by the equilibrium between hydrostatic pressure, which tends to force fluid out of the capillaries, and oncotic pressure, which acts to retain fluid within the vessel. The net flow of fluid outwards is balanced by 'suction' of fluid into the lymphatics, which returns it to the bloodstream. Similar principles govern the volume of the peritoneal and pleural spaces.]

**Osmotic pressure**

Osmotic pressure is the primary determinant of the distribution of water among the three major compartments. The concentrations of the major solutes in the compartments differ, each having one solute that is primarily limited to that compartment and therefore determines its osmotic pressure:

• The intracellular fluid contains mainly potassium (K\(^+\)) (most of the cell Mg\(^{2+}\) is bound and osmotically inactive).
• In the extracellular compartment, Na\(^+\) salts predominate in the *interstitial fluid*, and proteins in the plasma.

Regulation of the plasma volume is somewhat more complicated because of the tendency of the plasma proteins to hold water in the vascular space by an oncotic effect that is partly
counterbalanced by the hydrostatic pressure in the capillaries that is generated by cardiac contraction (Fig. 9.1). The composition of intracellular and extracellular fluids is shown in Box 9.1.

Osmotically active solutes cannot freely leave their compartment. The capillary wall, for example, is relatively impermeable to plasma proteins, and the cell membrane is ‘impermeable’ to Na⁺ and K⁺ because the Na⁺/K⁺-adenosine triphosphatase (ATPase) pump largely restricts Na⁺ to the extracellular fluid and K⁺ to the intracellular fluid. By contrast, Na⁺ freely crosses the capillary wall and achieves similar concentrations in the interstitium and plasma; as a result, it does not contribute to fluid distribution between these compartments. Similarly, urea crosses both the capillary wall and the cell membrane, and is osmotically inactive. Thus, the retention of urea in renal failure does not alter the distribution of the total body water.

To conclude, body Na⁺ stores are the primary determinant of the extracellular fluid volume. Thus, the extracellular volume – and therefore tissue perfusion – are maintained by appropriate alterations in Na⁺ excretion. For example, if Na⁺ intake is increased, the extra Na⁺ will initially be added to the extracellular fluid. The associated increase in extracellular osmolality will cause water to move out of the cells, leading to extracellular volume expansion. Balance is restored by excretion of the excess Na⁺ in the urine.

**Distribution of different types of replacement fluids**

Figure 9.2 shows the relative effects on the compartments of the addition of identical volumes of water, saline and colloid solutions. Thus, 1 L of water given intravenously as 5% glucose
(which is rapidly metabolized to energy, water and carbon dioxide) is distributed equally into all compartments, whereas the same amount of 0.9% saline remains in the extracellular compartment. The latter is thus the correct treatment for extracellular water depletion – sodium keeping the water in this compartment. The addition of 1 L of colloid with its high oncotic pressure stays in the vascular compartment and was a treatment for hypovolaemia, but 0.9% saline is now used.

**FIGURE 9.2** Relative effects of the addition of 1 L of (A) water, (B) saline 0.9% and (C) a colloid solution.

**Regulation of extracellular volume (Fig. 9.3)**
The extracellular volume is determined by the sodium concentration. The regulation of extracellular volume is dependent upon a tight control of sodium balance, which is exerted by
normal kidneys. Renal Na\(^+\) excretion varies directly with the effective circulating volume. In a 70 kg man, plasma fluid constitutes one-third of extracellular volume (4.6 L); of this, 85% (3.9 L) lies in the venous side and only 15% (0.7 L) resides in the arterial circulation.

The fullness of the arterial vascular compartment (effective arterial blood volume, EABV) is the primary determinant of renal sodium and water excretion: that is, the effective circulatory volume for the purposes of body fluid homeostasis.
The fullness of the arterial compartment depends upon a relationship between cardiac output and peripheral arterial resistance. Thus, diminished EABV is initiated by a fall in cardiac output or a fall in peripheral arterial resistance (an increase in the holding capacity of the arterial vascular tree). When the EABV is expanded, the urinary Na⁺ excretion is increased and can exceed 100 mmol/L. By contrast, the urine can be rendered virtually free of Na⁺ in the presence of EABV depletion and normal renal function.

These changes in Na⁺ excretion can result from alterations both in the filtered load, determined primarily by the glomerular filtration rate (GFR), and in tubular reabsorption, which is affected by multiple factors. In general, it is changes in tubular reabsorption that constitute the main adaptive response to fluctuations in the effective circulating volume. How this occurs can be appreciated from Box 9.2 and Figure 9.4, and from Figure 20.3 (see p. 725), which depicts the sites and determinants of segmental Na⁺ reabsorption. Although the loop of Henle and distal tubules make a major overall contribution to net Na⁺ handling, transport in these segments primarily varies with the amount of Na⁺ delivered; that is, reabsorption is flow-dependent. In comparison, the neurohumoral regulation of Na⁺ reabsorption according to body needs occurs primarily in the proximal tubules and collecting ducts. The diseases associated with malfunction of each section of the tubule are shown in Box 9.3.

                              | Secretion of potassium  
                              | Secretion of bicarbonate or H⁺  
                              | Liddle syndrome (see p. 166)  
                              | Pseudohypoaldosteronism type 1 (see p. 167)  
                              | Nephrogenic diabetes insipidus: resistance to actions of vasopressin. Leads to large volume of dilute urine with polyuria/polydipsia  
                              | Syndrome of inappropriate antidiuretic hormone secretion (SIADH; see pp. 1234–1235)  
                              | Type 1 renal tubular acidosis (see p. 178)                                                                                 |

**Neurohumoral regulation of extracellular volume**

This is mediated by volume receptors that sense changes in the EABV rather than alterations in the sodium concentration. These receptors are distributed in both the renal and cardiovascular tissues.

- **Intrarenal receptors.** Receptors in the walls of the afferent glomerular arterioles respond, via the juxtaglomerular apparatus, to changes in renal perfusion, and control the activity of the renin–angiotensin–aldosterone system (see pp. 727–728). In addition, sodium concentration in the distal tubule and sympathetic nerve activity alter renin release from the juxtaglomerular cells. Prostaglandins I₂ and E₂ are also generated within the kidney in response to angiotensin II, acting to maintain glomerular filtration rate and sodium and water excretion, and modulating the sodium-retaining effect of this hormone.

- **Extrarenal receptors.** These are located in the vascular tree in the left atrium and major thoracic veins, and in the carotid sinus body and aortic arch. These volume receptors respond to a slight reduction in effective circulating volume and this results in increased sympathetic nerve activity and a rise in catecholamines. In addition, volume receptors in the cardiac atria control the release of a powerful natriuretic hormone – atrial natriuretic peptide (ANP) – from granules located in the atrial walls (see p. 983).

  High-pressure arterial receptors (carotid, aortic arch, juxtaglomerular apparatus) predominate over low-pressure volume receptors in volume control in mammals. The low-pressure volume receptors are distributed in thoracic tissues (cardiac atria, right ventricle, thoracic veins, pulmonary vessels) and their role in the volume regulatory system is marginal.
Aldosterone and possibly ANP are responsible for day-to-day variations in Na\(^+\) excretion, through their respective ability to augment and diminish Na\(^+\) reabsorption in the collecting ducts.

- **A salt load**, for example, leads to an increase in the effective circulatory and extracellular volume, raising both renal perfusion pressure, and atrial and arterial filling pressure. The increase in the renal perfusion pressure reduces the secretion of renin, and subsequently that of angiotensin II and aldosterone (see Fig. 20.6), whereas the rise in atrial and arterial filling pressure increases the release of ANP. These factors combine to reduce Na\(^+\) reabsorption in the collecting duct, thereby promoting excretion of excess Na\(^+\).

- By contrast, in patients on a low Na\(^+\) intake or in those who become volume-depleted as a result of vomiting and diarrhoea, the ensuing decrease in effective volume enhances the activity of the renin–angiotensin–aldosterone system and reduces the secretion of ANP. The net effect is enhanced Na\(^+\) reabsorption in the collecting ducts, leading to a fall in Na\(^+\) excretion. This increases the extracellular volume towards normal.

With **more marked hypovolaemia**, a decrease in GFR leads to an increase in proximal and thin ascending limb Na\(^+\) reabsorption, which contributes to Na\(^+\) retention. This is brought about by enhanced sympathetic activity acting directly on the kidneys and indirectly by stimulating the secretion of renin/angiotensin II (see Fig. 9.3B) and non-osmotic release of antidiuretic hormone (ADH), also called vasopressin. The pressure natriuresis phenomenon may be the final defence against changes in the effective circulating volume. Marked persistent hypovolaemia leads to systemic hypotension and increased salt and water absorption in the proximal tubules and ascending limb of Henle. This process is partly mediated by changes in renal interstitial hydrostatic pressure and local prostaglandin and nitric oxide production. Recurrent episodes of hypovolaemia may, over time, lead to chronic kidney disease (CKD, Mesoamerican nephropathy). This condition is seen in young to middle-aged male agricultural workers along the Pacific coast in Central America, where strenuous work in high temperatures is thought to be a cause.

**Volume regulation in oedematous conditions**

Sodium and water are retained despite increased extracellular volume in oedematous conditions such as cardiac failure, hepatic cirrhosis and hypoalbuminaemia. Here the principal mediator of salt and water retention is the concept of arterial underfilling due to either reduced cardiac output or diminished peripheral arterial resistance. Arterial underfilling in these settings leads to reduction of pressure or stretch (i.e. ‘unloading’ of arterial volume receptors), which results in activation of the sympathetic nervous system, activation of the renin–angiotensin–aldosterone system and non-osmotic release of ADH. These neurohumoral mediators promote salt and water retention in the face of increased extracellular volume (see Fig. 9.3A).

**Mechanism of impaired escape from actions of aldosterone and resistance to ANP**
Not only is the activity of the renin–angiotensin–aldosterone system increased in oedematous conditions such as cardiac failure, hepatic cirrhosis and hypoalbuminaemia, but also the action of aldosterone is more persistent than in normal subjects and patients with primary hyperaldosteronism (Conn syndrome), who have increased aldosterone secretion (see p. 1230).

In normal subjects, high doses of mineralocorticoids initially increase renal sodium retention so that the extracellular volume is increased by 1.5–2 L. However, renal sodium retention then ceases, sodium balance is re-established, and there is no detectable oedema. This escape from mineralocorticoid-mediated sodium retention explains why oedema is not a characteristic feature of primary hyperaldosteronism. The escape is dependent on an increase in delivery of sodium to the site of action of aldosterone in the collecting ducts. The increased distal sodium delivery is achieved by high extracellular volume-mediated arterial overfilling. This suppresses sympathetic activity and angiotensin II generation, and increases cardiac release of ANP with resultant increase in renal perfusion pressure and GFR. The net result of these events is reduced sodium absorption in the proximal tubules and increased distal sodium delivery, which overwhelms the sodium-retaining actions of aldosterone.

In patients with the above oedematous conditions, such as heart failure, escape from the sodium-retaining actions of aldosterone does not occur and therefore they continue to retain sodium in response to aldosterone. Accordingly, they have substantial natriuresis when given spironolactone, which blocks mineralocorticoid receptors. Alpha-adrenergic stimulation and elevated angiotensin II increase sodium transport in the proximal tubule, and reduced renal perfusion and GFR further increase sodium absorption from the proximal tubules by presenting less sodium and water in the tubular fluid. Sodium delivery to the distal portion of the nephron, and thus the collecting duct, is reduced. Similarly, increased cardiac ANP release in these conditions requires optimum sodium concentration at the site of its action in the collecting duct for its desired natriuretic effects. Decreased sodium delivery to the collecting duct is therefore the most likely explanation for the persistent aldosterone-mediated sodium retention, absence of escape phenomenon and resistance to natriuretic peptides in these patients (see Fig. 9.3B).

Regulation of water excretion

Body water homeostasis is affected by thirst and the urine-concentrating and diluting functions of the kidney. These, in turn, are controlled by intracellular osmoreceptors, principally in the hypothalamus, to some extent by volume receptors in capacitance vessels close to the heart, and via the renin–angiotensin system. Of these, the major and best-understood control is via osmoreceptors. Changes in the plasma Na+ concentration and osmolality are sensed by osmoreceptors that influence both thirst and the release of ADH (vasopressin) from the supraoptic and paraventricular nuclei of the anterior hypothalamus.

ADH plays a central role in urinary concentration by increasing the water permeability of the normally impermeable cortical and medullary collecting ducts. There are three major G-protein coupled receptors for vasopressin (ADH):

- $V_{1A}$ found in vascular smooth muscle cells: activation induces vasoconstriction.
- $V_{1B}$ in the anterior pituitary and throughout the brain: this mediates the effect of ADH on the pituitary, leading to ACTH release.
- $V_2$ receptors in the principal cells of the kidney distal convoluted tubule and collecting ducts: these mediate the ADH response.

The ability of ADH to increase the urine osmolality is related indirectly to transport in the ascending limb of the loop of Henle, which reabsorbs NaCl without water. This process, which is the primary step in the counter-current mechanism, has two effects: it makes the tubular fluid dilute and the medullary interstitium concentrated. In the absence of ADH, little water is reabsorbed in the collecting ducts, and a dilute urine is excreted. By contrast, the presence of ADH promotes water reabsorption in the collecting ducts down the favourable osmotic gradient between the tubular fluid and the more concentrated interstitium. As a result, there is an increase in urine osmolality and a decrease in urine volume.

The cortical collecting duct has two cell types (see also p. 724) with very different functions:

- **Principal cells** (about 65%) have sodium and potassium channels in the apical membrane and, as in all sodium-reabsorbing cells, Na+/K+-ATPase pumps in the basolateral membrane.
- **Intercalated cells**, in comparison, do not transport NaCl (since they have a lower level of Na+/K+-ATPase activity) but play a role in hydrogen and bicarbonate handling and in potassium reabsorption in states of potassium depletion.

The ADH-induced increase in collecting duct water permeability occurs primarily in the principal cells. ADH acts on $V_2$ (vasopressin) receptors located on the basolateral surface of principal cells, resulting in the activation of adenyl cyclase. This leads to protein kinase activation and to pre-formed cytoplasmic vesicles that contain unique water channels (called aquaporins) moving to and then being inserted into the luminal membrane. Four renal aquaporins have been well characterized and are localized in different areas of the cells of the collecting duct. The water channels span the luminal membrane and permit water movement into the cells down a favourable osmotic gradient *(Fig. 9.5)*. This water is then rapidly returned to the systemic circulation across the basolateral membrane. When the ADH effect has worn off, the water channels aggregate within clathrin-coated pits, from which they are removed from the luminal membrane by endocytosis and returned to the cytoplasm. A defect in any step in this pathway, such as in attachment of ADH to its receptor or the function of the water channel, can cause resistance to the action of ADH and an increase in urine output. This disorder is called *nephrogenic diabetes insipidus*. 
Plasma osmolality

In addition to influencing the rate of water excretion, ADH plays a central role in osmoregulation because its release is directly affected by the plasma osmolality. At a plasma osmolality of <275 mosmol/kg, which usually represents a plasma Na⁺ concentration of <135–137 mmol/L, there is essentially no circulating ADH. As the plasma osmolality rises above this threshold, however, the secretion of ADH increases progressively.

Two simple examples will illustrate the basic mechanisms of osmoregulation, which is so efficient that the plasma Na⁺ concentration is normally maintained within 1–2% of its baseline value.

1. **Ingestion of a water load** leads to an initial reduction in the plasma osmolality, thereby diminishing the release of ADH. The ensuing reduction in water reabsorption in the collecting ducts allows the excess water to be excreted in a dilute urine.

2. **Water loss** resulting from sweating is followed by, in sequence, a rise in both plasma osmolality and ADH secretion, enhanced water reabsorption, and the appropriate excretion of a small volume of concentrated urine. This renal effect of ADH minimizes further water loss but does not replace the existing water deficit. Thus, optimal osmoregulation requires an increase in water intake, which is mediated by a concurrent stimulation of thirst. The importance of thirst can also be illustrated by studies in patients with central diabetes insipidus, who are deficient in ADH. These patients often complain of marked polyuria, which is caused by the decline in water reabsorption in the collecting ducts. However, they do not typically become hypernatraemic because urinary water loss is offset by the thirst mechanism.
Osmoregulation versus volume regulation

A common misconception is that regulation of the plasma Na\(^{+}\) concentration is closely correlated with the regulation of Na\(^{+}\) excretion. It is, however, related to volume regulation, which has different sensors and effectors (volume receptors) from those involved in water balance and osmoregulation (osmoreceptors).

The roles of these two pathways should be considered separately when evaluating patients.

- **A water load** is rapidly excreted (in 4–6 h) by inhibition of ADH release so that there is little or no water reabsorption in the collecting ducts. This process is normally so efficient that volume regulation is not affected and there is no change in ANP release or in the activity of the renin–angiotensin–aldosterone system. Thus, a dilute urine is excreted and there is little alteration in the excretion of Na\(^{+}\).

- **0.9% saline** administration, by contrast, causes an increase in volume but no change in plasma osmolality. In this setting, ANP secretion is increased, aldosterone secretion is reduced and ADH secretion does not change. The net effect is the appropriate excretion of the excess Na\(^{+}\) in a relatively iso-osmotic urine.

In some cases, both volume and osmolality are altered and both pathways are activated. For example, if a person with normal renal function eats salted crisps and peanuts without drinking any water, the excess Na\(^{+}\) will increase the plasma osmolality, leading to osmotic water movement out of the cells and increased extracellular volume. The rise in osmolality will stimulate both ADH release and thirst (the main reason why many restaurants and bars supply free salted foods), whereas the hypervolaemia will enhance the secretion of ANP and suppress that of aldosterone. The net effect is increased excretion of Na\(^{+}\) without water.

This principle of separate volume and osmoregulatory pathways is also evident in the syndrome of inappropriate antidiuretic hormone secretion (SIADH). Patients with SIADH (see pp. 1234–1235) have impaired water excretion and hyponatraemia (dilutional) caused by the persistent presence of ADH. However, the release of ANP and aldosterone is not impaired and, thus, Na\(^{+}\) handling remains intact. These findings have implications for the correction of the hyponatraemia in this setting, which initially requires restriction of water intake.

ADH is also secreted by non-osmotic stimuli such as stress (e.g. surgery, trauma), markedly reduced effective circulatory volume (e.g. cardiac failure, hepatic cirrhosis), psychiatric disturbance and nausea, irrespective of plasma osmolality. This is mediated by the effects of sympathetic overactivity on supraoptic and paraventricular nuclei. In addition to water retention, ADH release in these conditions promotes vasoconstriction owing to the activation of V\(_{1A}\) (vasopressin) receptors distributed in the vascular smooth muscle cells.

Regulation of cell volume

Most cells respond to swelling or shrinkage by activating specific metabolic or membrane-transport processes that return cell volume to its normal resting state. Within minutes of exposure to hypotonic solutions and resulting cell swelling, a common feature of many cells is the increase in plasma membrane potassium and chloride conductance. Although extrusion of
intracellular potassium certainly contributes to a regulatory volume decrease, the role of chloride efflux itself is modest, given the relatively low intracellular chloride concentration. Other intracellular osmolytes, such as taurine and other amino acids, are transported out of the cell to achieve a regulatory volume decrease. By contrast, these regulatory mechanisms are operative in reverse to protect cell volume under hypertonic conditions, as is the case in the renal medulla. The tubular cells at the tip of renal papillae, which are constantly exposed to a hypertonic extracellular milieu, maintain their cell volume on a long-term basis by actively taking up smaller molecules, such as betaine, taurine and myoinositol, and by synthesizing more sorbitol and glycerophosphocholine.

**Increased extracellular volume**
Increased extracellular volume occurs in numerous disease states. The physical signs depend on the distribution of excess volume and on whether the increase is local or systemic. According to Starling principles, distribution depends on:

- venous tone, which determines the capacitance of the blood compartment and thus hydrostatic pressure
- capillary permeability
- oncotic pressure – mainly dependent on serum albumin
- lymphatic drainage.

Depending on these factors, fluid accumulation may result in expansion of interstitial volume, blood volume or both.

**Clinical features**
Peripheral oedema is caused by expansion of the extracellular volume by at least 2 L (15%). The ankles are normally the first part of the body to be affected, although they may be spared in patients with lipodermatosclerosis (where the skin is tethered and cannot expand to accommodate the oedema). Oedema may be noted in the face, particularly in the morning. In a patient in bed, oedema may accumulate in the sacral area. Expansion of the interstitial volume also causes pulmonary oedema, pleural effusion, pericardial effusion and ascites. Expansion of the blood volume (overload) causes a raised jugular venous pressure, cardiomegaly, added heart sounds and basal crackles, as well as a raised arterial blood pressure.

**Aetiology**
Extracellular volume expansion is due to sodium chloride retention. Increased oral salt intake does not normally cause volume expansion because of rapid homeostatic mechanisms that increase salt excretion. However, a rapid intravenous infusion of a large volume of saline will cause volume expansion. Most causes of extracellular volume expansion are associated with renal sodium chloride retention.
**Heart failure**

Reduction in cardiac output and the consequent fall in effective circulatory volume and arterial filling lead to activation of the renin–angiotensin–aldosterone system, non-osmotic release of ADH, and increased activity of the renal sympathetic nerves via volume receptors and baroreceptors (see **Fig. 9.3B**). Sympathetic overdrive also indirectly augments ADH and renin–angiotensin–aldosterone response in these conditions. The cumulative effect of these mediators results in increased peripheral and renal arteriolar resistance and water and sodium retention. These factors lead to extracellular volume expansion and increased venous pressure, causing oedema formation.

**Hepatic cirrhosis**

The mechanism is complex but involves peripheral vasodilatation, due to increased nitric oxide generation, resulting in reduced EABV and arterial filling. This leads to an activation of a chain of events common also to other conditions with marked peripheral vasodilatation and heart failure (see **Fig. 9.3**). The cumulative effect results in increased peripheral and renal resistance, water and sodium retention, and oedema formation.

**Nephrotic syndrome**

Interstitial oedema is a common clinical finding with hypoalbuminaemia, particularly in the nephrotic syndrome. Expansion of the interstitial compartment is secondary to the accumulation of sodium in the extracellular compartment. This is due to an imbalance between oral (or parenteral) sodium intake and urinary sodium loss, as well as alterations of fluid transfer across capillary walls. The intrarenal site of sodium retention is the cortical collecting duct (CCD), where Na⁺/K⁺-ATPase expression and activity are increased threefold along the basolateral surface (see **Fig. 9.4**). In addition, amiloride-sensitive epithelial sodium channel activity is also increased in the CCD. The renal sodium retention should normally be counterbalanced by increased secretion of sodium in the inner medullary collecting duct, brought about by the release of ANP. This regulatory pathway is altered in patients with nephrotic syndrome by enhanced **kidney-specific** catabolism of cyclic guanosine monophosphate (cGMP, the second messenger for ANP) following phosphodiesterase activation.

Oedema generation was classically attributed to the decrease in plasma oncotic pressure and the subsequent increase in the transcapillary oncotic gradient. However, the oncotic pressure and transcapillary oncotic gradient remain unchanged and the transcapillary hydrostatic pressure gradient is not altered.

The mechanism for oedema seen in nephrotic syndrome is increased capillary hydraulic conductivity (a measure of permeability). This is determined by intercellular macromolecular complexes between the endothelial cells consisting of tight junctions (made of occludins, claudins and zonula occludens (ZO) proteins) and adherens junctions (made of cadherin, catenins and actin cytoskeleton). Elevated tumour necrosis factor alpha (TNF-α) levels in nephrotic syndrome activate protein kinase C, which changes phosphorylation of occludin and
capillary permeability. In addition, increased circulating ANP can increase capillary hydraulic conductivity by altering the permeability of intercellular junctional complexes. Furthermore, reduction in effective circulatory volume and the consequent fall in cardiac output and arterial filling can lead to a chain of events, as in cardiac failure and cirrhosis (see above and Fig. 9.3). These factors result in extracellular volume expansion and oedema formation.

**Sodium retention**

A decreased GFR decreases the renal capacity to excrete sodium. This may be acute, as in the acute nephritic syndrome (see p. 740), or may occur as part of the presentation of chronic kidney disease (CKD). In end-stage renal failure, extracellular volume is controlled by the balance between salt intake and its removal by dialysis.

Numerous drugs cause renal sodium retention, particularly in patients whose renal function is already impaired:

- **Oestrogens** cause mild sodium retention, due to a weak aldosterone-like effect. This is the reason for weight gain in the premenstrual phase.
- **Mineralocorticoids and liquorice** (the latter potentiates the sodium-retaining action of cortisol) have aldosterone-like actions.
- **Non-steroidal anti-inflammatory drugs (NSAIDs)** cause sodium retention in the presence of activation of the renin–angiotensin–aldosterone system by heart failure, in cirrhosis and in renal artery stenosis.
- **Thiazolidinediones (TZDs)**; see p. 1253) are widely used to treat type 2 diabetes. Their mechanism of action is attributed to binding and activation of the peroxisome proliferator-activated receptor gamma (PPAR-γ) system. PPARs are nuclear transcription factors, essential to the control of energy metabolism, which are modulated via binding with tissue-specific fatty acid metabolites. Of the three PPAR isoforms, γ has been extensively studied and is expressed at high levels in adipose and liver tissues, macrophages, pancreatic β cells and principal cells of the collecting duct. These drugs have been associated with salt and water retention and are contraindicated in patients with heart failure. TZD-induced oedema (like insulin) is also due to upregulation of epithelial Na transporter channel (ENaC) but by different pathways. Diuretics of choice for TZD-induced oedema are amiloride and triamterene.

Substantial amounts of sodium and water may accumulate in the body without clinically obvious oedema or evidence of raised venous pressure. In particular, several litres may accumulate in the pleural space or as ascites; these spaces are then referred to as ‘third spaces’. Bone may also act as a ‘sink’ for sodium and water.

**Other causes of oedema**

- Initiation of insulin treatment for type 1 diabetes and refeeding after malnutrition are both associated with the development of transient oedema. The mechanism is complex but involves upregulation of ENaC in the principal cell of the collecting duct. This transporter is
amiloride-sensitive, which makes amiloride or triamterene the diuretic of choice in insulin-induced oedema.

- Oedema may result from increased capillary pressure owing to relaxation of pre-capillary arterioles. The best example is the peripheral oedema caused by dihydropyridine calcium-channel blockers such as nifedipine, which affects up to 10% of the patients. Oedema is usually resolved by stopping the offending drug.

- Oedema is also caused by raised interstitial oncotic pressure as a result of increased capillary permeability to proteins. This can occur as part of a rare complement-deficiency syndrome; with therapeutic use of interleukin 2 in cancer chemotherapy; or in ovarian hyperstimulation syndrome (see p. 1222).

**Idiopathic oedema of women**

This, by definition, occurs in women without heart failure, hypoalbuminaemia, and renal or endocrine disease. Oedema is intermittent and often worse in the premenstrual phase. The condition remits after the menopause. Patients complain of swelling of the face, hands, breasts and thighs, and a feeling of being bloated. Sodium retention during the day and increased sodium excretion during recumbency are characteristic; an abnormal fall in plasma volume on standing, caused by increased capillary permeability to proteins, may be the cause of this. The oedema may respond to diuretics but returns when they are stopped. A similar syndrome of diuretic-dependent sodium retention can be caused by abuse of diuretics – for instance, as part of an attempt to lose weight – but not all women with idiopathic oedema admit to having taken diuretics, and the syndrome was described before diuretics were introduced for clinical use, so the cause remains unclear.

**Local increase in oedema**

This does not reflect disturbances of extracellular volume control per se but can cause clinical confusion. Examples are ankle oedema due to venous damage following thrombosis or surgery, ankle or leg oedema due to immobility, oedema of the arm due to subclavian thrombosis, and facial oedema due to superior vena caval obstruction.

**Management**

The underlying cause should be treated where possible. Heart failure, for example, should be treated and offending drugs such as NSAIDs withdrawn.

Sodium restriction has only a limited role but is useful in patients who are resistant to diuretics. Sodium intake can easily be reduced to approximately 100 mmol (2 g) daily; reductions below this are often difficult to achieve without affecting the palatability of food.

Manœuvres that increase venous return (e.g. strict bed rest or water immersion) stimulate salt and water excretion by effects on cardiac output and ANP release, but they are seldom of practical value.

The mainstay of treatment is the use of **diuretic agents**, which increase sodium, chloride and
water excretion in the kidney (Box 9.4). These agents act by interfering with membrane ion pumps that are present on numerous cell types; they mostly achieve specificity for the kidney by being secreted into the proximal tubule, resulting in much higher concentrations in the tubular fluid than in other parts of the body.

### Clinical use of diuretics

**Loop diuretics**

These potent diuretics are useful in the treatment of any cause of systemic extracellular volume overload. They stimulate excretion of both sodium chloride and water by blocking the sodium-potassium-2-chloride (NKCC2) channel in the thick ascending limb of Henle (Fig. 9.6) and are useful in stimulating water excretion in states of relative water overload. They also act by causing increased venous capacitance, resulting in rapid clinical improvement in patients with
left ventricular failure, preceding the diuresis. Unwanted effects include:
- urate retention, causing gout
- hypokalaemia
- hypomagnesaemia
- decreased glucose tolerance
- allergic tubulointerstitial nephritis and other allergic reactions
- myalgia – especially with high-dose bumetanide
- ototoxicity (due to an action on sodium pump activity in the inner ear) – particularly with furosemide
- interference with excretion of lithium, resulting in toxicity.

**FIGURE 9.6** Transport mechanisms in the thick ascending limb of the loop of Henle. Sodium chloride is reabsorbed in the thick ascending limb by the bumetanide-sensitive sodium–potassium–2–chloride co-transporter (NKCC2). The electroneutral transporter is driven by the low intracellular sodium and chloride concentrations generated by the Na⁺/K⁺-ATPase and the kidney-specific basolateral chloride channel (CLC-Kb). The availability of luminal potassium is rate-limiting for NKCC2, and recycling of potassium through the ATP-regulated potassium channel (renal outer medulla K⁺ channel, ROMK) ensures the efficient functioning of the NKCC2 and generates a lumen-positive transepithelial potential. Calcium and magnesium, along with potassium and sodium, are also absorbed paracellularly in the thick ascending loop. **Bartter syndrome:** loss of function mutations for the different types of syndrome. (a) NKCC2 (type I). (b) ROMK (type II). (c) CLC-Kb (type III). (d) Barttin (type IV). In addition, type V may be caused by a gain of function mutation of the calcium-sensing receptor (not shown).

There is little to choose between the drugs in this class. Bumetanide has a better oral bioavailability than furosemide, particularly in patients with severe peripheral oedema, and has more beneficial effects than furosemide on venous capacitance in left ventricular failure.

**Thiazide diuretics**
Thiazide diuretics (see p. 985) are less potent than loop diuretics. They act by blocking a
sodium chloride channel in the **distal convoluted tubule** (Gitelman syndrome; see p. 166) (Fig. 9.7). They cause relatively more urate retention, glucose intolerance and hypokalaemia than loop diuretics. They interfere with water excretion and may cause hyponatraemia, particularly if combined with amiloride or triamterene. This effect is clinically useful in diabetes insipidus. Thiazides reduce peripheral vascular resistance by mechanisms that are not completely understood but do not appear to depend on their diuretic action, and are widely used in the treatment of essential hypertension. They are also used extensively in mild to moderate cardiac failure. Thiazides reduce calcium excretion. This effect is useful in patients with idiopathic hypercalciuria but may cause hypercalcaemia. Numerous agents are available, with varying half-lives but little else to choose between them. Metolazone is not dependent for its action on glomerular filtration, and therefore retains its potency in renal impairment.

**FIGURE 9.7** Transport mechanisms in the distal convoluted tubule. (a) Sodium chloride is usually reabsorbed by the apical thiazide-sensitive sodium–chloride co-transporter (NCCT) in the distal convoluted tubule. (b) The electroneutral transporter is driven by the low intracellular sodium and chloride concentrations generated by the Na"/K"-ATPase, and an undefined basolateral chloride channel. In this nephron segment, there is an apical calcium channel and a basolateral sodium-coupled exchanger. The mechanisms for the transport of magnesium are similar to those for calcium. TRPM6 is a member of the transient receptor potential family. Mutation of NCCT leads to decreased reabsorption of sodium chloride and increased absorption of calcium (Gitelman syndrome). Overactivity of NCCT leads to Gordon syndrome (see pp. 167–168).

**Potassium-sparing diuretics**

Potassium-sparing diuretics (see Fig. 9.8) are of two types:

- **Aldosterone antagonists**, which compete with aldosterone in the collecting ducts and reduce sodium absorption, e.g. spironolactone and eplerenone (which has a shorter half-life). Spironolactone is used in patients with heart failure because it significantly reduces the mortality in these individuals by antagonizing the fibrotic effect of aldosterone on the heart. Eplerenone is devoid of antiandrogenic or antiprogesterone properties.
- **Amiloride and triamterene**, which inhibit sodium uptake by blocking epithelial sodium channels in the collecting duct and reduce renal potassium excretion by reducing lumen-negative transepithelial voltage. They are mainly used as potassium-sparing agents with thiazide or loop diuretics.

![Aldosterone-regulated transport in the cortical collecting ducts.](image)

**FIGURE 9.8** Aldosterone-regulated transport in the cortical collecting ducts. Under normal conditions, the *epithelial sodium channel* is the rate-limiting barrier for the normal entry of sodium from the lumen into the cell. The resulting lumen-negative transepithelial voltage (indicated by the minus sign) drives potassium secretion from the principal cells and proton secretion from the α-intercalated cells (see Fig. 9.12). (a) Site of action of amiloride and triamterene and mutation of epithelial sodium channel gene (*Liddle syndrome*) produces reabsorption of sodium and increased secretion of potassium (not shown). (b) Site of action of aldosterone antagonists. Mutation of the gene encoding mineralocorticoid receptor leads to salt wasting and decreased secretion of potassium.

**Carbonic anhydrase inhibitors**

These are relatively weak diuretics and are seldom used, except in the treatment of glaucoma. They cause metabolic acidosis and hypokalaemia.

**Aquaretics (vasopressin or antidiuretic hormone antagonists)**

Vasopressin V<sub>2</sub> receptor antagonists are very useful agents in the treatment of conditions associated with elevated levels of vasopressin, such as heart failure, cirrhosis and SIADH (see p. 1235). Non-peptide vasopressin V<sub>2</sub> receptor antagonists are efficacious in producing free water diuresis in humans. Studies in patients with heart failure and cirrhosis suggest that such agents will allow normalization of serum osmolality with less water restriction (see p. 164).

**Resistance to diuretics**

Resistance may occur as a result of:
• poor bioavailability
• reduced GFR, which may be due to decreased circulating volume despite oedema (e.g. nephrotic syndrome, cirrhosis with ascites) or intrinsic renal disease
• activation of sodium-retaining mechanisms, particularly aldosterone.

**Intravenous administration** of diuretics may establish a diuresis. **High doses** of loop diuretics are required to achieve adequate concentrations in the tubule if GFR is depressed. However, the daily dose of furosemide must be limited to a maximum of 2 g for an adult because of ototoxicity. Intravenous albumin solutions restore plasma oncotic pressure temporarily in the nephrotic syndrome and allow mobilization of oedema but do not increase the natriuretic effect of loop diuretics.

**Combinations** of various classes of diuretics are extremely helpful in patients with resistant oedema. A loop diuretic plus a thiazide inhibit two major sites of sodium reabsorption; this effect may be further potentiated by addition of a potassium-sparing agent. Metolazone in combination with a loop diuretic is particularly useful in refractory congestive cardiac failure because its action is less dependent on glomerular filtration. However, this potent combination can cause severe electrolyte imbalance. Both aminophylline and dopamine increase renal blood flow and may be useful in refractory cardiogenic sodium retention. In addition, theophyllines, by inhibiting phosphodiesterase activity in the inner medullary collecting duct, prolong the action of cGMP (a second messenger of ANP).

**Effects on renal function**

All diuretics may increase plasma urea concentrations by increasing urea reabsorption in the medulla. Thiazides may also promote protein breakdown. In certain situations, diuretics also decrease GFR:

• Excessive diuresis causes volume depletion and pre-renal failure.
• Diuretics can cause allergic tubulointerstitial nephritis.
• Thiazides may directly cause a drop in GFR; the mechanism is complex and not fully understood.

**Further reading**

Decreased extracellular volume

Deficiency of sodium and water causes shrinkage both of the interstitial space and of the blood volume, and may have profound effects on organ function.

Clinical features

Symptoms

Thirst, muscle cramps, nausea and vomiting, and postural dizziness occur. Severe depletion of circulating volume causes hypotension and impairs cerebral perfusion, causing confusion and eventual coma.

Signs

Signs can be divided into those due to loss of interstitial fluid and those due to loss of circulating volume.

• **Loss of interstitial fluid** leads to loss of skin elasticity (‘turgor’) – the rapidity with which the skin recoils to normal after being pinched. Skin turgor decreases with age, particularly at the peripheries. The turgor over the anterior triangle of the neck or on the forehead is a very useful sign in all ages.

• **Loss of circulating volume** leads to decreased pressure in the venous and (if severe) arterial compartments. Loss of up to 1 L of extracellular fluid in an adult may be compensated for by vasoconstriction and may cause no physical signs.

  Loss of more than this amount causes the following:

Postural hypotension

Normally, the blood pressure rises if a subject stands up, as a result of increased venous return due to vasoconstriction (this maintains cerebral perfusion). Loss of extracellular fluid (underfill) prevents this and causes a fall in blood pressure. This is one of the earliest and most reliable signs of volume depletion, as long as the other causes of postural hypotension are excluded (Box 9.5).

---

Box 9.5

**Postural hypotension: some causes of a fall in blood pressure from lying to standing**

**Decreased circulating volume (hypovolaemia)**

**Autonomic failure**

• Diabetes mellitus
• Systemic amyloidosis
• Shy–Drager syndrome
• Parkinson's disease
• Ageing

**Interference with autonomic function by drugs**

• Tricyclic antidepressants

**Interference with peripheral vasoconstriction by drugs**

• Nitrates
• Calcium-channel blockers
• α-Adrenoceptor-blocking drugs

*Prolonged bed rest (cardiovascular deconditioning)*

**Low jugular venous pressure**

In hypovolaemic patients, the jugular venous pulsation can be seen only with the patient lying completely flat, or even head down, because the right atrial pressure is lower than 5 cmH₂O.

**Peripheral venoconstriction**

This causes cold skin with empty peripheral veins, which are difficult to cannulate just when the patient needs intravenous therapy the most! This sign is often absent in sepsis, where peripheral vasodilatation contributes to effective hypovolaemia.

**Tachycardia**

This is not always a reliable sign. Beta-blockers and other antiarrhythmics may prevent tachycardia, and hypovolaemia may activate vagal mechanisms and actually cause bradycardia.

**Aetiology**

Salt and water may be lost from the kidneys, the gastrointestinal tract or the skin. Examples are given in *Box 9.6*.

---

**Box 9.6**

**Causes of extracellular volume depletion (hypovolaemia)**

**Haemorrhage**

• External
• Concealed, e.g. leaking aortic aneurysm
**Burns**

**Gastrointestinal losses**
- Vomiting
- Diarrhoea
- Ileostomy losses
- Ileus

**Renal losses**
- Diuretic use
- Impaired tubular sodium conservation
- Reflux nephropathy
- Papillary necrosis
  - Analgesic nephropathy
  - Diabetes mellitus

**Sickle cell disease**

In addition, there are a number of situations where signs of volume depletion occur despite a normal or increased body content of sodium and water:
- Septicaemia causes vasodilatation of both arterioles and veins, resulting in greatly increased capacitance of the vascular space. In addition, increased capillary permeability to plasma proteins leads to loss of fluid from the vascular space to the interstitium.
- Diuretic treatment of heart failure or nephrotic syndrome may lead to rapid reduction in plasma volume. Mobilization of oedema may take much longer.
- There may be inappropriate diuretic treatment of oedema (e.g. when the cause is local rather than systemic).

**Investigations**

Blood tests are, in general, not helpful in the assessment of extracellular volume. Plasma urea may be raised owing to increased urea reabsorption and, later, to pre-renal failure (when the creatinine rises as well), but this is very non-specific. Urinary sodium is low if the kidneys are functioning normally, but is misleading if the cause of the volume depletion involves the kidneys (e.g. diuretics, intrinsic renal disease). Urine osmolality is high in volume depletion (owing to increased water reabsorption) but may also often mislead.

Assessment of volume status is shown in Box 9.7.

---

**Box 9.7**

**Assessment of volume status**
Best achieved by simple clinical observations, which you should carry out yourself. Check:
- Jugular venous pressure
- Central venous pressure: both basal and after intravenous fluid challenge (see pp. 1146–1147)
- Postural changes in blood pressure
- Chest X-ray
- Serial weights of the patient
- Urine output measurements at regular intervals

Management
The overriding principle is to replace what is missing.

Haemorrhage
The rational treatment of acute haemorrhage is the infusion of a combination of red cells and a plasma substitute or (if unavailable) whole blood. (Chronic anaemia causes salt and water retention rather than volume depletion by a mechanism common to conditions with peripheral vasodilatation.)

Loss of plasma
Loss of plasma, as occurs in burns or severe peritonitis, should be treated with human plasma or a plasma substitute (see pp. 1157–1158).

Loss of water and electrolytes
Loss of water and electrolytes, as occurs with vomiting, diarrhoea or excessive renal losses, should be treated by replacement of the loss. If possible, this should be with oral water and sodium salts. These are available as slow sodium (600 mg, approximately 10 mmol each of Na\(^+\) and Cl\(^-\) per tablet), the usual dose of which is 6–12 tablets/day with 2–3 L of water. They are used in mild or chronic salt and water depletion, such as that associated with renal salt wasting.

Sodium bicarbonate (500 mg, 6 mmol each of Na\(^+\) and HCO\(_3^-\) per tablet) is given in doses of 6–12 tablets/day with 2–3 L of water. This is used in milder chronic sodium depletion with acidosis (e.g. CKD, post-obstructive renal failure, renal tubular acidosis). Sodium bicarbonate is less effective than sodium chloride in causing positive sodium balance. Oral rehydration solutions are described in Box 11.32.

Intravenous fluids
These are sometimes required (Box 9.8). Rapid infusion (e.g. 1000 mL per hour or even faster) of 0.9% Na Cl is necessary if there is hypotension and evidence of impaired organ perfusion (e.g. oliguria, confusion). Repeated clinical assessments are vital in this situation, usually
complemented by frequent measurements of central venous pressure (see p. 1146 for the management of shock). Severe hypovolaemia induces venoconstriction, which maintains venous return; over-rapid correction does not give time for this to reverse, resulting in signs of circulatory overload (e.g. pulmonary oedema), even if a total body extracellular fluid deficit remains. In less severe extracellular fluid depletion (such as in a patient with postural hypotension complicating acute tubular necrosis), the fluid should be replaced at a rate of 1000 mL every 4–6 h, again with repeated clinical assessment. If all that is required is avoidance of fluid depletion during surgery, 1–2 L can be given over 24 h, remembering that surgery is a stimulus to sodium and water retention and that over-replacement may be as dangerous as under-replacement. Regular monitoring by fluid balance charts, body weight and plasma biochemistry is mandatory.

**Box 9.8**

**Intravenous fluids in general use for fluid and electrolyte disturbances**

* 1. Volume expansion in hypovolaemic patients. Rarely, to maintain fluid balance when there are large losses of sodium. The sodium (150 mmol/L) is higher than in plasma and hypernatraemia can result. It is often necessary to add KCl 20–40 mmol/L.

  3. To replace water. Can be given with or without potassium chloride. May be alternated with 0.9% saline as an alternative to (2).

  4. For volume expansion in hypovolaemic, acidic patients, alternating with (1). Occasionally, for maintenance of fluid balance combined with (2) in salt-wasting, acidic patients.

  5. For volume expansion in hypovolaemic patients. May be better than 0.9% saline for patients with sepsis and relative hypovolaemia.

bHartmann’s solution also contains 2 mmol/L of calcium.

**Loss of water alone**

This causes extracellular volume depletion only in severe cases because the loss is spread evenly among all the compartments of body water. In the rare situations where there is a true deficiency of water alone, as in diabetes insipidus or in a patient who is unable to drink (e.g.
after surgery), the correct treatment is to give water.

If intravenous treatment is required, water is given as 5% glucose with K⁺ because pure
water would lead to osmotic lysis of blood cells.

Disorders of Sodium Concentration

These are best thought of as disorders of body water content. As discussed above, sodium
content is regulated by volume receptors; water content is adjusted to maintain, in health, a
normal osmolality and (in the absence of abnormal osmotically active solutes) a normal
sodium concentration. Disturbances of sodium concentration are caused by disturbances of
water balance.

Hyponatraemia

Hyponatraemia (Na <135 mmol/L) is the most common biochemical abnormality in
hospitalized patients, with up to 35% of inpatients developing hyponatraemia during their stay.
The causes depend on the associated changes in extracellular volume:
• hyponatraemia with hypovolaemia (*Box 9.9*)

*Box 9.9*

Causes of hyponatraemia with decreased extracellular volume
(hypovolaemia)

Extrarenal (urinary sodium <20 mmol/L)
• Vomiting
• Diarrhoea
• Haemorrhage
• Burns
• Pancreatitis

Kidney (urinary sodium >20 mmol/L)
• Osmotic diuresis (e.g. hyperglycaemia, severe uraemia)
• Diuretics
• Adrenocortical insufficiency
• Tubulointerstitial renal disease
• Unilateral renal artery stenosis
• Recovery phase of acute tubular necrosis

• hyponatraemia with euvolaemia *(Box 9.10)*

**Box 9.10**

*Causes of hyponatraemia with normal extracellular volume (euvolaemia)*

**Abnormal antidiuretic hormone (ADH) release**
• Vagal neuropathy (failure of inhibition of ADH release)
• Deficiency of adrenocorticotrophic hormone (ACTH) or glucocorticoids (Addison's disease)
• Hypothyroidism
• Severe potassium depletion

**Syndrome of inappropriate antidiuretic hormone secretion (SIADH)**
• See *Box 26.46*

**Psychiatric illness**
• ‘Psychogenic polydipsia’
• Non-osmotic ADH release?
• Antidepressant therapy

**Increased sensitivity to ADH**
• Chlorpropamide
• Tolbutamide

**ADH-like substances**
• Oxytocin
• Desmopressin

**Unmeasured osmotically active substances stimulating osmotic ADH release**
• Glucose
• Chronic alcohol misuse
• Mannitol
• Sick-cell syndrome (leakage of intracellular ions)

• hyponatraemia with hypervolaemia (*Box 9.11*).

---

**Box 9.11**

**Causes of hyponatraemia with increased extracellular volume (hypervolaemia)**

- Heart failure
- Liver failure
- Oliguric kidney injury
- Hypoalbuminaemia

---

Rarely, hyponatraemia may be a ‘pseudo-hyponatraemia’. This occurs in hyperlipidaemia (either high cholesterol or high triglyceride) or hyperproteinaemia where there is a spuriously low measured sodium concentration, the sodium being confined to the aqueous phase but having its concentration expressed in terms of the total volume of plasma. In this situation, plasma osmolality is normal and therefore treatment of ‘hyponatraemia’ is unnecessary. Note that artefactual ‘hyponatraemia’, caused by taking blood from the limb into which fluid of low sodium concentration is being infused, should be excluded.

---

**Hyponatraemia with hypovolaemia**

This is due to salt loss in excess of water loss; the causes are listed in *Box 9.9*. In this situation, ADH secretion is initially suppressed (via the hypothalamic osmoreceptors) but, as fluid volume is lost, volume receptors override the osmoreceptors and stimulate both thirst and the release of ADH. This is an attempt by the body to defend circulating volume at the expense of osmolality.

With extrarenal losses and normal kidneys, the urinary excretion of sodium falls in response to the volume depletion, as does water excretion, leading to concentrated urine containing <10 mmol/L of sodium. However, in salt-wasting kidney disease, renal compensation cannot occur and the only physiological protection is increased water intake in response to thirst.

---

**Clinical features**

With sodium depletion, the clinical picture is usually dominated by features of volume
depletion (see p. 159). The diagnosis is usually obvious where there is a history of gut losses, diabetes mellitus or diuretic abuse. Examination of the patient is often more helpful than the biochemical investigations, which include plasma and urine electrolytes and osmolality.

**Box 9.12** shows the potential daily losses of water and electrolytes from the gut. Losses due to renal or adrenocortical disease may be less easily identified but a urinary sodium concentration of >20 mmol/L, in the presence of clinically evident volume depletion, suggests a renal loss.

**Management**

This is directed at the primary cause whenever possible.

In a healthy patient:

- Give oral electrolyte–glucose mixtures (see pp. 288–289).
- Increase salt intake with slow sodium 60–80 mmol/day.

In a patient with vomiting or severe volume depletion:

- Give intravenous fluid with potassium supplements, i.e. 1.5–2 L 5% glucose (with 20 mmol K⁺) and 1 L 0.9% saline over 24 h plus measurable losses.
- Correction of acid–base abnormalities is usually not required.

**Hyponatraemia with euvolaemia**

Hyponatraemia with euvolaemia (see **Box 9.10**) results from an intake of water in excess of the kidney's ability to excrete it (dilutional hyponatraemia); there is no change in body sodium content but the plasma osmolality is low.

- With normal kidney function, dilution hyponatraemia is uncommon even if a patient drinks
approximately 1 L per hour.

• The most common iatrogenic cause is over-generous infusion of 5% glucose into postoperative patients; in this situation, it is exacerbated by an increased ADH secretion in response to stress.

• Postoperative hyponatraemia is a common clinical problem (almost 1% of patients) with symptomatic hyponatraemia occurring in 20% of these patients.

• Marathon runners who drink excess water can become hyponatraemic. Even so-called ‘isotonic sports drinks’ can lead to hyponatraemia, as they contain little sodium, their osmolality being made up with carbohydrates, which are metabolized into energy and water.

• Premenopausal females are at most risk for developing hyponatraemic encephalopathy postoperatively, with postoperative ADH values in young females being 40 times higher than in young males.

To prevent hyponatraemia, avoid using hypotonic fluids postoperatively and administer 0.9% saline unless clinically contraindicated. The serum sodium should be measured daily in any patient receiving continuous parenteral fluid.

Some degree of hyponatraemia is usual in acute oliguric kidney injury, while in CKD it is most often due to ill-given advice to ‘push’ fluids.

### Clinical features

#### Dilutional hyponatraemia

Symptoms of dilutional hyponatraemia are common when hyponatraemia develops acutely (<48 h, often postoperatively). Overt neurological symptoms rarely occur until the serum sodium is less than 125 mmol/L and are more usually associated with values around 115 mmol/L or lower, particularly when chronic. In elderly patients, however, even mild hyponatraemia with a serum sodium of 130–135 mmol/L has been associated with increased falls risk and subtle changes in cognition. They are due to the movement of water into brain cells in response to the fall in extracellular osmolality.

#### Hyponatraemic encephalopathy

Symptoms and signs include headache, confusion and restlessness leading to drowsiness, myoclonic jerks, generalized convulsions and eventually coma. Magnetic resonance imaging (MRI) of the brain may reveal cerebral oedema but, in the context of electrolyte abnormalities and neurological symptoms, can help to make a confirmatory diagnosis.

#### Risk factors for developing hyponatraemic encephalopathy

The brain's adaptation to hyponatraemia initially involves extrusion of blood and CSF, as well as sodium, potassium and organic osmolytes, in order to decrease brain osmolality. Various factors can interfere with successful adaptation. These factors, rather than the absolute change
in serum sodium, predict whether a patient will suffer hyponatraemic encephalopathy.

- **Children** under 16 years are at increased risk due to their relatively large brain-to-intracranial volume ratio compared with adults.

- **Premenopausal women** are more likely to develop encephalopathy than postmenopausal females and males because of inhibitory effects of sex hormones and the effects of vasopressin on cerebral circulation, resulting in vasoconstriction and hypoperfusion of the brain.

- **Hypoxaemia** is a major risk factor for hyponatraemic encephalopathy. Patients with hyponatraemia who develop hypoxia, due to either non-cardiac pulmonary oedema or hypercapnic respiratory failure, have a high risk of mortality. Hypoxia is the strongest predictor of mortality in patients with symptomatic hyponatraemia.

### Investigations

The cause of hyponatraemia with apparently normal extracellular volume requires investigation:

- **Plasma and urine electrolytes and osmolalities.** The plasma concentrations of sodium, chloride and urea are low, giving a low osmolality. The urine sodium concentration is usually high and the urine osmolality is typically higher than the plasma osmolality. However, maximal dilution (<50 mosmol/kg) is not always present.

- **Further investigations.** These are needed to exclude Addison's disease, hypothyroidism, syndrome of inappropriate ADH secretion (SIADH) and water retention induced by drugs, e.g. chlorpropamide.

  Potassium depletion and magnesium depletion potentiate ADH release and are causes of diuretic-associated hyponatraemia.

  SIADH is often over-diagnosed. Some causes are associated with a lower set-point for ADH release, rather than completely autonomous ADH release; an example is chronic alcohol use.

### Management **(Box 9.13)**

The underlying cause should be corrected where possible.

- **Most patients.** Most cases are simply managed by restriction of water intake (to 1000 or even 500 mL/day) with review of diuretic therapy. Magnesium and potassium deficiency must be corrected. In mild sodium deficiency, 0.9% saline given slowly (1 L over 12 h) is sufficient.

- **Acute onset with symptoms.** The most common cause of acute hyponatraemia in adults is postoperative iatrogenic hyponatraemia. Excessive water intake associated with psychosis, marathon running and use of Ecstasy (a recreational drug) are other causes. All are acute medical emergencies and should be treated aggressively and immediately. In patients who
demonstrate severe neurological signs, such as fits, coma or cerebral oedema, *hypertonic saline* (3%, 513 mmol/L) should be used. It must be given very slowly (not more than 70 mmol/h), the aim being to increase the serum sodium by 4–6 mmol/L in the first 4 hours, but the absolute change should not exceed 15–20 mmol/L over 48 hours. In general, the plasma sodium should not be corrected to >125–130 mmol/L. Assuming that total body water comprises 50% of total body weight, 1 mL/kg of 3% sodium chloride will raise the plasma sodium by 1 mmol/L.

• **Symptomatic hyponatraemia in patients with intracranial pathology.** This should be managed aggressively and immediately with 3% saline, as for acute hyponatraemia.

• **Chronic/asymptomatic hyponatraemia.** If hyponatraemia has developed slowly, as it does in the majority of patients, the brain will have adapted by decreasing intracellular osmolality and the hyponatraemia can be corrected slowly.

---

**Box 9.13**

**Key points in the management of hyponatraemia**

- Always treat the underlying cause
- What is the volume status of the patient?
  - If hypovolaemic: rehydrate with 0.9% saline
  - If euvoalaemic (SIADH): restrict fluid to 500–700 mL/day
  - If hypervolaemic (chronic kidney disease/heart failure): restrict fluid and salt
- Does the patient have symptomatic hyponatraemia (seizures/coma)?
  - Yes: involve critical care input early; 3% saline 1 mL/kg over 1 h
- Is the hyponatraemia acute or chronic?
  - If acute: more likely to develop symptomatic hyponatraemia
  - If chronic: increased risk of osmotic demyelination due to rapid correction
  - If unsure: give 3% saline very slowly
- Check sodium levels frequently: may need to check Na every 1–2 h
- Correction must not exceed 10 mmol in first 24 h and 18 mmol in 48 h

However, clinically, it can be difficult to know how long the hyponatraemia has been present for and 3% hypertonic saline may still be required.

**Osmotic demyelination syndrome**

**Avoiding osmotic demyelination syndrome**

A rapid rise in extracellular osmolality, particularly if there is an ‘overshoot’ to high serum sodium and osmolality, will result in the osmotic demyelination syndrome (ODS), formerly known as central pontine demyelination, which is a devastating neurological complication.
Plasma sodium concentration in patients with hyponatraemia should not rise by more than 8 mmol/L per day. The rate of rise of plasma sodium should be even lower in patients at higher risk for ODS: for example, those with alcohol excess, cirrhosis, malnutrition or hypokalaemia. Other factors predisposing to demyelination are pre-existing hypoxaemia and central nervous system radiation (see above). ODS is diagnosed by the appearance of characteristic hypointense lesions on T₁-weighted images and hyperintense lesions on T₂-weighted images on MRI; these can take 2 weeks or more to appear.

The pathophysiology of ODS is not fully understood. The most plausible explanation is that the brain loses organic osmolytes very quickly in order to adapt to hyponatraemia so that osmolarity is similar between the intracellular and extracellular compartments. However, neurones reclaim organic osmolytes slowly in the phase of rapid correction of hyponatraemia, resulting in a hypo-osmolar intracellular compartment and shrinkage of cerebral vascular endothelial cells. Consequently, the blood–brain barrier is functionally impaired, allowing lymphocytes, complement and cytokines to enter the brain, damage oligodendrocytes, activate microglial cells and cause demyelination.

The most crucial issue in the treatment of hyponatraemia is to prevent rapid correction. A rapid rise in plasma sodium is almost always due to a water diuresis, which happens when vasopressin (ADH) action stops suddenly: for example, with volume repletion in patients with intravascular volume depletion, cortisol replacement in patients with Addison's disease, or resolution of non-osmotic stimuli for vasopressin release such as nausea or pain. Sometimes, however, chronic hyponatraemia can develop in the absence of vasopressin excess. Even in these cases, water diuresis due to increased distal delivery of filtrate is the main cause of rapid rise in plasma sodium.

In the absence of vasopressin, it is generally assumed that the total urine volume is equal to the volume of filtrate delivered to the distal nephron, which is the GFR minus the volume reabsorbed in the proximal convoluted tubule. Approximately 80% of the GFR is reabsorbed in proximal convoluted tubule under normal circumstance (and increases even more in the presence of intravascular volume depletion). However, in real life, water excretion will be less than the volume of distal delivery of filtrate, even in the absence of vasopressin, because a significant degree of water is reabsorbed in the inner medullary collecting duct through its residual water permeability, prompted by a very high osmotic force in the interstitium (see Fig. 20.3).

Even a modest water diuresis in the elderly with reduced muscle mass is large enough to cause a rapid rise in plasma sodium. Moreover, there is a higher risk for ODS if hypokalaemia is present. In such cases, if plasma sodium rises too quickly due to anticipated water diuresis, administration of desmopressin to stop the water diuresis is beneficial. If plasma sodium rises regardless, then lowering plasma sodium to the maximum limit of correction (<8 mmol/L per day) with the administration of 5% glucose solution is the best strategy.

**Reversible hyponatraemia culminating in hypernatraemia**

In many patients, the cause of water retention is reversible (e.g. hypovolaemia, thiazide
diuretics). On correction of the cause, vasopressin levels fall and plasma sodium rises by up to 2 mmol/L per hour as a result of excretion of dilute urine. This excessive water diuresis should be anticipated and prevented by use of desmopressin.

Patients who are chronically hyponatraemic with concomitant hypokalaemia are especially susceptible to overcorrection. Plasma sodium is a function of the ratio of exchangeable body sodium plus potassium to total body water, so potassium administration increases sodium concentration. For example, a mildly symptomatic hyponatraemic patient with a plasma sodium of <120 mmol/L and potassium of <2 mmol/L can potentially develop ODS as a result of overcorrection of hyponatraemia simply as a direct result of replacing the large potassium deficit.

**Antidiuretic hormone antagonists (vasopressin antagonists)**

Vasopressin V₂ receptor antagonists (see p. 158), which produce a free water diuresis, are being used in clinical trials for the treatment of hyponatraemic encephalopathy. Three oral agents, lixivaptan, tolvaptan and satavaptan, are selective for the V₂ (antidiuretic) receptor, while conivaptan blocks both V₁A and V₂ receptors.

These agents produce a selective water diuresis without affecting sodium and potassium excretion; they raise the plasma sodium concentration in patients with hyponatraemia caused by SIADH, heart failure and cirrhosis.

The efficacy of oral tolvaptan in ambulatory patients has been demonstrated in individuals with hyponatraemia (mean plasma sodium 129 mmol/L) caused by SIADH, heart failure or cirrhosis who had a sustained rise in plasma sodium to 136 mmol/L for 4 weeks. Tolvaptan is now approved for use in patients with euvoalaemic hyponatraemia and those with SIADH. In addition, intravenous conivaptan is available and is also approved for the treatment of euvoalaemic hyponatraemia (i.e. SIADH) in some countries. The approved dosing for conivaptan is a 20 mg bolus followed by continuous infusion of 20 mg over 1–4 days. The continuous infusion increases the risk of phlebitis, which requires the use of large veins and change of infusion site every 24 hours.

**Hyponatraemia with hypervolaemia**

The common causes of hyponatraemia due to water excess are shown in Box 9.11. In all these conditions, there is usually an element of reduced GFR with avid reabsorption of sodium and chloride in the proximal tubule. This leads to reduced delivery of chloride to the ‘diluting’ ascending limb of the loop of Henle and a reduced ability to generate ‘free water’, with a consequent inability to excrete dilute urine. This is commonly compounded by the administration of diuretics that block chloride reabsorption and interfere with the dilution of filtrate either in the loop of Henle (loop diuretics) or distally (thiazides).

**Syndrome of inappropriate ADH secretion**
This is described on pages 1234–1235. There is inappropriate secretion of ADH, causing water retention and hyponatraemia.

### Hypernatraemia

This is much rarer than hyponatraemia and nearly always indicates a water deficit. Causes are listed in *Box 9.14*.

#### Box 9.14

**Causes of hypernatraemia**

**Antidiuretic hormone (ADH) deficiency**

- Pituitary diabetes insipidus (see pp. 1233–1234)

**Iatrogenic**

- Administration of hypertonic sodium solutions
- Administration of drugs with a high sodium content (e.g. piperacillin)
- Use of 8.4% sodium bicarbonate after cardiac arrest

**Insensitivity to ADH (nephrogenic diabetes insipidus)**

- Lithium
- Tetracyclines
- Amphotericin B
- Acute tubular necrosis
- Osmotic diuresis
- Total parenteral nutrition
- Hyperosmolar hyperglycaemic state (see p. 1264)

**Plus**

- Deficient water intake: impaired thirst or consciousness
- Excessive water loss through skin or lungs

Hypernatraemia is always associated with increased plasma osmolality, which is a potent stimulus to thirst. None of the factors listed in *Box 9.14* causes hypernatraemia unless thirst sensation is abnormal or access to water limited. For instance, a patient with diabetes insipidus will maintain a normal serum sodium concentration by maintaining a high water intake until an intercurrent illness prevents this. Thirst is frequently deficient in elderly people, making them more prone to water depletion. Hypernatraemia may occur in the presence of normal, reduced or expanded extracellular volume, and does not necessarily imply that total
body sodium is increased.

Clinical features

Symptoms of hypernatraemia are non-specific. Nausea, vomiting, fever and confusion may occur. A history of longstanding polyuria, polydipsia and thirst suggests diabetes insipidus. Assessment of extracellular volume status guides resuscitation. Mental state should be assessed. Convulsions occur in severe hypernatraemia.

Investigations

Simultaneous urine and plasma osmolality and sodium should be measured. Plasma osmolality is high in hypernatraemia. Passage of urine with an osmolality lower than that of plasma in this situation is clearly abnormal and indicates diabetes insipidus. In pituitary diabetes insipidus, urine osmolality will increase after administration of desmopressin; the drug (a vasopressin analogue) has no effect in nephrogenic diabetes insipidus (see p. 1234). If urine osmolality is high, this suggests either an osmotic diuresis due to an unmeasured solute (e.g. in parenteral feeding) or excessive extrarenal loss of water (e.g. heat stroke).

Management

Treatment is that of the underlying cause. For example:

• In ADH deficiency, replace ADH in the form of desmopressin, a stable non-pressor analogue of ADH.

• Remember to withdraw nephrotoxic drugs where possible and replace water either orally or, if necessary, intravenously.

In severe (>170 mmol/L) hypernatraemia, 0.9% saline (150 mmol/L) should be used initially. Avoid too rapid a drop in serum sodium concentration; the aim is correction over 48 hours, as over-rapid correction may lead to cerebral oedema.

In less severe (e.g. >150 mmol/L) hypernatraemia, the treatment is 5% glucose or 0.45% saline; the latter is obviously preferable in hyperosmolar diabetic coma. Very large volumes – 5 L/day or more – may need to be given in diabetes insipidus.

If there is clinical evidence of volume depletion (see p. 159), this implies that there is a sodium deficit as well as a water deficit. Treatment of this is discussed on page 160.

Nemerovski C, Hutchinson DJ. Treatment of hypervolemic or euvoletic hyponatremia
Disorders of Potassium Concentration

Regulation of serum potassium concentration

The World Health Organization (WHO) recommends a dietary intake of 90 mmol/day to reduce blood pressure; most people have a dietary intake of between 80 and 150 mmol daily, depending upon fruit and vegetable intake. Most of the body's potassium (3500 mmol in an adult) is intracellular. Serum potassium levels are controlled by:

• uptake of K\(^+\) into cells
• renal excretion
• extrarenal losses (e.g. gastrointestinal).

Uptake of potassium into cells is governed by the activity of the Na\(^+\)/K\(^+\)-ATPase in the cell membrane and by H\(^+\) concentration.

Uptake is **stimulated** by:

• insulin
• β-adrenergic stimulation
• theophyllines.

Uptake is **decreased** by:

• α-adrenergic stimulation
• acidosis – K\(^+\) exchanged for H\(^+\) across cell membranes
• cell damage or cell death – resulting in massive K\(^+\) release.

The **kidney** plays the pivotal role in the maintenance of potassium balance by varying its secretion with changes in dietary intake. Over 90% of the filtered potassium is reabsorbed in the proximal tubule and the loop of Henle and only <10% of the filtered load is delivered to the early distal tubule. Potassium absorption in the proximal tubule is entirely passive and follows that of sodium and water, while its reabsorption in the thick ascending limb of the loop of Henle is mediated by the sodium–potassium-2–chloride co-transporter. However, potassium
is secreted by the principal cells in the cortical and outer medullary collecting tubule. Secretion in these segments is very tightly regulated in health and can be varied according to individual needs; it is responsible for most of urinary potassium excretion.

Renal excretion of potassium is increased by aldosterone, which stimulates $K^+$ and $H^+$ secretion in exchange for $Na^+$ in the principal cells of the collecting duct (Fig. 9.8). Because $H^+$ and $K^+$ are interchangeable in the exchange mechanism, acidosis decreases and alkalosis increases the secretion of $K^+$. Aldosterone secretion is stimulated by hyperkalaemia and increased angiotensin II levels, as well as by some drugs, and this acts to protect the body against hyperkalaemia and against extracellular volume depletion. The body adapts to dietary deficiency of potassium by reducing aldosterone secretion. However, because aldosterone is also influenced by volume status, conservation of potassium is relatively inefficient, and significant potassium depletion may therefore result from prolonged dietary deficiency.

A number of drugs affect $K^+$ homeostasis by affecting aldosterone release (e.g. heparin, NSAIDs) or by directly affecting renal potassium handling (e.g. diuretics).

Other endogenous proteins and metabolites also affect potassium homeostasis. Klotho, an anti-ageing protein expressed in the distal tubule (and other organs), increases potassium excretion. CD63, a tetra-spanning protein, inhibits its excretion. Moreover, protein kinase A- and C-mediated phosphorylation inhibits conductance of $K^+$ channels in the principal cells of the collecting duct but the cytochrome P450-epoxygenase-mediated metabolite of arachidonic acid (11–12-epoxyeicosatrienoic acid) activates these channels and plays a role in overall potassium homeostasis.

Normally, only about 10% of daily potassium intake is excreted in the gastrointestinal tract. Vomit contains around 5–10 mmol/L of $K^+$, but prolonged vomiting causes hypokalaemia by inducing sodium depletion, stimulating aldosterone, which increases renal potassium excretion. Potassium is secreted by the colon, and diarrhoea contains 10–30 mmol/L of $K^+$; profuse diarrhoea can therefore induce marked hypokalaemia. Colorectal villous adenomas may rarely produce profuse diarrhoea and $K^+$ loss.

---

**Hypokalaemia**

**Aetiology**

**Common causes**

The most common causes of chronic hypokalaemia are diuretic treatment (particularly thiazides) and hyperaldosteronism. Acute hypokalaemia is often caused by intravenous fluids without potassium and redistribution into cells, particularly in the case of diabetic ketoacidosis (see pp. 1261–1264), where the use of fluids without potassium combined with insulin treatment can cause a rapid fall in the serum potassium. The common causes are shown in Box 9.15.
Box 9.15

Causes of hypokalaemia

Increased renal excretion
(Urinary K⁺ > 20 mmol/day)
- Diuretics:
  - Thiazides
  - Loop diuretics

Increased aldosterone secretion
- Liver failure
- Heart failure
- Nephrotic syndrome
- Cushing syndrome
- Conn syndrome
- ACTH-producing tumours

Exogenous mineralocorticoid
- Corticosteroids
- Liquorice (potentiates renal actions of cortisol)

Renal disease
- Renal tubular acidosis types 1 and 2
- Renal tubular damage (diuretic phase)
- Acute leukaemia
- Nephrotoxicity:
  - Amphotericin
  - Aminoglycosides
  - Cytotoxic drugs
- Release of urinary tract obstruction
- Bartter syndrome
- Liddle syndrome
- Gitelman syndrome

Reduced intake of K⁺
- Intravenous fluids without K⁺
- Dietary deficiency
Redistribution into cells

- β-Adrenergic stimulation
- Acute myocardial infarction
- Beta-agonists, e.g. fenoterol, salbutamol
- Insulin treatment, e.g. treatment of diabetic ketoacidosis
- Correction of megaloblastic anaemia, e.g. B₁₂ deficiency
- Alkalosis
- Hypokalaemic periodic paralysis

Gastrointestinal losses

(Urinary K⁺ <20 mmol/day)

- Vomiting
- Severe diarrhoea
- Purgative abuse
- Villous adenoma
- Ileostomy or uterosigmoidostomy
- Fistulae
- Ileus/intestinal obstruction

Rare causes

These rare causes are discussed in detail because they show the mechanisms of how diuretics can affect the kidney.

Bartter syndrome

Bartter syndrome (clinically similar to the effects of treatment with loop diuretics) consists of metabolic alkalosis, hypokalaemia, hypercalciuria, occasionally hypomagnesaemia (see p. 170), normal blood pressure, and an elevated plasma renin and aldosterone. The primary defect in this disorder is an impairment in sodium and chloride reabsorption in the thick ascending limb of the loop of Henle (see Fig. 9.6). Mutation in the genes encoding either the sodium–potassium-2–chloride co-transporter (NKCC2), the ATP-regulated renal outer medullary potassium channel (ROMK) or kidney-specific basolateral chloride channels (CLC-Kb) – Bartter syndrome types I, II and III, respectively – causes loss of function of these channels, with consequent impairment of sodium and chloride reabsorption. There is also an increased intrarenal production of prostaglandin E₂ (PGE₂), which is secondary to sodium and volume depletion, hypokalaemia and the consequent neurohumoral response rather than a primary defect. PGE₂ causes vasodilatation and may explain why the blood pressure remains normal.

Barttin, a β-subunit for CLC-Ka and CLC-Kb chloride channels, is encoded by the BSND
(Bartter syndrome with sensorineural deafness) gene. Loss-of-function mutations cause type IV Bartter syndrome, which is associated with sensorineural deafness and renal failure. Barttin co-localizes with a subunit of the chloride channel in basolateral membranes of the renal tubule and inner ear epithelium. It appears to mediate chloride exit in the thick ascending limb (TAL) of the loop of Henle and chloride recycling in potassium-secreting strial marginal cells in the inner ear. A very rare variant of type IV is a disorder with an impairment of both chloride channels (CLC-Ka and CLC-Kb), producing the same phenotypic defects.

A gain-of-function mutation of the calcium-sensing receptor (CaSR), which leads to autosomal dominant hypocalcaemia, has also been recognized in Bartter syndrome. In the kidney, the CaSR is expressed mainly in the basolateral membrane of cortical TAL. Activation of CaSR by high calcium or magnesium or by gain-of-function mutation triggers intracellular signalling, including release of arachidonic acid and inhibition of adenylate cyclase. Both actions result in inhibition of ROMK activity, which in turn leads to reduction in the lumen-positive electrical potential and transcellular absorption of calcium. This effect of CaSR explains why patients with mutations in this receptor may present with hypocalcaemia, hypercalciuria and renal wasting of NaCl, resulting in a Bartter-like syndrome.

In summary, these defects in sodium chloride transport initiate the following sequence, which is almost identical to that seen with chronic ingestion of a loop diuretic: the initial salt loss leads to mild volume depletion, resulting in activation of the renin–angiotensin–aldosterone system; the combination of hyperaldosteronism and increased distal flow (owing to the reabsorptive defect) enhances potassium and hydrogen secretion at the secretory sites in the collecting tubules, leading to hypokalaemia and metabolic alkalosis.

**Diagnostic pointers** include high urinary potassium and chloride despite low serum values, as well as increased plasma renin. (N.B. In primary aldosteronism, renin levels are low.) Hyperplasia of the juxtaglomerular apparatus is seen on renal biopsy (careful exclusion of diuretic abuse is necessary). Hypercalciuria is a common feature but magnesium wasting, though rare, also occurs.

**Treatment** is with combinations of potassium supplements, amiloride and indometacin.

**Gitelman syndrome**

Gitelman syndrome (similar to the effects of treatment with thiazide diuretics) is a phenotype variant of Bartter syndrome characterized by hypokalaemia, metabolic alkalosis, hypocalciuria, hypomagnesaemia, normal blood pressure, and elevated plasma renin and aldosterone. There are striking similarities between Gitelman syndrome and the biochemical abnormalities induced by chronic thiazide diuretic administration. Thiazides act in the distal convoluted tubule to inhibit the function of the apical sodium–chloride co-transporter (NCCT) (see *Fig. 9.7*). Analysis of the gene encoding the NCCT has identified loss-of-function mutations in Gitelman syndrome.

As in Bartter syndrome, defective NCCT function leads to increased solute delivery to the collecting duct, with resultant solute wasting, volume contraction and an aldosterone-mediated increase in potassium and hydrogen secretion. Unlike in Bartter syndrome, the degree of
volume depletion and hypokalaemia is not sufficient to stimulate PGE$_2$ production. Impaired function of NCCT is predicted to cause hypocalciuria, as does thiazide administration. Impaired sodium reabsorption across the apical membrane, coupled with continued intracellular chloride efflux across the basolateral membrane, causes the cell to become hyperpolarized. This in turn stimulates calcium reabsorption via apical, voltage-activated calcium channels. Decreased intracellular sodium also facilitates calcium efflux via the basolateral sodium–calcium exchanger. The mechanism for urinary magnesium losses is described on pages 169–170.

**Treatment** consists of potassium and magnesium supplementation (MgCl$_2$) and a potassium-sparing diuretic. Volume resuscitation is usually not necessary, because patients are not dehydrated. Elevated PGE$_2$ does not occur (see above) and, therefore, NSAIDs are not indicated in this disorder.

**Liddle syndrome**

This is characterized by potassium wasting, hypokalaemia and alkalosis, but is associated with low renin and aldosterone production, and high blood pressure. There is a mutation in the gene encoding for the amiloride-sensitive epithelial sodium channel in the distal tubule/collecting duct. This leads to constitutive activation of the epithelial sodium channel, resulting in excessive sodium reabsorption with coupled potassium and hydrogen secretion. Unregulated sodium reabsorption across the collecting tubule causes volume expansion, inhibition of renin and aldosterone secretion, and development of low-renin hypertension (see **Fig. 9.8**).

**Therapy** consists of sodium restriction, along with amiloride or triamterene administration. Both are potassium-sparing diuretics that directly close the sodium channels. The mineralocorticoid antagonist spironolactone is ineffective, since the increase in sodium-channel activity is not mediated by aldosterone.

**Hypokalaemic periodic paralysis**

This condition may be precipitated by carbohydrate intake, suggesting that insulin-mediated potassium influx into cells may be responsible. This syndrome also occurs in association with hyperthyroidism (thyrotoxic periodic paralysis; see p. 889), which occurs in Asians.
Clinical features

Hypokalaemia is usually asymptomatic but severe hypokalaemia (<2.5 mmol) causes muscle weakness. Potassium depletion may also cause symptomatic hyponatraemia (see p. 162).

Hypokalaemia is associated with an increased frequency of atrial and ventricular ectopic beats. This association may not always be causal because adrenergic activation (for instance, after myocardial infarction) results in both hypokalaemia and increased cardiac irritability. Hypokalaemia in patients without cardiac disease is unlikely to lead to serious arrhythmias.

Hypokalaemia seriously increases the risk of digoxin toxicity by increasing binding of digoxin to cardiac cells, potentiating its action and decreasing its clearance.

Chronic hypokalaemia is associated with interstitial renal disease but the pathogenesis is not completely understood.

Management

The underlying cause should be identified and treated where possible. Box 9.16 shows some examples.

<table>
<thead>
<tr>
<th>Cause</th>
<th>Treatment</th>
</tr>
</thead>
<tbody>
<tr>
<td>Dietary deficiency</td>
<td>Increase intake of fresh fruit/vegetables or oral potassium supplements (20–40 mmol daily). (Potassium supplements can cause gastrointestinal irritation)</td>
</tr>
<tr>
<td>Hyperaldosteronism, e.g. cirrhosis, thiazide therapy</td>
<td>Spironolactone/epiirenone. Co-prescription of a potassium-sparing diuretic with a similar onset and duration of action</td>
</tr>
<tr>
<td>Intravenous fluid replacement</td>
<td>Add 20 mmol of K⁺/L of fluid with monitoring</td>
</tr>
</tbody>
</table>

Acute hypokalaemia may correct spontaneously. In most cases, withdrawal of oral diuretics or purgatives, accompanied by the oral administration of potassium supplements in the form of slow-release potassium or effervescent potassium, is all that is required. Intravenous potassium replacement is needed only in conditions such as cardiac arrhythmias, muscle weakness or severe diabetic ketoacidosis. When intravenous therapy is used in the presence of poor renal function, replacement rates <2 mmol per hour should only be used, with hourly monitoring of serum potassium and electrocardiogram changes. Ampoules of potassium should be thoroughly mixed in 0.9% saline; do not use a glucose solution, as this would make hypokalaemia worse.

The treatment of adrenal disorders is described on page 1199.

Failure to correct hypokalaemia may be due to concurrent hypomagnesaemia. Serum
Magnesium should be measured and any deficiency corrected.

**Hyperkalaemia**

**Aetiology**

**Common causes**

Acute self-limiting hyperkalaemia occurs normally after vigorous exercise and is of no pathological significance. Hyperkalaemia in all other situations is due either to increased release from cells or to failure of excretion *(Box 9.17)*. The most common causes are renal impairment and drug interference with potassium excretion. The combination of angiotensin-converting enzyme (ACE) inhibitors with potassium-sparing diuretics or NSAIDs is particularly dangerous.

**Box 9.17**

**Causes of hyperkalaemia**

**Decreased excretion**

- Acute kidney injury
- Drugs:
  - Amiloride
  - Triamterene
  - Spironolactone/eplerenone
  - ACE inhibitors/ACE blockers
  - NSAIDs
- Ciclosporin treatment
- Heparin treatment
- Aldosterone deficiency
- Hyporeninaemic hypoaldosteronism (RTA type 4)
- Addison's disease
- Acidosis
- Gordon syndrome

**Increased release from cells**

(Decreased Na⁺/K⁺-ATPase activity)

- Acidosis
- Diabetic ketoacidosis
• Rhabdomyolysis/tissue damage
• Tumour lysis
• Succinylcholine (amplified by muscle denervation)
• Digoxin poisoning
• Vigorous exercise (α-adrenergic; transient)

**Increased extraneous load**

• Potassium chloride
• Salt substitutes
• Transfusion of stored blood

**Spurious**

• Increased *in vitro* release from abnormal cells
• Leukaemia
• Infectious mononucleosis
• Thrombocytosis
• Familial pseudohyperkalaemia, e.g. haemolysis in syringe
• Increased release from muscles
• Vigorous fist clenching during phlebotomy
  
  ACE, angiotensin-converting enzyme; NSAIDs, non-steroidal anti-inflammatory drugs; RTA, renal tubular acidosis.

---

*Common causes.*

**Rare causes**

**Hyporeninaemic hypoaldosteronism**

This is also known as type 4 renal tubular acidosis (see p. 177). Hyperkalaemia occurs because of acidosis and hypoaldosteronism.

**Pseudohypoaldosteronism type 1 (autosomal recessive and dominant types)**

This is a disease of infancy, apparently due to resistance to the action of aldosterone. It is characterized by hyperkalaemia and evidence of sodium wasting (hyponatraemia, extracellular volume depletion). Autosomal recessive forms result from loss of function because of mutations in the gene for epithelial sodium-channel activity (the opposite to Liddle syndrome). Pseudohypoaldosteronism type 1 involves multiple organ systems and is especially marked in the neonatal period. With aggressive salt replacement and control of hyperkalaemia, these children can survive and the disorder appears to become less severe with age. The autosomal
dominant type is due to mutations affecting the mineralocorticoid receptor (see Fig. 9.8). These patients present with salt wasting and hyperkalaemia but do not have other organ-system involvement.

Hyperkalaemic periodic paralysis
Hyperkalaemic periodic paralysis (see p. 891) is precipitated by exercise, and is caused by an autosomal dominant mutation of the skeletal muscle sodium-channel gene.

Gordon syndrome (familial hyperkalaemic hypertension, pseudohypoaldosteronism type 2)
This appears to be a mirror image of Gitelman syndrome (see p. 166), in which primary renal retention of sodium causes hypertension, volume expansion, low renin/aldosterone, hyperkalaemia and metabolic acidosis. There is also an increased sensitivity of sodium reabsorption to thiazide diuretics, suggesting that the thiazide-sensitive sodium–chloride co-transporter (NCCT) is involved (see Fig 9.7). Genetic analyses, however, have excluded abnormalities in NCCT. The involvement of two loci on chromosomes 1 and 12 and further genetic heterogeneity have also been found. These genes do not correspond to ionic transporters but to unexpected proteins, WNK (with no lysine kinase) 1 and WNK 4, which are two closely related members of a novel serine–threonine kinase family. WNK 4 normally inhibits NCCT by preventing its membrane translocation from the cytoplasm. Loss-of-function mutation in WNK 4 results in escape of NCCT from normal inhibition and its overactivity, as seen from the patient's phenotype. WNK 1 is an inhibitor of WNK 4 and, in some patients with Gordon syndrome, gain-of-function mutation in WNK 1 results in functional deficiency of WNK 4 and overactivity of NCCT.

Suxamethonium and other depolarizing muscle relaxants
These cause release of potassium from cells. Induction of muscle paralysis during general anaesthesia may result in a rise of plasma potassium of up to 1 mmol/L. This is not usually a problem unless there is pre-existing hyperkalaemia.

Clinical features
Serum potassium of >7.0 mmol/L is a medical emergency and is associated with ECG changes (Fig. 9.9). Severe hyperkalaemia may be asymptomatic and may predispose to sudden death from asystolic cardiac arrest. Muscle weakness is often the only symptom, unless (as is commonly the case) the hyperkalaemia is associated with metabolic acidosis, causing Kussmaul respiration. Hyperkalaemia causes depolarization of cell membranes, leading to decreased cardiac excitability, hypotension, bradycardia and eventual asystole.
Management

Treatment for severe hyperkalaemia requires both urgent measures to save lives and maintenance therapy to keep potassium down, as summarized in Box 9.18. The cause of the hyperkalaemia should be found and treated.

---

**Box 9.18**

**Correction of severe hyperkalaemia**

Stop all potassium supplements and drugs reducing urinary excretion of potassium.

**Immediate**

- ECG monitor and i.v. access

**Protect myocardium**

- 10 mL of 10% calcium gluconate i.v. over 5 min
- Effect is temporary but dose can be repeated after 15 min

**Drive K⁺ into cells**

- Insulin 10 units + 50 mL of 50% glucose i.v. over 10–15 min, followed by regular checks of blood glucose and plasma K⁺
- Repeat as necessary:
  - and/or correction of severe acidosis (pH <6.9) – infuse NaHCO₃ (1.26%)
  - and/or salbutamol 0.5 mg in 100 mL of 5% glucose over 15 min (rarely used)

**Later**

**Deplete body K⁺ (to decrease plasma K⁺ over the next 24 h)**

- Polystyrene sulphonate resins:
- 15 g orally up to three times daily with laxatives
- 30 g rectally followed 9 h later by an enema
• Haemodialysis or peritoneal dialysis if the above fails

High potassium levels are cardiotoxic, as they inactivate sodium channels. Divalent cations, e.g. calcium, restore the voltage dependability of the channels. Calcium ions protect the cell membranes from the effects of hyperkalaemia but do not alter the potassium concentration.

Supraphysiological intravenous insulin (20 units) drives potassium into the cell and lowers plasma potassium by 1 mmol in 60 min, but must be accompanied by intravenous glucose to avoid hypoglycaemia. Regular measurements of blood glucose for at least 6 h after use of insulin should be performed and extra glucose must be available for immediate use. The use of glucose alone in non-diabetic patients, to stimulate endogenous insulin release, does not produce the high levels of insulin required and therefore is not recommended.

**Intravenous or nebulized salbutamol** (10–20 mg) has not yet found widespread acceptance and may cause disturbing muscle tremors at the doses required.

Correction of acidosis with hypertonic (8.4%) sodium bicarbonate causes volume expansion due to the high sodium concentration, and should only be used in emergency situations; 1.26% is used with severe acidosis (pH <6.9). Gastric aspiration will remove potassium and leads to alkalosis.

**Ion-exchange resins** (polystyrene sulphonate resins) are used as maintenance therapy to keep potassium down after emergency treatment. They make use of the ion fluxes that occur in the gut to remove potassium from the body and are the only way, short of dialysis, of removing potassium from the body. They may cause fluid overload (resonium contains Na+) or hypercalcaemia (calcium resonium). Resins do not appear to enhance the excretion of potassium significantly, beyond the effect of diarrhoea induced by osmotic or secretory cathartics. Two new binders (patiromer and zirconium) selectively bind potassium in the gut. They may be more potent than traditional polystyrene sulphonate resins.

In general, all of these measures are simply ways of buying time either to correct the underlying disorder or to arrange removal of potassium by dialysis, which is the definitive treatment for hyperkalaemia in renal failure.

Disorders of Magnesium Concentration

Magnesium (Mg\(^{2+}\)) plays a pivotal role in many biological processes such as enzymatic reactions, gene transcription, bone remodelling and neuromuscular stability. Approximately 99% of the Mg\(^{2+}\) in the body is in the intracellular compartment, mainly in bone (approximately 85%) and in muscle and soft tissues (approximately 14%). The other 1% is in the extracellular fluid.

Plasma magnesium levels are normally maintained within the range 0.7–1.1 mmol/L (1.4–2.2 mEq/L). The average daily magnesium intake is 15 mmol, which is absorbed mainly in the small intestine and, to a lesser extent, in the colon. In the healthy adult, there is no net gain or loss of magnesium from bone, so that balance is achieved by the urinary excretion of the net magnesium absorbed. The kidney reabsorbs between approximately 95% and 98% of the filtered Mg\(^{2+}\) and plays a major role in maintaining plasma Mg\(^{2+}\) concentrations within the normal range.

Control and renal handling of magnesium

Cortical thick ascending limb of Henle

Approximately 30% of Mg\(^{2+}\) is bound to plasma proteins but the remaining fraction is freely filterable. The major site of magnesium transport is the cortical thick ascending limb (cTAL) of the loop of Henle, where 65–70% of the filtered load is reabsorbed, with only 10–20% being reabsorbed in the proximal tubule (see Fig. 9.6). This transport is passive, paracellular and carried out by tight junction proteins (paracellin-1 and claudins). This process is driven by the lumen-positive electrochemical gradient, characteristic of this segment. This voltage gradient is created by the apical disproportionate net transport of two Cl\(^{-}\) to one Na\(^{+}\) (by the bumetanide-sensitive sodium–potassium-2–chloride transporter) and the secretion of K\(^{+}\) (via the ROMK) (see Fig. 9.6). Loss-of-function mutations in these key reabsorptive processes lead to hypomagnesaemia as part of the distinctive clinical syndromes described below.

Bartter syndrome

Hypomagnesaemia is rare in Bartter syndrome (see p. 166). This is because the transepithelial voltage, which is responsible for magnesium reabsorption, is preserved and any additional filtered magnesium will be offset by a compensatory increase in absorption in the distal convoluted tubule.

Familial hypomagnesaemia, hypercalciuria and nephrocalcinosis

Familial hypomagnesaemia, hypercalciuria and nephrocalcinosis (FHHNC) is characterized by
excessive renal magnesium and calcium wasting; the main defect lies in cTAL. Ten different mutations have been identified in a novel gene that encodes for paracellin-1 and claudins 16/19 complex, in the tight junction proteins (see p. 94).

Individuals develop bilateral nephrocalcinosis and progressive CKD. Patients also have elevated parathyroid hormone levels, which precedes any reduction in GFR. A substantial proportion of patients show incomplete distal renal tubular acidosis, hypocitraturia and hyperuricaemia. Extrarenal involvement, such as myopia, nystagmus and chorioretinitis, has been reported.

**Distal convoluted tubule**

The reabsorption rate in the distal convoluted tubule (DCT) – 10% – is much lower than in the cTAL, but it defines the final urinary excretion, as there is no significant reabsorption in the collecting duct; 3–5% of filtered magnesium is finally excreted in the urine. Magnesium reabsorption in the DCT is transcellular and active (see Fig. 9.7). The DCT has a slight lumen-negative voltage of approximately −5 mV. The luminal Mg^{2+} concentration in the DCT ranges between 0.2 and 0.7 mmol/L, whereas the intracellular concentration of Mg^{2+} is estimated to be maintained at around 0.2–1.0 mmol/L. Therefore the voltage difference across the apical membrane plays a key role in Mg^{2+} transport within the DCT.

**Magnesiotropic proteins**

These include the following:

- **TRPM6**, the transient receptor potential channel melastatin member 6, is an Mg^{2+}-permeable channel that is also expressed in the luminal membrane of the intestinal epithelium. Inactivating mutations of TRPM6 (a rare autosomal recessive disease) thus cause a combination of impaired gut absorption of Mg^{2+} and renal wasting known as hypomagnesaemia with secondary hypocalcaemia (HSH). Clinically, patients have disturbed neuromuscular excitability, muscle spasms, tetany and generalized convulsions. Severe hypomagnesaemia (0.1–0.4 mmol/L) is seen due to impaired intestinal Mg^{2+} absorption and renal reabsorption.

- **The pro-epidermal growth factor (EGF)** resides on the basolateral surface of the DCT cells. It markedly stimulates the activity of TRPM6. Loss-of-function mutation results in an autosomal recessive form of isolated renal hypomagnesaemia (IRH). IRH presents with hypomagnesaemia (0.53–0.66 mmol/L) and an inappropriately high fractional excretion of Mg^{2+} with epileptic seizures and moderate mental retardation. In contrast to HSH, Ca^{2+} handling is not affected in IRH patients. Cancer therapies that inhibit EGF also cause hypomagnesaemia by the above mechanism.

- **Thiazide-sensitive Na^{+}–Cl^{−} co-transporter in the DCT** plays a role in sodium and chloride absorption and maintenance of lumen-negative voltage. Loss-of-function mutation in this co-transporter results in Gitelman syndrome (see p. 166 and Fig. 9.7). Hypomagnesaemia is likely to be due to a reduced abundance of TRPM6. The observed hypocalciuria is caused by
an increased proximal tubular reabsorption, a process that occurs in response to the mild volume depletion.

- **The γ-subunit of the Na⁺/K⁺-ATPase** on the basolateral aspect of the DCT plays a pivotal role in the sodium and chloride absorption and maintenance of lumen-negative voltage (a key requirement for magnesium absorption) in this segment of the nephron. A loss-of-function mutation in the FXYD2 gene (transcription factor for the gamma chain of Na⁺/K⁺-ATPase) causes **isolated dominant hypomagnesaemia**. The affected individuals present with renal Mg²⁺ wasting, accompanied by hypocalciuria.

- **The HNF1b gene** encodes a transcription factor linked to the regulation of the FXYD2 gene. Defects in the HNF1b gene have been implicated in genetic defects of β-cell function (see Box 27.4). Interestingly, almost half of the carriers of a mutation in the HNF1b gene display hypomagnesaemia (<0.65 mmol/L) due to renal wasting of Mg²⁺. As in patients with FXYD2 mutations, hypocalciuria is present.

- **ATP-sensitive inward rectifier potassium channel 10 (Kir4.1)** is present on the basolateral surface of the DCT. It allows K⁺ ions to recycle across the basolateral membrane, thereby maintaining an adequate supply of K⁺ to sustain the high Na⁺/K⁺-ATPase activity observed in this segment. Loss of its function has been linked to the hypomagnesaemic (EAST) syndrome, in which the impaired electrogenic Na⁺/K⁺-ATPase transport causes depolarization of the apical membrane and reduces inward transport of Mg²⁺ via TRPM6. Patients have epilepsy, ataxia, sensorineural deafness (Kir 4.1 is present in the inner ear), and tubulopathy (of a Gitelman-like phenotype).

### Hypomagnesaemia

In addition to the familial causes described above, hypomagnesaemia most often develops as a result of deficient intake, defective gut absorption, or excessive gut or urinary loss (Box 9.19). It can also occur with acute pancreatitis, possibly owing to the formation of magnesium soaps in the areas of fat necrosis and drug treatment with aminoglycosides and cisplatinum compounds. The serum magnesium is usually <0.7 mmol/L (1.4 mEq/L). Due to the severe effects of hypomagnesaemia, routine measurements of serum Mg²⁺ should be conducted in the critically ill, as well as in patients who are exposed to drugs and other conditions associated with Mg²⁺ deficiency.

### Box 9.19

**Causes of hypomagnesaemia**

**Decreased magnesium absorption**

- Malabsorption (severe)
- Malnutrition
• Alcohol excess
• Hypomagnesaemia with secondary hypocalcaemia (see p. 1239)

Increased renal excretion
• Drugs:
  – Loop diuretics
  – Thiazide diuretics
  – Digoxin
  – Proton pump inhibitors
• Diabetic ketoacidosis
• Hyperaldosteronism
• SIADH
• Alcohol excess
• Hypercalciuria
• 1,25-(OH)-vitamin D₃ deficiency
• Drug toxicity:
  – Amphotericin
  – Aminoglycosides
  – Cisplatin
  – Ciclosporin

Gut losses
• Prolonged nasogastric suction
• Excessive purgation
• Gastrointestinal/biliary fistulae
• Severe diarrhoea

Inherited tubular wasting
• Bartter syndrome
• Familial hypomagnesaemia, hypercalciuria and nephrocalcinosis
• Isolated dominant hypomagnesaemia
• Gitelman syndrome (see p. 166)
• Isolated recessive hypomagnesaemia
• Hypomagnesaemia with secondary hypocalcaemia (HSH)
• EAST syndrome

Miscellaneous
• Acute pancreatitis
  EAST, epilepsy, ataxia, sensorineural deafness and tubulopathy; SIADH, syndrome of
Clinical features
Symptoms and signs (indicating a deficit of 0.5–1 mmol/kg) include irritability, tremor, ataxia, carpopedal spasm, hyper-reflexia, confusional and hallucinatory states, and epileptiform convulsions. An ECG may show a prolonged QT interval, broad flattened T waves and occasional shortening of the ST segment.

Management
This involves the withdrawal of precipitating agents such as diuretics or purgatives. If symptomatic (or with hypocalcaemia), give a parenteral infusion of 50 mmol of magnesium chloride in 1 L of 5% glucose or other isotonic fluid over 12–24 h. This should be repeated daily and continued for 2 days after normal plasma levels have been achieved.

Relationship between hypomagnesaemia and plasma calcium
Calcium deficiency usually, but not always, develops with hypomagnesaemia. Hypomagnesaemia can be further subdivided into three main groups:

• **Hypercalciuria** with hypomagnesaemia. This occurs from defects in Mg$^{2+}$ absorption in cTAL, such as in several forms of Bartter syndrome, loop diuretic administration and FHHNC.

• **Normocalciuria**. This includes autosomal dominant hypomagnesaemia due to mutations in Kv1.1, and IRH due to mutations in the EGF gene.

• **Hypocalciuria with hypomagnesaemia**. This is a hallmark feature of thiazide diuretic use and Gitelman syndrome, and has also been reported in the EAST syndrome, due to mutations in NCC and Kir4.1, respectively. Genetic defects of β-cell function and isolated dominant hypomagnesaemia (IDH) caused by mutations in HNF1b (see p. 169) and FXYD2 also lead to hypomagnesaemia with accompanying hypocalciuria.

Relationship between hypomagnesaemia and plasma potassium
Magnesium depletion can lead to refractory hypokalaemia. The intracellular magnesium blocks secretory K$^+$ currents through ROMK channels; therefore, magnesium depletion promotes K$^+$ loss. Furthermore, this magnesium-mediated inhibition of K$^+$ secretion increases as extracellular K$^+$ decreases, which appropriately reduces K$^+$ loss in the presence of K$^+$ deficiency. Close monitoring, with potassium supplements if necessary, is required in patients presenting with primary symptomatic low plasma magnesium levels.

Hypermagnesaemia
This primarily occurs in patients with acute or chronic kidney disease given magnesium-
containing laxatives or antacids. It can also be induced by magnesium-containing enemas. Mild hypermagnesaemia may occur in patients with adrenal insufficiency. Causes are given in Box 9.20.

**Box 9.20**

**Causes of hypermagnesaemia**

- Impaired renal excretion:
  - Chronic kidney disease
  - Acute kidney injury
- Increased magnesium intake:
  - Purgatives, e.g. magnesium sulphate
  - Antacids, e.g. magnesium trisilicate
- Haemodialysis with high [Mg\(^{2+}\)] dialysate

**Clinical features**

Symptoms and signs relate to neurological and cardiovascular depression, and include weakness with hyporeflexia proceeding to narcosis, respiratory paralysis and cardiac conduction defects. Symptoms usually develop when the plasma magnesium level exceeds 2 mmol/L (4 mEq/L).

**Management**

Treatment requires withdrawal of any magnesium therapy. An intravenous injection of 10 mL of calcium gluconate 10% (2.25 mmol calcium) is given to antagonize the effects of hypermagnesaemia, along with glucose and insulin (as for hyperkalaemia; see p. 168) to lower the plasma magnesium level. Dialysis may be required in patients with severe kidney disease.

**Further reading**

Phosphate forms an essential part of most biochemical systems. The regulation of plasma phosphate level is both direct and closely linked to calcium. About 85% of all body phosphorus is within bone, plasma phosphate normally ranging from 0.80 to 1.15 mmol/L (2.5–3.6 mg/dL) and accounts for only 1% of the total body phosphate. However, plasma phosphate levels correlate in most circumstances with total body sodium. Phosphate reabsorption from the glomerular filtrate occurs entirely and actively in the renal proximal tubule and is hormonally regulated. It is decreased by parathyroid hormone (PTH), mediated by a cyclic adenosine monophosphate (cAMP)-dependent mechanism; thus primary hyperparathyroidism is associated with low plasma levels of serum phosphate. Other factors that are known to control phosphate reabsorption in the proximal tubule are 1,25-dihydroxyvitamin D₃, sodium delivery to the proximal tubule, serum concentrations of calcium, bicarbonate, carbon dioxide tension, glucose, alanine, serotonin, dopamine and sympathetic activity.

Osteoblast-secreted phosphaturic factors (phosphatonin), such as fibroblast growth factor 23 (FGF23), matrix extracellular phosphoglycoprotein (MEPG) and frizzled-related protein 4 (FRP-4), play a role in phosphate homeostasis. FGF23 is the most extensively investigated phosphatonin. It binds to its receptor, FGFR1, in the kidney and causes phosphaturia; it also regulates vitamin D by inactivation of 1α-hydroxylase (CYP27B1) and upregulation of 24 hydroxylase (CYP24A1) enzymes, with the net result of low 1,25-vitamin D synthesis. Serum FGF23 is also the earliest marker of abnormal phosphate handling in CKD patients, occurring before changes in serum phosphate, calcium or PTH (Fig. 9.10). Moreover, FGF23 requires Klotho (see p. 165) to act as a co-receptor with FGFR1 for its activity. Loss-of-function mutation in either FGF23 or Klotho results in a similar phenotype of shortened lifespan, premature ageing (see p. 109) and hyperphosphataemia, and, as expected from the mode of action, increases 1,25 vitamin D levels. Klotho can also inhibit phosphate absorption directly in the absence of FGF23 or PTH.
Phosphate absorption is an active process carried out by a family of sodium–phosphate co-transporters (NPT) in the gut and kidneys. NPT2a and NPT2c are expressed in the brush border of the renal proximal tubule whilst NPT2b is expressed in lungs and intestine. NPT2a plays a central role in the renal reabsorption of phosphate but essentially requires a companion protein called sodium hydrogen exchanger regulatory factor 1 (NHERF1) for membrane sorting. Intestinal absorption is carried out by NPT2b but its mutation does not cause any alteration in serum phosphate due to compensation by the renal expression of NPT2a and possibly NPT2c. Under normal circumstances, plasma phosphate levels are kept constant; for example, after a phosphate-rich meal, the bone releases FGF23, which inhibits NPT2a and causes phosphate excretion. Moreover, phosphate in the plasma causes the release of PTH, either directly or indirectly by lowering ionized calcium. PTH also inhibits NPT2a, NPT2C and NHERF1, resulting in phosphaturia (Fig. 9.10). These two principal mechanisms keep plasma phosphate levels within normal limits on a daily basis.

Hypophosphataemia
Significant hypophosphataemia (<0.4 mmol/L or <1.25 mg/dL) occurs in a number of clinical situations, owing to redistribution into cells, renal losses or decreased intake (Box 9.21).

**Box 9.21**

**Causes of hypophosphataemia**

**Redistribution**

- Respiratory alkalosis
- Treatment of diabetic ketoacidosis (insulin drives phosphate into cells)
- Refeeding (particularly with carbohydrate) after fasting or starvation
- After parathyroidectomy (hungry bone disease)

**Decreased intake/absorption**

- Diet
- Malabsorption
- Vomiting
- Gut phosphate binders, e.g. sevelamer
- Vitamin D deficiency
- Alcohol withdrawal

**Renal losses**

- Hyperparathyroidism
- Renal tubular defects
- Diuretics
- Tenofovir treatment

**Hypophosphataemic rickets**

- Vitamin D-dependent rickets types I and II
- Tumour-induced
- Autosomal dominant and recessive
- X-linked dominant
- Dent's disease

Clinical features include:

- muscle weakness, e.g. diaphragmatic weakness, decreased cardiac contractility, skeletal muscle rhabdomyolysis
- a left shift in the oxyhaemoglobin dissociation curve (reduced 2,3-bisphosphoglycerate, 2,3-
BPG) and rarely haemolysis

- confusion, hallucinations and convulsions.

Mild hypophosphataemia often resolves without specific treatment. However, diaphragmatic weakness may be severe in acute hypophosphataemia, and may impede the weaning of a patient from a ventilator. Interestingly, chronic hypophosphataemia (in X-linked hypophosphataemia) is associated with normal muscle power.

### Aetiology

Primary hyperparathyroidism is a common cause of hypophosphataemia. Very rarely, gain-of-function mutations of the PTH1 receptor cause hypophosphataemia and Jansen's metaphyseal chondrodysplasia due to constitutive activation of PTH signalling, even in the presence of low or absent circulating PTH levels.

Hypophosphataemia can be part of osteomalacia and rickets due to vitamin D deficiency, either dietary (globally, the most common cause) or genetic, and is usually accompanied by hypocalcaemia (calcipenic) and secondary hyperparathyroidism.

**Vitamin D-dependent rickets type I**

Also known as *pseudo-vitamin D-deficient rickets*, this is caused by 1α-hydroxylase deficiency due to inactivating mutations in its gene. This condition manifests clinically in the first year of life with severe hypocalcaemia, often complicated by tetany, moderate hypophosphataemia and enamel hypoplasia. The characteristic biochemical findings are normal serum levels of 25-hydroxyvitamin D, low values of 1,25-dihydroxyvitamin D and, usually, relatively high PTH levels. The treatment of choice is replacement therapy with calcitriol.

**Vitamin D-dependent rickets type II**

This is a form of vitamin D resistance and is known as *hereditary vitamin D-resistant rickets*. It is an autosomal recessive disorder and is usually caused by loss-of-function mutations in the gene encoding the vitamin D receptor. The clinical manifestations vary widely, depending upon the type of mutation within the vitamin D receptor and the amount of residual vitamin D receptor activity. Affected children usually develop rickets within the first 2 years of life, with alopecia in two-thirds of cases, which is due to lack of vitamin D receptor action within keratinocytes. The treatment involves a therapeutic trial of calcitriol and calcium supplementation. Long-term infusion of calcium into a central vein is a possible alternative for severely resistant patients. Oral calcium therapy may be sufficient once radiographic healing has been observed.

### Decreased renal reabsorption of phosphate

**Excessive phosphatonin (FGF23)**
This condition also occurs in patients with **tumour-induced osteomalacia** (TIO), **X-linked dominant hypophosphataemic rickets** (XLR) and **autosomal dominant hypophosphataemic rickets** (ADHR). These syndromes have similar biochemical and osseous phenotypes. Patients have osteomalacia or rickets, reduced tubular phosphate reabsorption, hypophosphataemia, normal or low serum calcium, normal PTH and PTH-related protein concentrations, and normal or low 1,25-dihydroxyvitamin D₃. Urinary cAMP levels are generally in the normal range.

In **TIO**, there is excessive production of phosphaturic agents (which are normally produced by osteoblasts and function as hormones by acting on kidneys and regulating phosphate absorption and vitamin D activation): for example, FGF23, MEPG and FRP-4. These are resistant to degradation by **PHEX** (phosphate-regulating gene with homologies to endopeptidases on the X chromosome). The result is excess inhibition of the sodium–phosphate co-transporter in the proximal tubule and phosphaturia.

In **ADHR**, FGF23 is mutated so that it is resistant to PHEX proteolysis. In XLR, mutations in PHEX prevent binding to FGF23 and FRP-4, resulting in a net relative excess of phosphatonin.

Normal adaptive increases in 1,25-dihydroxyvitamin D₃ synthesis in response to low phosphate levels do not occur in TIO, ADHR and XLR, aggravating phosphaturia (**Fig. 9.10**).

**Autosomal recessive hypophosphataemia with high FGF23** levels has been described in patients with mutations in the gene encoding dentin matrix protein 1 (**DMP1**), which is a transcription factor produced by odontoblasts, osteoblasts and osteocytes. It is also secreted and can modulate the formation of mineralized matrix.

**Reduced NPT2a/NHERF1 activity**

Mutations in NPT2a (sodium–phosphate co-transporter 2a) and NHERF1 (sodium hydrogen regulator factor 1) have been identified in patients with low phosphate levels and a reduced ratio of the maximum tubular reabsorption of phosphate (TmP) normalized for GFR (TmP/GFR ratio). Heterozygous loss-of-function mutation in NPT2a and NHERF1 in patients is characterized by hypophosphataemia, low TmP/GFR and normal PTH. Carriers of these mutations do not have hypercalcaemia, which means these mutations do not affect the action of PTH on bones.

**Dent's disease**

Dent's disease is the generally accepted name for a group of hereditary tubular disorders, including X-linked recessive nephrolithiasis with chronic renal disease, X-linked recessive hypophosphataemic rickets, and idiopathic low-molecular-weight proteinuria. It is characterized by low-molecular-weight proteinuria, hypercalciuria, hyperphosphaturia, nephrocalcinosis, kidney stones and eventual renal failure, with some patients developing rickets or osteomalacia.

Dent's disease is caused, in 60% of cases, by loss-of-function mutation of a proximal tubular endosomal chloride channel, CLC5. Mutations in OCRL1 occur in 15% of cases. This chloride
channel, along with the proton pump, is essential for acidification of proximal tubular endosomes. The process is linked with normal endocytosis, degradation and recycling of absorbed proteins, vitamins and hormones. Defective endosomal acidification (owing to the mutated CLC5 gene) results in impaired endosomal degradation and recycling of endocytosed hormones such as PTH with the clinical phenotype of hyperparathyroidism. Moreover, the receptors (megalin and cubilin) for reabsorption of low-molecular-weight proteins and albumin in the proximal tubules are decreased in Dent's disease. This explains the low-molecular-weight proteinuria and excessive urinary leaks of cytokines, hormones and chemokines. This urinary profile is associated with progressive renal fibrosis and more rapid decline in renal function.

**Diagnosis**

Patients with hypophosphataemia should have their urinary fractional excretion of phosphate measured. A value of <0.7 mmol/L indicates renal phosphate wasting. If PTH levels are high, then the patient is very likely to have hyperparathyroidism, either primary or secondary to vitamin D deficiency (acquired or genetic) or Dent's disease. If PTH levels are low, then the only possibility is gain-of-function mutation in PTH1R. If PTH levels are normal, then assess FGF23 levels. High FGF23 serum levels will indicate possible mutated genes in FGF23/Klotho, PHEX and DMP1. Normal FGF23 and PTH levels point to mutations in NPT2a, NPT2c and NHERF1.

**Management**

Oral phosphate supplementation and calcitriol (1,25-dihydroxyvitamin D) administration is required if there is vitamin D deficiency.

Treatment of *acute hypophosphataemia* is with intravenous phosphate at a maximum rate of 9 mmol every 12 hours. Repeated measurements of calcium and phosphate are required, as over-rapid administration of phosphate may lead to severe hypocalcaemia, particularly in the presence of alkalosis. *Chronic hypophosphataemia* can be corrected with oral effervescent sodium phosphate.

**Hyperphosphataemia**

Hyperphosphataemia is common in patients with CKD (see p. 779 and Box 9.22). Hyperphosphataemia is usually asymptomatic but may result in precipitation of calcium phosphate, particularly in the presence of a normal or raised calcium level or of alkalosis. Uraemic itching may be caused by a raised calcium phosphate product. Prolonged hyperphosphataemia causes hyperparathyroidism and periarticular and vascular calcification.

---

**Box 9.22**
Causes of hyperphosphataemia

- Acute kidney injury
- Chronic kidney disease
- Phosphate-containing enemas
- Hyperparathyroidism/pseudohyperparathyroidism
- Tumour lysis
- Rhabdomyolysis
- Familial tumoral calcinosis

Familial tumoral calcinosis is characterized by calcifications of muscles, skin, eyelids and vessels, as well as hyperostosis. Absence of glycosylation of FGF23 makes it unstable and more sensitive to proteolysis. This results in its deficiency and hyperphosphataemia due to increased renal phosphate reabsorption through increased NPT2a activity.

Usually, no treatment is required for acute hyperphosphataemia, as the causes are self-limiting. Treatment of chronic hyperphosphataemia is with gut phosphate binders and dialysis (see p. 780).

Acid–Base Disorders

The concentration of hydrogen ions in both extracellular and intracellular compartments is extremely tightly controlled, and very small changes lead to major cell dysfunction. The blood pH is tightly regulated and is normally maintained at between 7.38 and 7.42. Any deviation from this range indicates a change in the hydrogen ion concentration [H+] because blood pH is the negative logarithm of [H+] (Box 9.23). The [H+] at a physiological blood pH of 7.40 is 40 nmol/L. An increase in the [H+] (a fall in pH) is termed acidaemia. A decrease in [H+] (a rise in the blood pH) is termed alkalaemia. The disorders that cause these changes in the blood pH are acidosis and alkalosis, respectively.
### Relationship between [H+] and pH

### Normal acid–base physiology

The normal adult diet contains 70–100 mmol of acid (H⁺). Throughout the body there are buffers that minimize any changes in blood pH that these ingested hydrogen ions might cause. Such buffers include intracellular proteins (e.g. haemoglobin) and tissue components (e.g. the calcium carbonate and calcium phosphate in bone), as well as the bicarbonate–carbonic acid buffer pair generated by the hydration of carbon dioxide. This buffer pair is clinically most relevant, in part because its contribution can be measured and because alterations in this buffer pair reveal changes in all other buffer systems. Bicarbonate ions [HCO₃⁻] and carbonic acid (H₂CO₃) exist in equilibrium; and in the presence of carbonic anhydrase, carbonic acid dissociates to carbon dioxide and water, as expressed in the following equation:

\[
\text{H}^+ \text{HCO}_3^- \rightleftharpoons \text{H}_2\text{CO}_3 \rightarrow \text{CO}_2 + \text{H}_2\text{O}.
\]

The addition of hydrogen ions drives the reaction to the right, decreasing the plasma bicarbonate concentration [HCO₃⁻] and increasing the arterial carbon dioxide pressure (\(P_a\text{CO}_2\)). As shown in the following Henderson–Hasselbalch equation, a fall in the plasma [HCO₃⁻] increases [H⁺] and thus lowers blood pH:

\[
[H^+] = 181 \times P_a\text{CO}_2[HCO_3^-]
\]

where [H⁺] is expressed in nmol/L, \(P_a\text{CO}_2\) in kilopascals, [HCO₃⁻] in mmol/L and 181 is the dissociation coefficient of carbonic acid. Alternatively the equation can be expressed as:
pH = pK + log[HCO$_3^-$]/[H$_2$CO$_3$]

where pK = 6.1. Thus, the bicarbonate used in the buffering process must be regenerated to maintain normal acid–base balance.

Although the acidaemia stimulates an increase in ventilation, which blunts this change in pH, increased ventilation does not regenerate the bicarbonate used in the buffering process. Consequently, the kidney must excrete hydrogen ions to return the plasma [HCO$_3^-$] to normal. Maintenance of a normal plasma [HCO$_3^-$] under physiological conditions depends not only on daily regeneration of bicarbonate but also on reabsorption of all bicarbonate filtered across the glomerular capillaries.

**Renal reabsorption of bicarbonate**

The plasma [HCO$_3^-$] is normally maintained at approximately 25 mmol/L. In individuals with a normal GFR (120 mL/min), about 4500 mmol of bicarbonate is filtered each day. If this filtered bicarbonate were not reabsorbed, the plasma [HCO$_3^-$] would fall, along with blood pH. Thus, maintenance of normal plasma [HCO$_3^-$] requires that essentially all of the bicarbonate in the glomerular filtrate be reabsorbed (Fig. 9.11).

![FIGURE 9.11 Resorption of sodium bicarbonate in the renal (mainly proximal) tubule. Bicarbonate is reclaimed by the secretion of H$^+$ in exchange for Na$^+$ into the tubule. This results in the formation of H$_2$CO$_3$, which is then broken down to CO$_2$. This is reabsorbed and converted back to H$_2$CO$_3$, which now dissociates into H$^+$ and HCO$_3^-$. The net result is reabsorption of Na$^+$ and HCO$_3^-$. This process is dependent on carbonic anhydrase within the cells and on the luminal surface of the tubular cell.](image)

The proximal convoluted tubule reclaims 85–90% of filtered bicarbonate; by contrast, the distal nephron reclaims very little. This difference is caused by the greater quantity of luminal
(brush border) carbonic anhydrase in the proximal tubule than in the distal nephron. As a result of these quantitative differences, bicarbonate that escapes reabsorption in the proximal tubule is excreted in the urine.

Proximal tubular bicarbonate reabsorption is catalysed by the Na\(^+\)/K\(^+\)-ATPase pump located in the basolateral cell membrane. By exchanging peritubular potassium ions for intracellular sodium ions, the pump keeps the intracellular sodium concentration low, allowing sodium ions to enter the cell by moving down the sodium concentration gradient from the tubule lumen to the cell interior. Hydrogen ions are transported in the opposite direction (at the Na\(^+\)–H\(^+\) antiporter), thereby maintaining electroneutrality. Before bicarbonate enters the proximal tubule, it combines with secreted hydrogen ions, forming carbonic acid. In the presence of luminal carbonic anhydrase (CA-IV), carbonic acid rapidly dissociates into carbon dioxide and water, which can then rapidly enter the proximal tubular cell. In the cell, carbon dioxide is hydrated by cytosolic carbonic anhydrase (CA-II), ultimately forming bicarbonate, which is then transported down an electrical gradient from the cell interior, across the membrane into the peritubular fluid, and into the blood. In this process, each hydrogen ion secreted into the proximal tubule lumen is reabsorbed and can be resecreted; there is no net loss of hydrogen ions or net gain of bicarbonate ions.

**Renal excretion of \([H^+]\) (Fig. 9.12)**

More acid is secreted into the proximal tubule (up to 4500 nmol of hydrogen ions each day) than in any other nephron segment. However, the hydrogen ions secreted into the proximal tubule are almost completely reabsorbed with bicarbonate; consequently, proximal tubular hydrogen ion secretion does not contribute significantly to hydrogen ion elimination from the body. The excretion of the daily acid load requires hydrogen ion secretion in more distal nephron segments.
Renal excretion of H⁺. H⁺ excretion is indirectly controlled by aldosterone in the cortical collecting ducts. Aldosterone enhances sodium absorption and potassium excretion by opening sodium channels and enhancing the activity of the Na⁺/K⁺-ATPase in the principal cell. These actions set up an electrochemical gradient favouring H⁺ excretion. Aldosterone also facilitates H⁺ excretion by stimulating H⁺-ATPase in the intercalated cell.

Most dietary hydrogen ions come from sulphur-containing amino acids that are metabolized to sulphuric acid (H₂SO₄), which then reacts with sodium bicarbonate as follows:

\[
H₂SO₄ + 2NaHCO₃ → Na₂SO₄ + 2CO₂ + 2H₂O.
\]

Excess sulphate is excreted in the urine, whereas excess hydrogen ions are buffered by bicarbonate and lower the plasma [HCO₃⁻]. This fall in plasma [HCO₃⁻] leads to a slight decrease in the blood pH, although a smaller decrease in the blood pH than would have occurred if buffer were unavailable. The subsequent excretion of hydrogen ions takes place primarily in the collecting duct and results in the regeneration of 1 mmol of bicarbonate for every mmol of hydrogen ions excreted in the urine.

The collecting duct has three types of cells:

- The **principal cell** with an aldosterone-sensitive Na⁺ absorption site. These cells reabsorb Na⁺ and H₂O and secrete K⁺ under the influence of aldosterone.

- The **α-intercalated cell**, which possesses the proton pump for the active secretion of hydrogen ions in exchange for reabsorption of K⁺ ions. Aldosterone increases H⁺ ion secretion.

- The **β-intercalated cells** are mirror images of α-intercalated cells. Here the H⁺-ATPase pump is located in the basolateral rather than the apical membrane, whereby H⁺ ions are secreted into the peritubular capillary. The HCO₃⁻ ions, on the other hand, are secreted into the tubular lumen by an anion exchanger in the apical membrane. The identity of this transporter is...
uncertain, however, as it does not appear to represent the same Cl\(^{-}\)-HCO\(_3\)^{-} exchanger that is present in the basolateral membrane of the H\(^{+}\)-secreting intercalated cells.

Secretion of hydrogen ions from the cortical collecting duct is indirectly linked to sodium reabsorption.

- Aldosterone has several facilitating effects on hydrogen ion secretion. Aldosterone opens sodium channels in the luminal membrane of the principal cell and increases Na\(^{+}\)/K\(^{+}\)-ATPase activity. The subsequent movement of cationic sodium into the principal cell creates a negative charge within the tubule lumen. Potassium ions from the principal cells and hydrogen ions from the α-intercalated cells move out from the cells down the electrochemical gradient and into the lumen.

- Aldosterone also stimulates directly the H\(^{+}\)-ATPase in the α-intercalated cell, further enhancing hydrogen ion secretion. The H\(^{+}\) to be secreted arises from the reassociation of H\(_2\)O and CO\(_2\) in the presence of carbonic anhydrase; thus, a bicarbonate molecule is regenerated each time an H\(^{+}\) is eliminated in the urine.

When hydrogen ions are secreted into the lumen of the collecting tubule, a tiny, but physiologically critical, fraction of these excess hydrogen ions remains in solution. Here, they increase the urinary [H\(^{+}\)] and lower urinary pH below 4.0. Nevertheless, below this urine pH, inhibition of proton-secreting pumps, such as H\(^{+}\)-ATPase, severely restricts kidney secretion of more hydrogen ions. Consequently, secretion of hydrogen ions depends on the presence of buffers in the urine that maintain the urine pH at a level higher than 4.0.

In the presence of alkali excess, the homeostatic needs are reversed. Although the kidney can excrete excess alkaline load by reducing reabsorption of filtered bicarbonate in the proximal and distal tubule, the collecting ducts also contribute by secreting bicarbonate brought about by switching to β-intercalated cells. This switch enables kidneys to secrete bicarbonate and conserve H\(^{+}\) ions.

**Buffer systems in acid excretion**

Two buffer systems are involved in acid excretion: the titratable acids, such as phosphate, and the ammonia system. Each system is responsible for excreting about half of the daily acid load of 50–100 mmol under physiological conditions (*Fig. 9.12*).

**Titratable acid**

A titratable acid is a filtered buffer substance having a conjugate anion that can be titrated within the pH range occurring physiologically in the urine. Phosphoric acid (pK\(_a\) 6.8) is the usual titratable urinary buffer. Hydrogen ions bind to the conjugate anions of the titratable acids and are excreted in the urine. For each hydrogen ion excreted in this form, a bicarbonate ion is regenerated within the cell and returned to the blood (*Fig. 9.12*).

**Ammonium (NH\(_4\)^{+}\)**

In the setting of metabolic acidosis, titratable acids cannot increase significantly because the
availability of titratable acid is fixed by the plasma concentration of the buffer and by the GFR. The ammonia buffer system, by contrast, can increase several hundred-fold when necessary. Consequently, impaired renal excretion of hydrogen ions is always associated with a defect in ammonium excretion (Fig. 9.13).

![Figure 9.13](image) The ammonia buffering system in the kidney. All ammonia used to buffer H⁺ in the collecting duct is synthesized in the proximal convoluted tubule, and glutamine is the main source of this ammonia. As glutamine is metabolized, α-ketoglutarate (α-KG) is formed, which ultimately breaks down to bicarbonate that is then secreted into the peritubular fluid at an Na⁺-HCO₃⁻ co-transporter.

All ammonia used to buffer urinary hydrogen ions in the collecting tubule is synthesized in the proximal convoluted tubule. Glutamine is the primary source of ammonia. It undergoes deamination catalysed by glutaminase, resulting in α-ketoglutaric acid (Fig. 9.13) and ammonia. Once formed, ammonia can diffuse into the proximal tubule lumen and become acidified, forming ammonium. Once in the proximal tubule lumen, ammonium flows along the tubule to the thick ascending limb of the loop of Henle. Here, it is transported out of the tubule into the medullary interstitium. Ammonium then dissociates to ammonia, leading to a high interstitial ammonia concentration. The notion that ammonia diffuses down its concentration gradient into the lumen of the collecting tubule has been challenged by the discovery of rhesus (Rh)-associated glycoproteins acting as ammonia transport proteins, also called RhCG/Rhcg, which are expressed in the basolateral and apical surfaces of the DCT, inner medullary collecting duct and type α intercalated cells. These proteins play a fundamental role in renal ammonia excretion under both basal and acidotic states. Once secreted, NH₃ reacts with the hydrogen ions secreted by the collecting tubular cells to form ammonium. Because ammonium (NH₄⁺) is not lipid-soluble, it is trapped in the lumen and excreted in the urine as ammonium chloride. Two conditions predominantly promote ammonia synthesis by the proximal tubular cell: systemic acidosis and hypokalaemia.
Aetiology of acid–base disturbance

Acid–base disturbance may be caused by:

• abnormal CO₂ removal in the lungs (‘respiratory’ acidosis and alkalosis)
• abnormalities in the regulation of bicarbonate and other buffers in the blood (‘metabolic’ acidosis and alkalosis).

Both may, and usually do, coexist. For instance, metabolic acidosis causes hyperventilation (via medullary chemoreceptors, see p. 1061), leading to increased removal of CO₂ in the lungs and partial compensation for the acidosis. Conversely, respiratory acidosis is accompanied by renal bicarbonate retention, which could be mistaken for primary metabolic alkalosis. The situation is even more complex if a patient has both respiratory disease and a metabolic disturbance.

Diagnosis

Clinical history and examination usually point to the correct diagnosis. Box 9.24 shows the typical blood changes, but in complicated patients the acid–base nomogram (Fig. 9.14) is invaluable. The [H⁺] and PₐCO₂ are measured in arterial blood (for precautions), as well as the bicarbonate. If the values from a patient lie in one of the bands in the diagram, it is likely that only one abnormality is present. If the [H⁺] is high (pH low) but the PₐCO₂ is normal, the intercept lies between two bands: the patient has respiratory dysfunction, leading to failure of CO₂ elimination, but this is partly compensated for by metabolic acidosis, stimulating respiration and CO₂ removal (this is the most common ‘combined’ abnormality in practice).

Respiratory acidosis and alkalosis

Respiratory acidosis

This is caused by retention of CO₂, commonly seen in chronic obstructive pulmonary disease (COPD). The \( P_aCO_2 \) and \([H^+]\) rise. Renal retention of bicarbonate may partly compensate, returning the \([H^+]\) towards normal (see p. 1150).

Respiratory alkalosis

Increased removal of CO₂ is caused by hyperventilation, so there is a fall in \( P_aCO_2 \) and \([H^+]\) (see p. 1150).

Metabolic acidosis and alkalosis

Metabolic acidosis

This is due to the accumulation of any acid other than carbonic acid, and there is a primary decrease in the plasma \([HCO_3^-]\). Several disorders can lead to metabolic acidosis: acid administration, acid generation (e.g. lactic acidosis during shock or cardiac arrest), impaired
acid excretion by the kidneys, or bicarbonate losses from the gastrointestinal tract or kidneys. Calculation of the plasma anion gap is extremely useful in narrowing this differential diagnosis.

**The anion gap**

The first step is to identify whether the acidosis is due to retention of \( \text{H}^+\text{Cl}^- \) or to another acid. This is achieved by calculation of the anion gap.

- The normal cations present in plasma are \( \text{Na}^+ \), \( \text{K}^+ \), \( \text{Ca}^{2+} \), \( \text{Mg}^{2+} \).
- The normal anions present in plasma are \( \text{Cl}^- \), \( \text{HCO}_3^- \), negative charges present on albumin, phosphate, sulphate, lactate and other organic acids.
- The sums of the positive and negative charges are equal.
- Measurement of plasma \([\text{Na}^+]\), \([\text{K}^+]\), \([\text{Cl}^-]\) and \([\text{HCO}_3^-]\) is usually easily available.

As there are more unmeasured anions than cations, the *normal anion gap* is 12–16 mmol/L, although calculations with more sensitive methods place this at 3–9 mmol/L. Albumin normally makes up the largest portion of these unmeasured anions. As a result, a fall in the plasma albumin concentration from the normal value of about 40 g/L to 20 g/L may reduce the anion gap by as much as 6 mmol/L because each 1 g/L of albumin has a negative charge of 0.2–0.28 mmol/L.

**Metabolic acidosis with a normal anion gap**

If the anion gap is normal in the presence of acidosis, this suggests that \( \text{H}^+\text{Cl}^- \) is being retained or that \( \text{Na}^+\text{HCO}_3^- \) is being lost. Causes of a normal-anion-gap acidosis are given in Box 9.25. In these conditions, plasma bicarbonate decreases and is replaced by chloride to maintain electroneutrality. Consequently, these disorders are sometimes referred to collectively as hyperchloraemic acidoses.

### Box 9.25

**Causes of metabolic acidosis with a normal anion gap**

**Increased gastrointestinal bicarbonate loss**
- Diarrhoea
- Ileostomy
- Ureterosigmoidostomy

**Increased renal bicarbonate loss**
- Acetazolamide therapy
- Proximal (type 2) renal tubular acidosis
• Hyperparathyroidism
• Tubular damage, e.g. drugs, heavy metals, paraproteins

### Decreased renal hydrogen ion excretion

• Distal (type 1) renal tubular acidosis
• Type 4 renal tubular acidosis (aldosterone deficiency)

### Increased HCl production

• Ammonium chloride ingestion
• Increased catabolism of lysine, arginine

---

**Renal tubular acidosis**

The term ‘renal tubular acidosis’ (RTA) refers to systemic acidosis caused by impairment of the ability of the renal tubules to maintain acid–base balance. This group of disorders is uncommon and only rarely a cause of significant clinical disease.

**Type 4 renal tubular acidosis**

This results from a deficiency or unresponsiveness to aldosterone and, as such, type 4 RTA is also called ‘hyporeninaemic hypoaldosteronism’. This is the most common form of RTA. The cardinal features are hyperkalaemia and acidosis occurring in a patient with mild CKD, usually caused by tubulointerstitial disease (e.g. reflux nephropathy) or diabetes. Hyperkalaemia maintains the acidosis through impairment of ammonia production in the proximal tubule leading to a reduction in net acid excretion. Gordon syndrome (see pp. 167–168) shares biochemical abnormalities but differs in having normal GFR and hypertension. Plasma renin and aldosterone are found to be low, even after measures that would normally stimulate their secretion. Features of type 4 RTA are shown in Box 9.26. An identical syndrome is caused by chronic ingestion of NSAIDs, which impair renin and aldosterone secretion. In the presence of acidosis, urine pH may be low. Treatment is with fludrocortisone, sodium bicarbonate, diuretics or ion exchange resins to remove potassium, or a combination of these. Resolution of hyperkalaemia may correct the metabolic acidosis through increased ammonium excretion. Dietary potassium restriction alone is ineffective.

---

### Box 9.26

**Features of type 4 renal tubular acidosis (hyporeninaemic hypoaldosteronism)**

• Hyperkalaemia (in the absence of drugs known to cause hyperkalaemia)
• Low plasma bicarbonate and hyperchloraemia
• Normal adrenocorticotropic hormone (ACTH) stimulation test (see p. 1182)
• Low basal 24 h urinary aldosterone
• Subnormal response of plasma renin and plasma aldosterone to stimulation: samples taken over 2 h supine and again after 40 mg furosemide (80 mg if creatinine >120 µmol/L) and 4 h upright posture
• Correction of hyperkalaemia by fludrocortisone 0.1 mg daily

**Type 3 renal tubular acidosis**
This condition is vanishingly rare, and represents a combination of type 1 and type 2 RTA. Inherited type 3 RTA is caused by mutations resulting in carbonic anhydrase type II deficiency, which is characterized by osteopetrosis, RTA of mixed type, cerebral calcification and mental retardation.

**Type 2 (‘proximal’) renal tubular acidosis**
This is very rare in adult practice. It is caused by failure of sodium bicarbonate reabsorption in the proximal tubule. The cardinal features are acidosis, hypokalaemia, an inability to lower the urine pH below 5.5 despite systemic acidosis, and the appearance of bicarbonate in the urine despite a subnormal plasma bicarbonate. This disorder normally occurs as part of a generalized tubular defect, together with other features such as glycosuria and amino-aciduria. Inherited forms of isolated type 2 RTA are described as both autosomal dominant and recessive patterns of inheritance, where putative mutations are in the Na\(^+\)–H\(^+\) antiporter in the apical membrane and Na\(^+\)–HCO\(_3\)^− co-transporter in the basolateral membrane of proximal tubular cells, respectively (see Fig. 9.11). Treatment is with sodium bicarbonate; massive doses may be required to overcome the renal ‘leak’.

**Type 1 (‘distal’) renal tubular acidosis**
This is due to a failure of H\(^+\) excretion in the distal tubule (Box 9.27). It consists of:
• acidosis
• hypokalaemia (few exceptions)
• inability to lower the urine pH below 5.3 despite systemic acidosis
• low urinary ammonium production.

---

**Box 9.27**

**Causes of type 1 distal renal tubular acidosis**

**Primary**
• Idiopathic
• Genetic
• Marfan syndrome
• Ehlers–Danlos syndrome
• Sickle cell anaemia

**Nephrocalcinosis**
• Chronic hypercalcaemia
• Medullary sponge kidney

**Hypergammaglobulinaemic states**
• Amyloidosis\(^a\)
• Cryoglobulinaemia
• Chronic liver disease

**Drugs and toxins**
• Amphotericin B
• Lithium carbonate
• NSAIDs

\(^a\)May also cause proximal renal tubular acidosis.

These features may be present only in the face of increased acid production; hence the need for an acid load test in diagnosis (*Box 9.28*). Other features include:
• low urinary citrate (owing to increased citrate absorption in the proximal tubule, where it can be converted to bicarbonate)
• hypercalciuria.

---

**Box 9.28**

**Diagnosis of renal tubular acidosis**

Plasma $\text{HCO}_3^-$ <21 mmol/L, urine pH >5.3 = renal tubular acidosis.

**Distal RTA:** defect in dietary acid excretion. Urine pH always >5.5
**Proximal RTA:** defect in bicarbonate reabsorption. Urine pH variable

**Bicarbonate infusion test**

To differentiate between proximal and distal RTA, perform the bicarbonate infusion test:
• Use a bicarbonate infusion (0.5–1 mmol/kg per hour) to raise serum bicarbonate to 18–20 mmol/L.
• If urine pH rises to >7.5 and the fractional excretion of bicarbonate ($\text{Fe HCO}_3$)\(^a\) rises to >15%, then the defect is bicarbonate reabsorption and diagnosis is proximal RTA.
• If there is little change in urine pH and fractional excretion of bicarbonate remains low, the diagnosis is distal RTA.

**Acid load test**

If plasma HCO₃⁻ is >21 mmol/L but there is suspicion of partial renal tubular acidosis (e.g. nephrocalcinosis-associated diseases), an acid load test is required:
• Give 100 mg/kg ammonium chloride by mouth.
• Check urine pH hourly and plasma HCO₃⁻ at 3 h.
• Plasma HCO₃⁻ should drop below 21 mmol/L unless the patient vomits (in which case the test should be repeated with an antiemetic).
• If urine pH remains >5.3 despite a plasma HCO₃⁻ of 21 mmol/L, the diagnosis is confirmed.

\[ \text{Fe HCO}_3 = \frac{(\text{urine bicarbonate} \times \text{serum creatinine})}{(\text{serum bicarbonate/urine creatinine}) \times 100}. \]

These abnormalities result in osteomalacia, renal stone formation and recurrent urinary infections:
• **Osteomalacia** is caused by buffering of H⁺ by Ca²⁺ in bone, resulting in depletion of calcium from bone.
• **Renal stone formation** is caused by hypercalciuria, hypocitraturia (citrate inhibits calcium phosphate precipitation) and alkaline urine (which favours precipitation of calcium phosphate).
• **Recurrent urinary infections** are caused by renal stones.

Both autosomal dominant and recessive inheritance patterns have been reported in primary distal RTA. In autosomal recessive distal RTA, a substantial proportion of patients have sensorineural deafness, and this is associated with a loss-of-function mutation in the H⁺-ATPase at the apical surface of intercalated cells.

Treatment is with sodium bicarbonate, potassium supplements and citrate. Thiazide diuretics are useful because they cause volume contraction and increased proximal sodium bicarbonate reabsorption.

**Urinary anion gap**

Another useful tool in the evaluation of metabolic acidosis with a normal anion gap is the urinary anion gap:

\[
\text{URINARY ANION GAP} = \{\text{urinary}[\text{Na}^+] + \text{urinary}[\text{K}^+]\} - \text{urinary}[\text{Cl}^-].
\]

This calculation can be used to distinguish the normal-anion-gap acidosis caused by
diarrhoea (or other gastrointestinal alkali loss) from that caused by distal RTA. In both disorders, the plasma $[\text{K}^+]$ is characteristically low. In patients with RTA, urinary pH is always greater than 5.3.

Although excretion of urinary hydrogen ions in the patient with diarrhoea should acidify the urine, hypokalaemia leads to enhanced ammonia synthesis by the proximal tubular cells. Despite acidaemia, the excess urinary buffer increases the urine pH to a value above 5.3 in some patients with diarrhoea.

Whenever urinary acid is excreted as ammonium chloride, the increase in urinary chloride excretion decreases the urinary anion gap. Thus, the urinary anion gap should be negative in the patient with diarrhoea, regardless of the urine pH. On the other hand, although hypokalaemia may result in enhanced proximal tubular ammonia synthesis in distal RTA, the inability to secrete hydrogen ions into the collecting duct in this condition limits ammonium chloride formation and excretion; thus, the urinary anion gap is positive in distal RTA.

### Metabolic acidosis with a high anion gap

If the anion gap is increased, there is an unmeasured anion present in increased quantities. This is either one of the acids normally present in small but unmeasured quantities, such as lactate, or an exogenous acid. Causes of a high-anion-gap acidosis are given below and in Box 9.29.

#### Box 9.29

**Causes of metabolic acidosis with an increased anion gap:** think GOLD MARK

- Glycols (ethylene and propylene): ingestions (see pp. 75–76)
- Oxoproline (pyroglutamic acid): chronic paracetamol ingestion
- L-lactate: type A and type B
- D-Lactate: small bowel bacterial overgrowth
- Methanol: acute ingestion (see p. 78)
- Aspirin: salicylate overdose (see p. 81)
- Renal failure: accumulation of organic acids
- Ketoacidosis: diabetic, starvation, alcohol

### Chronic kidney disease

Chronic acidosis is most often caused by chronic kidney disease (CKD), in which there is a failure to excrete fixed acid. Up to 40 mmol of hydrogen ions may accumulate daily. These are
buffered by bone, in exchange for calcium. Chronic acidosis is therefore a major risk factor for renal osteodystrophy and hypercalciuria.

Chronic acidosis has also been shown to be a risk factor for muscle wasting in renal failure, and may also contribute to the inexorable progression of some types of renal disease.

Kidney disease causes acidosis in several ways:

• Reduction in the number of functioning nephrons decreases the capacity to excrete ammonia and H\(^+\) in the urine.
• Tubular disease may cause bicarbonate wasting.

Acidosis is a particular feature of those types of CKD in which the tubules are particularly affected, such as reflux nephropathy and chronic obstructive uropathy.

Uraemic acidosis should be corrected because of the effects on growth, muscle turnover and bones. Oral sodium bicarbonate 2–3 mmol/kg daily is usually enough to maintain serum bicarbonate above 20 mmol/L but may contribute to sodium overload. Calcium carbonate improves acidosis and also acts as a phosphate binder and calcium supplement, and is commonly used. Acidosis in end-stage kidney disease is usually fully corrected by adequate dialysis.

**Lactic acidosis**

Increased lactic acid production occurs when cellular respiration is abnormal, because of either a lack of oxygen in the tissues (‘type A’) or a metabolic abnormality, such as that induced by drugs such as metformin (‘type B’). The most common cause in clinical practice is type A lactic acidosis, occurring in septic or cardiogenic shock (see p. 1154). Significant acidosis can occur despite a normal blood pressure and \(P_a\)CO\(_2\), owing to splanchnic and peripheral vasoconstriction. Acidosis worsens cardiac function and vasoconstriction further, contributing to a downward spiral and fulminant production of lactic acid.

Raised serum D-lactate occurs with fermentation of glucose by abnormal bowel flora in the short gut syndrome.

**Ketoacidosis (see pp. 1261–1264)**

There is a high-anion-gap acidosis due to the accumulation of acetoacetic and hydroxybutyric acids, owing to increased production and some reduced peripheral utilization in diabetic ketoacidosis. Ketoacidosis without hypoglycaemia occurs in starvation and after alcohol overdose.

**Mixed metabolic acidosis**

Both types of acidosis may coexist. For instance, cholera would be expected to cause a normal-anion-gap acidosis owing to massive gastrointestinal losses of bicarbonate, but the anion gap is often increased owing to renal failure and lactic acidosis as a result of hypovolaemia.

To help ascertain if there is an additional normal-anion-gap acidosis as well as, for
example, a ketoacidosis, the delta anion gap can be calculated. This is the difference between the upper reference value of the anion gap and the calculated anion gap. This value should equal the fall in the bicarbonate concentration from the lower limit of normal. If the bicarbonate is significantly lower than predicted (>5 mmol/L), then an additional normal-anion-gap acidosis must be present. Similarly, if the bicarbonate is >5 mmol/L higher than expected, an additional normal-anion-gap alkalosis must be present.

### Clinical features of acidosis

Clinically, the most obvious effect is stimulation of respiration, leading to the clinical sign of ‘air hunger’, or Kussmaul respiration. Interestingly, patients with profound hyperventilation may not complain of breathlessness, although in others it may be a presenting complaint.

Acidosis increases delivery of oxygen to the tissues by shifting the oxyhaemoglobin dissociation curve to the right, but it also leads to inhibition of 2,3-BPG production, which returns the curve towards normal (see Fig. 25.2). Cardiovascular dysfunction is common in acidotic patients, although it is often difficult to dissociate the numerous possible causes of this. Acidosis is negatively inotropic. Severe acidosis also causes venoconstriction, resulting in redistribution of blood from the peripheries to the central circulation, and increased systemic venous pressure, which may worsen pulmonary oedema caused by myocardial depression. Arteriolar vasodilatation also occurs, further contributing to hypotension.

Cerebral dysfunction is variable. Severe acidosis is often associated with confusion and fits, but numerous other possible causes are usually present.

As mentioned earlier, acidosis stimulates potassium loss from cells, which may lead to potassium deficiency if renal function is normal, or to hyperkalaemia if renal potassium excretion is impaired.

### General treatment of acidosis

Treatment should be aimed at correcting the primary cause. In lactic acidosis caused by poor tissue perfusion (‘type A’), treatment should be aimed at maximizing oxygen delivery to the tissues by protecting the airway, and improving breathing and circulation. This usually requires inotropic agents, mechanical ventilation and invasive monitoring. In ‘type B’ lactic acidosis, treatment is directed at the underlying disorder – for example:

- insulin in diabetic ketoacidosis
- treatment of methanol and ethylene glycol poisoning with ethanol
- removal of salicylate by dialysis.

The question of whether severe acidosis should be treated with bicarbonate is extremely controversial:

- Rapid correction of acidosis may result in tetany and fits owing to a rapid decrease in ionized calcium.
• Administration of sodium bicarbonate (8.4%) provides 1 mmol/mL of sodium, which may lead to extracellular volume expansion, exacerbating pulmonary oedema.

• Bicarbonate therapy increases CO₂ production and will therefore correct acidosis only if ventilation can be increased to remove the added CO₂ load.

• The increased amounts of CO₂ generated may diffuse more readily into cells than bicarbonate, worsening intracellular acidosis.

Administration of sodium bicarbonate (50 mmol, as 50 mL of 8.4% sodium bicarbonate i.v.) is still occasionally given during cardiac arrest and is often necessary before arrhythmias can be corrected. Correction of hyperkalaemia associated with acidosis is also of undoubted benefit. In other situations, there is no clinical evidence to show that correction of acidosis improves outcome, but it is standard practice to administer sodium bicarbonate when [H⁺] is above 126 mmol/L (pH <6.9), using intravenous 1.26% (150 mmol/L) bicarbonate infused over 2–3 h with electrolyte and pH monitoring. Intravenous sodium lactate should never be given.

## Metabolic alkalosis

Metabolic alkalosis is common, comprising half of all the acid–base disorders in hospitalized patients. This observation should not be surprising since vomiting, the use of diuretics, and nasogastric suction are common among hospitalized patients. The mortality associated with metabolic alkalosis is substantial; the mortality rate is 45% in patients with an arterial pH of 7.55 and 80% when the pH is over 7.65. Although this relationship is not necessarily causal, severe alkalosis should be viewed with concern.

## Classification and definitions

Metabolic alkalosis has been classified on the basis of underlying pathophysiology (Box 9.30):

• **chloride depletion**, the most common cause, which can be corrected without potassium repletion

• **potassium depletion**, usually with mineralocorticoid excess

• **metabolic alkalosis**, due to both potassium and chloride depletion.

---

### Box 9.30

**Causes of metabolic alkalosis**

**Chloride depletion**

• Gastric losses: vomiting, mechanical drainage, bulimia

• Chloruretic diuretics, e.g. bumetanide, furosemide, chlorothiazide, metolazone
• Diarrhoeal states: villous adenoma, congenital chloridorrhoea
• Cystic fibrosis (high sweat chloride)

**Potassium depletion/mineralocorticoid excess**

• Primary aldosteronism
• Secondary aldosteronism
• Apparent mineralocorticoid excess:
  – Primary deoxycorticosterone excess: 11α- and 17α-hydroxylase deficiencies
  – Drugs: liquorice (glycyrrhizic acid) as a confection or flavouring, carbenoxolone
  – Liddle syndrome
  – Bartter and Gitelman syndromes and their variants
  – Laxative abuse, clay ingestion

**Hypercalcaemic states**

• Hypercalcaemia of malignancy
• Acute or chronic milk–alkali syndrome

**Others**

• Amoxicillin or penicillin therapy
• Bicarbonate ingestion: massive or smaller ingestion with kidney disease
• Recovery from starvation
• Hypoalbuminaemia

**Chloride** may be lost from the gut, kidney or skin. The loss of gastric fluid rich in acid results in alkalosis because bicarbonate generated during the production of gastric acid returns to the circulation. In Zollinger–Ellison syndrome (see p. 512) or gastric outflow obstruction, these losses can be massive. Although sodium and potassium loss in the gastric juice is variable, the obligate urinary loss of these cations is intensified by bicarbonaturia, which occurs during disequilibrium.

**Chloruretic agents** all directly produce loss of chloride, sodium and fluid in the urine. These losses in turn promote metabolic alkalosis by several mechanisms:

• Diuretic-induced increases in sodium delivery to the distal nephron enhance potassium and hydrogen ion secretion.
• Extracellular volume contraction stimulates renin and aldosterone secretion, which blunts sodium losses but accelerates potassium and hydrogen ion secretion.
• Potassium depletion augments bicarbonate reabsorption in the proximal tubule and stimulates ammonia production, which in turn will increase urinary net acid excretion.

Urinary losses of chloride exceed those for sodium and are associated with alkalosis, even when potassium depletion is prevented. The cessation of events that generate alkalosis is not
necessarily accompanied by resolution of the alkalosis. A widely accepted hypothesis for the maintenance of alkalosis is chloride depletion rather than volume depletion. Although normal functioning of the proximal tubule is essential for bicarbonate absorption, the collecting duct appears to be the major nephron site for altered electrolyte and proton transport in both maintenance and recovery from metabolic alkalosis. During maintenance, the α-intercalated cells in the cortical collecting duct do not secrete bicarbonate because insufficient chloride is available for bicarbonate exchange. When chloride is administered and luminal or cellular chloride concentration increases, bicarbonate is promptly excreted and alkalosis is corrected.

Metabolic alkalosis in hypokalaemia is generated primarily by an increased intracellular shift of hydrogen ion, causing intracellular acidosis. Potassium depletion is also associated with enhanced ammonia production and increased obligate net acid excretion. This is the corollary to the acidosis seen with hyperkalaemia in type 4 RTA. Infusion of potassium alone can correct systemic alkalosis and intracellular acidosis as cells exchange extracellular potassium for intracellular hydrogen, which can then buffer extracellular bicarbonate.

Milk–alkali syndrome in which both bicarbonate and calcium are ingested, produces alkalosis by vomiting, calcium-induced bicarbonate absorption and reduced GFR. Cationic antibiotics in high doses can cause alkalosis by obligatory bicarbonate loss in the urine.

Clinical features

The symptoms of metabolic alkalosis per se are difficult to separate from those of chloride, volume or potassium depletion. Tetany (see Box 26.50), apathy, confusion, drowsiness, cardiac arrhythmias and neuromuscular irritability are common when alkalosis is severe. The oxyhaemoglobin dissociation curve is shifted to the left. Respiration may be depressed.

Management

Chloride-responsive metabolic alkalosis

Although replacement of the chloride deficit is essential in chloride depletion states, selection of the accompanying cation – sodium, potassium or proton – is dependent on the assessment of extracellular fluid volume status (see p. 159), the presence or absence of associated potassium depletion, and the degree and reversibility of any depression of GFR. If kidney function is normal, bicarbonate and base equivalents will be excreted with sodium or potassium, and metabolic alkalosis will be rapidly corrected as chloride is made available.

If chloride and extracellular depletion coexist, then isotonic saline solution is appropriate therapy.

In the clinical setting of fluid overload, saline is contraindicated. In such situations, intravenous hydrochloride acid or ammonium chloride can be given. If GFR is adequate, acetazolamide, which causes bicarbonate diuresis by inhibiting carbonic anhydrase, can also be used. When the kidney is incapable of responding to chloride repletion, dialysis is necessary.
Chloride-resistant metabolic alkalosis

Metabolic alkalosis due to potassium depletion is managed by correction of the underlying cause (see ‘Hypokalaemia’, pp. 165–167). Mild to moderate alkalosis requires oral potassium chloride administration. However, the presence of a cardiac arrhythmia or generalized weakness requires intravenous potassium chloride.

Introduction

The interface between normal and abnormal nutrition can be difficult to define. There is no universally accepted definition of malnutrition, but a reasonable definition is as follows: ‘Malnutrition is a state of nutrition in which a deficiency, excess or imbalance of energy, protein and other nutrients causes measurable adverse effects on tissue/body form (body shape, size and composition) and function, and on clinical outcome.’

In developing countries, the lack of food and poor usage of the available food, often in association with ongoing inflammatory processes, result in what has traditionally been called protein–energy malnutrition (PEM). However, nutrient deficiencies often accompany PEM and they may contribute to its development. Worldwide, in 2011, 165 million children under 5 years of age were affected by stunting, and at least 52 million by wasting. Obesity has also been a growing problem in developing countries and the combination of stunting with obesity has been increasing. In developed countries, excess food is available, and overweight and obesity are the most common nutritional problems. However, under-nutrition (often referred to as ‘malnutrition’) continues to remain a major clinical and public health problem worldwide.

Diet and disease are inter-related in many ways:

• Excess energy intake contributes to a number of diseases, including ischaemic heart
disease and diabetes, particularly when high in animal (saturated) fat content.

- **There is a relationship between food intake and cancer**, as found in many epidemiological studies. An excess of energy-rich foods (i.e. those containing fat and sugar), often combined with physical inactivity, plays a role in the development of certain cancers, while diets high in vegetables and fruits reduce the risk of most epithelial cancers. Numerous carcinogens, intentional additions (e.g. nitrates for preserving foods) or accidental contaminants (e.g. moulds producing aflatoxin and fungi) may also be involved in the development of cancer.

- **The proportion of processed foods eaten may affect the development of disease**. Some processed convenience foods have a high sugar and fat content and therefore predispose to dental caries and obesity, respectively. They also have a low fibre content, and dietary fibre can help in the prevention of a number of diseases (see p. 188).

- **Long-term under-nutrition is implicated in disease** by some epidemiological studies; for example, low growth rates in utero are associated with high death rates from cardiovascular disease in adult life.

In the UK, dietary reference values for food, energy and nutrients are stated as reference nutrient intakes (RNIs), on the basis of data from the Food and Agriculture Organization (FAO-WHO), United Nations University (UNU) expert committee and elsewhere. The RNI is sufficient, or more than sufficient, to meet the nutritional needs of 97.5% of healthy people in a population. Most people's daily requirements are less than this, and so an estimated average requirement (EAR) is also given, which will certainly be adequate for most. A lower reference nutrient intake (LRNI), which fails to meet the requirements of 97.5% of the population, is also given. The RNI figures quoted in this chapter are for the age group 19–50 years. These represent values for healthy subjects and are not always appropriate for patients with disease.

**Water and Electrolyte Balance**

Water and electrolyte balance is dealt with fully in Chapter 9. About 1 L of water is required in the daily diet to balance insensible losses but much more is usually drunk, the kidneys being able to excrete large quantities. The daily RNI for sodium is 70 mmol (1.6 g) but daily sodium intake varies in the range 90–440 mmol (2–10 g). These are needlessly high intakes of sodium, which are thought by some to play a role in causing hypertension (see p. 1046). The World Health Organization (WHO) also recommends at least 90 mmol (3.5 g) potassium, which would reduce blood pressure and cardiovascular risk of stroke and coronary artery disease.

**Dietary Requirements**

**Energy**

Food is necessary to provide the body with energy (*Fig. 10.1*). The SI unit of energy is the joule (J), and 1 kJ = 0.239 kcal. The conversion factor of 4.2 kJ, equivalent to 1.00 kcal, is
Energy balance is the difference between energy intake and energy expenditure. Weight gain or loss is a simple but accurate way of indicating differences in energy balance.
Energy requirements

There are two approaches to assessing energy requirements for subjects who are weight-stable and close to energy balance:

• assessment of energy intake
• assessment of total energy expenditure.

Energy intake

Energy intake can be estimated from dietary surveys and, in the past, this has been used to decide daily energy requirements. However, measurement of energy expenditure gives a more accurate assessment of requirements.

Energy expenditure

Daily energy expenditure (Fig. 10.2) is the sum of:

• the basal metabolic rate (BMR)
• the thermic effect of food eaten
• occupational activities
• non-occupational activities.

![Figure 10.2](image)

**FIGURE 10.2** Daily energy expenditure in an active and a sedentary 70-kg adult. BMR, basal metabolic rate; DIT, dietary-induced thermogenesis; PAR, physical activity ratio.

**Total energy expenditure** can be measured using a double-labelled water technique. Water containing the stable isotopes $^2$H and $^{18}$O is given orally. As energy is expended, carbon dioxide and water are produced. The difference between the rates of loss of the two isotopes is used to calculate the carbon dioxide production, which is then used to calculate energy expenditure. This can be done on urine samples over a 2–3-week period with the subject ambulatory. The technique is accurate, but it is expensive and requires the availability of a mass spectrometer. An alternative tracer technique for measuring total energy expenditure is to
estimate CO₂ production by isotopic dilution. A subcutaneous infusion of labelled bicarbonate is administered continuously by a minipump, and urine is collected to measure isotopic dilution by urea, which is formed from CO₂. Other methods for estimating energy expenditure, such as heart rate monitors or activity monitors, are also available but are less accurate.

**Basal metabolic rate** can be calculated by measuring oxygen consumption and CO₂ production, but it is more usually taken from standardized tables (Box 10.1) that only require knowledge of the subject's age, weight and sex.

Thus, for example, to determine the daily energy expenditure of a 73-year-old, 50-kg female doctor, with a BMR of 4805 kJ/day, who spends one-third of a day sleeping, working and engaged in non-occupational activities, the latter at a PAR of 2.1, the following calculation ensues:

\[
= (4805 \text{ kJ/day}) \times [0.3 \times 1.7] + (0.3 \times 2.10) = 6919 \text{ kJ (1655 kcal/day)}
\]

In the UK, the estimated ‘average’ daily energy requirement is:
- for a 55-year-old female – 8100 kJ (1940 kcal)
- for a 55-year-old male – 10 600 kJ (2550 kcal).

This is at present made up of about 50% carbohydrate, 35% fat, 15% protein ± 5% alcohol. In developing countries, however, carbohydrate may be >75% of the total energy input, and fat <15% of the total energy input.

Energy requirements increase during the growing period, with pregnancy and lactation, and sometimes following infection or trauma. In general, the increased BMR associated with inflammatory or traumatic conditions is counteracted or more than counteracted by a decrease in physical activity, so that total energy requirements are not increased.

In the basal state, energy demands for resting muscle are 20% of the total energy required, those for abdominal viscera 35–40%, those for brain 20% and those for heart 10%. There can be more than a 50-fold increase in muscle energy demands during exercise.

### Energy stores

Although virtually all body fat and glycogen are available for oxidation, less than half the protein is available for oxidation. Figure 10.3 shows that fat accounts for the largest reserves of energy in both lean and obese subjects. The size of the stores determines survival during starvation.
Body weight

Body weight depends on energy balance. Intake depends not only on food availability but also on a number of complex inter-relationships that include the stimulus of good food, the role of hunger, metabolic changes (e.g. hypoglycaemia), and the pleasure and habit of eating. Some people are able to keep their body weight constant within a few kilograms for many years, but most gradually increase their weight owing to a small but continuous increase of intake over expenditure. A gain or loss of energy of 25–29 MJ (6000–7000 kcal) would, respectively, increase or decrease body weight by approximately 1 kg.

Protein

In the UK, the adult daily RNI for protein is 0.75 g/kg, with protein representing at least 10% of the total energy intake. Most affluent people eat more than this, consuming 80–100 g of protein per day.
The total amount of nitrogen excreted in the urine represents the balance between protein breakdown and synthesis. In order to maintain nitrogen balance, at least 40–50 g of dietary protein are needed. The amount of protein oxidized can be calculated from the amount of nitrogen excreted in the urine over 24 hours using the following equation:

$$\text{Grams of protein required} = \text{Urinary nitrogen} \times 6.25$$

(most proteins contain about 16% of nitrogen)

In practice, urinary urea is more easily measured and forms 80–90% of the total urinary nitrogen (N). In healthy individuals, urinary nitrogen excretion reflects protein intake. However, excretion does not match intake in catabolic conditions (negative N balance), or during growth or repletion following an illness (positive N balance).

Protein contains many **amino acids**:

- **Indispensable (essential)**. There are nine amino acids that cannot be synthesized and must be provided in the diet: tryptophan, histidine, methionine, threonine, isoleucine, valine, phenylalanine, lysine and leucine.

- **Dispensable (non-essential)**. These are amino acids that can be synthesized in the body (some may still be needed in the diet unless adequate amounts of their precursors are available).

Animal proteins (e.g. in milk, meat and eggs) contain a good balance of all the indispensable amino acids, but many proteins from vegetables are deficient in at least one indispensable amino acid. In developing countries, protein intake derives mainly from vegetable proteins. By combining foodstuffs with different low concentrations of indispensable amino acids (e.g. maize with legumes), protein intake can be adequate, provided enough vegetables are available.

Loss of protein from the body (negative N balance) occurs not only because of inadequate protein intake, but also because of inadequate energy intake. When there is loss of energy from the body, more protein is directed towards oxidative pathways and, eventually, gluconeogenesis for energy.

**Role of amino acids**

- **Glutamine** is quantitatively the most significant amino acid in the circulation and in inter-organ exchange.

- **Alanine** is released from muscle; it is deaminated and converted into pyruvic acid before entering the citric acid cycle.

- **Homocysteine** is a sulphur-containing amino acid that is derived from methionine in the diet. A raised plasma concentration is an independent risk factor for vascular disease.

Amino acids are utilized to synthesize products other than protein or urea. For example:
• **Glycine** is required for haem production.
• **Tyrosine** is required for melanin and thyroid hormones.
• **Glutamine, aspartate and glycine** are required for nucleic acid bases.
• **Glutamate, cysteine and glycine** are required for glutathione, which is part of the defence system against free radicals.

**Fat**

Dietary fat is chiefly in the form of triglycerides, which are esters of glycerol and free fatty acids. Fatty acids vary in chain length and in saturation (**Box 10.3**). The hydrogen molecules related to the double bonds can be in the cis or the trans position; most natural fatty acids in food are in the cis position (**Box 10.4**).

<tr>
<td>Trans fatty acids</td>
<td>Hydrogenated fat or oils, e.g. in margarine, cakes, biscuits</td>
</tr>
</tbody>
</table>

The **essential fatty acids** (EFAs) are linoleic and α-linolenic acid, both of which are precursors of prostaglandins. Eicosapentaenoic and docosahexaenoic acid are also necessary, but can be made to a limited extent in the tissues from linoleic and linolenic acid, and thus a dietary supply is not essential.

**Synthesis of triglycerides**, sterols and phospholipids is very efficient. Even with low-fat diets, subcutaneous fat stores can be normal.

**Dietary fat** provides 37 kJ (9 kcal) of energy per gram. A high-fat intake has been implicated in the causation of:
- cardiovascular disease
- cancer (e.g. breast, colon and prostate)
- obesity
- type 2 diabetes.

The data on causation are largely epidemiological and disputed by many. Nevertheless, it is often suggested that the consumption of saturated fatty acids should be reduced, accompanied by an increase in monounsaturated fatty acids, such as those in olive oil (the ‘Mediterranean diet’), or polyunsaturated fatty acids. Any increase in polyunsaturated fats should not, however, exceed 10% of the total food energy, particularly as this requires a big dietary change.

**Trans fats (partly hydrogenated fatty acids)**

Increased consumption of hydrogenated vegetable and fish oils in margarines has led to increased *trans* fatty acid consumption. *Trans* fatty acids (also called *trans* fats) behave as if they were saturated fatty acids, increasing circulating low-density lipoprotein (LDL) and decreasing high-density lipoprotein (HDL) cholesterol concentrations, which, in turn, raise the risk of cardiovascular disease. In most countries, nutrition labels for all conventional foods and supplements must indicate the *trans* fatty acid content. The usage of *trans* fatty acids from partially hydrogenated oils has now been banned in many countries.

**Polyunsaturated fatty acids**

The *n*-6 polyunsaturated fatty acids (**PUFAs**) are components of membrane phospholipids, influencing membrane fluidity and ion transport. They also have antiarrhythmic, antithrombotic and anti-inflammatory properties, all of which are potentially helpful in preventing cardiovascular disease.

The *n*-3 **PUFAs** increase circulating HDL cholesterol and lower triglycerides, both of which...
might reduce cardiovascular risk. Some of the actions of \( n-3 \) PUFAs are mediated by a range of leukotrienes and eicosanoids, which differ in pattern and functions from those produced from \( n-6 \) PUFAs.

**Epidemiological studies and clinical intervention studies** suggest that \( n-3 \) PUFAs may have effects in the secondary prevention of cardiovascular disease and ‘all-cause mortality’ (e.g. a 20–30% reduction in mortality from cardiovascular disease, according to some studies). The benefits, which have been noted as early as 4 months after intervention, have been attributed largely to the antiarrhythmic effects of \( n-3 \) PUFAs, but some work suggests that \( n-3 \) PUFAs, administered as capsules, can be rapidly incorporated into atheromatous plaques, stabilizing them and preventing rupture. Whether these effects are due directly to \( n-3 \) PUFAs or other changes in the diet is still debated.

The **GISSI Prevention Trial**, which followed over 11 000 patients for 3.5 years after a myocardial infarction, administered fish oils (eicosapentaenoic acid, EPA, and docosahexaenoic acid, DHA) in the form of capsules and demonstrated a striking benefit in reducing mortality. In contrast, a more recent study in patients with cardiovascular risk factors and no history of myocardial infarction found no effect of \( n-3 \) PUFAs on cardiovascular mortality and morbidity. The reasons for the discrepancy between these two studies are unclear, but the beneficial effect of \( n-3 \) PUFAs in those with a history of myocardial infarction may have been due to the antiarrhythmic effects of \( n-3 \) PUFAs, averting fatal ventricular arrhythmias. Another recent study in patients with glucose intolerance/diabetes and cardiovascular risk factors also did not find a beneficial effect of \( n-3 \) PUFAs on cardiovascular events.

### Recommendations for fat intake

The British Nutrition Foundation and the American Heart Association presently recommend a two-fold increase of the current intake of total \( n-3 \) PUFAs (a several-fold increase in the intake of fish oils, and a 50% increase in the intake of \( \alpha \)-linolenic acid). Implementing this recommendation will mean either a major change in the dietary habits of populations that eat little fish, or ingestion of capsules containing fish oils. Some government agencies have warned of the hazards of eating certain types of fish, which increase the risk of mercury poisoning and possibly other toxicities.

The current recommendations for fat intake for the UK are shown in **Box 10.5**.

</tbody>
</table>

*Recent recommendations suggest <5% of total energy consumption.

Values in parentheses are goals for the intake of populations, as given by the World Health Organization (including populations who are already on low-fat diets). Some of the extreme ranges are not realistic short-term goals for developed countries, e.g. 75% of total energy from carbohydrate and 15% fat. When total energy intake is 2500 kcal (10 500 kJ) per day, 55% of intake comes from carbohydrate (344 g, i.e. 1376 kcal (5579 kJ)) and 30% from fat (83 g, i.e. 747 kcal (3137 kJ)). PUFAs, polyunsaturated fatty acids.

**Cholesterol**

Cholesterol is found in all animal products. Eggs are particularly rich in cholesterol, which is virtually absent from plants. The average daily intake in the UK is 300–500 mg. Cholesterol is also synthesized (see Fig. 14.4), and only very high or low dietary intakes will significantly affect blood levels.

**Essential fatty acid deficiency**

Essential fatty acid deficiency may accompany PEM, but it has been clearly defined as a clinical entity only in patients on long-term parenteral nutrition given glucose, protein and no fat. Alopecia, thrombocytopenia, anaemia and dermatitis occur within weeks, with an increased ratio of triene (n-9) to tetraene (n-6) in plasma fatty acids.

**Carbohydrate**

Carbohydrates are readily available in the diet, providing 17 kJ (4 kcal) per gram of energy (15.7 kJ (3.75 kcal) per gram monosaccharide equivalent). Carbohydrate intake comprises:

- polysaccharide starch
- disaccharides (mainly sucrose)
- monosaccharides (glucose and fructose).
Carbohydrate is cheap, compared with other foodstuffs; a great deal is therefore eaten, usually more than required. WHO suggests that sugar intake should be <5% of a person's total energy consumption.

**Dietary fibre**

Dietary fibre, which is largely *non-starch polysaccharide* (NSP; entirely NSP according to some authorities), is often removed in the processing of food. This leaves highly refined carbohydrates, such as sucrose, which contribute to the development of dental caries and obesity. Lignin is included in dietary fibre in some classification systems but it is not a polysaccharide. It is only a minor component of the human diet.

The principal classes of NSP are:

- cellulose
- hemicelluloses
- pectins
- gums.

None of these is digested by gut enzymes. However, NSP is partly broken down in the gastrointestinal tract, mainly by colonic bacteria, producing gas and volatile fatty acids, e.g. butyrate.

All plant food, when unprocessed, contains NSP, so that all unprocessed food eaten will increase the NSP content of the diet. Bran, the fibre from wheat, provides an easy way of adding additional fibre to the diet; it increases faecal bulk and is helpful in the treatment of constipation.

The average daily intake of NSP in the diet is approximately 16 g. NSP deficiency is accepted as an entity by many authorities and it is suggested that the total NSP be increased to up to 30 g daily. This could be achieved by increased consumption of bread, potatoes, fruit and vegetables, with a reduction in sugar intake in order not to increase total calories. Each extra gram of fibre daily adds approximately 3–5 g to the daily stool weight. Pectins and gums have also been added to food to slow down monosaccharide absorption, and this is particularly useful in type 2 diabetes.

Eating a diet rich in plant foods (fruits, vegetables, cereals and whole grain – the main sources of dietary fibre) is broadly recommended for general health promotion, including protection against ischaemic heart disease, stroke and certain types of cancers. This has been attributed to a lipid-lowering effect and to the presence of protective substances, such as vitamin and non-vitamin antioxidants and other vitamins such as folic acid, which is linked to homocysteine metabolism, a risk factor for cardiovascular disease. Fermentation of fibre in the colon may protect against the development of colonic cancer. However, associated lifestyle factors, such as low physical activity, may also help explain some of those associations.

**Health promotion**

Many chronic diseases – particularly obesity, diabetes mellitus and cardiovascular disease –
cause premature mortality and morbidity, and are potentially preventable by dietary change. This is a global problem; for example, obesity affects 1 in 9 adults in the world, and the body mass index (BMI) is now similar in high- and middle-income groups. Reduction in salt and fat intake, combined with exercise and stopping smoking, would have a major effect on the health of the population.

**Box 10.5** suggests the composition of the ‘ideal healthy diet’. The values given are based on the principle of:

- reducing total fat in the diet, particularly saturated fat
- increasing consumption of fish, which contains \( n-3 \) (or \( \omega-3 \)) PUFAs
- increasing intake of whole-grain cereals and green and orange vegetables and fruits, leading to an increase in fibre and antioxidants.

Reductions in dietary sodium and cholesterol have also been suggested. There would be no disadvantage in this, and most studies have suggested some benefit.

**Fortification of foods**

Fortification of foods with specific nutrients is common. In the UK, *margarine* and *milk* are fortified with vitamins A and D, *flour* with calcium, iron, thiamine and niacin, and *breakfast cereals* with several vitamins and iron. Not all substances used in fortification have nutritive value. For example, *Olestra*, a polymer of sucrose and six or more triglycerides, has been used to combat obesity. It is not absorbed and is therefore used particularly in savoury snack foods (where it has FDA approval) as a ‘fake fat’. Therefore, it results in a reduction in total calories. It has side-effects, such as loose stools and abdominal cramps, and its use is being carefully monitored.

**Nutrient goals and dietary guidelines**

The interests of the individual are often different from those associated with government policy. A distinction needs to be made between nutrient goals and dietary guidelines:

- **Nutrient goals** refer to the national intakes of nutrients that are considered appropriate for optimal health in the population.
- **Dietary guidelines** refer to the dietary methods used to achieve these goals.

Since dietary habits vary in different countries, dietary guidelines may also differ, even when the nutrient goals are the same. Nutrient goals are based on scientific information that links nutrient intake to disease. Although the information is incomplete, it includes evidence from a wide range of sources, including experimental animal studies, clinical studies, and both short-term and long-term epidemiological studies.

## Protein–Energy Malnutrition

### Developed countries

Starvation uncomplicated by disease is relatively uncommon in developed countries, although some degree of under-nourishment is seen in very poor areas. Most nutritional problems occurring in the population at large are due to eating wrong combinations of foodstuffs, such as an excess of refined carbohydrate or a diet low in fresh vegetables. Under-nourishment associated with disease is common in hospitals and nursing homes, and *Box 10.6* gives a list of conditions in which malnutrition is often seen. Surgical complications, with sepsis, are a common cause. Many patients are admitted to hospital under-nourished, and a variety of chronic conditions predispose to this state (*Box 10.7*).

### Box 10.6

</tbody>
</table>

*GIT, gastrointestinal tract.

The majority of the weight loss, leading to malnutrition, is due to **poor intake secondary to the anorexia associated with the underlying condition**. Disease may also contribute by causing malabsorption and increased catabolism, which is mediated by complex changes in cytokines, hormones, side-effects of drugs, and immobility. The elderly are particularly at risk of malnutrition because they often suffer from diseases and psychosocial problems, such as social isolation or bereavement (Box 10.7).

Pathophysiology of starvation

In the first 24 h following low dietary intake, the body relies for energy on the breakdown of hepatic glycogen to glucose (**Fig. 10.4**). Hepatic glycogen stores are small and therefore gluconeogenesis is soon necessary to maintain glucose levels. Gluconeogenesis takes place mainly from pyruvate, lactate, glycerol and amino acids, especially alanine and glutamine. The majority of protein breakdown takes place in muscle, with eventual loss of muscle bulk.
**Lipolysis**, the breakdown of the body's fat stores, also occurs. It is inhibited by insulin, but the level of this hormone falls off as starvation continues. The stored triglyceride is hydrolysed by lipase to glycerol, which is used for gluconeogenesis, and also to non-esterified fatty acids, which can be used directly as a fuel or oxidized in the liver to ketone bodies.

**Adaptive processes** take place as starvation continues, to prevent the body's available protein being completely utilized. There is a decrease in metabolic rate and total body energy expenditure. Central nervous metabolism changes from glucose as a substrate to ketone bodies. Gluconeogenesis in the liver decreases, as does protein breakdown in muscle, both of these processes being inhibited directly by ketone bodies. Most of the energy at this stage comes from adipose tissue, with some gluconeogenesis from amino acids, particularly from alanine in the liver and glutamine in the kidney.

The **metabolic response to prolonged starvation** differs between lean and obese individuals. One of the major differences concerns the proportion of energy derived from protein oxidation, which determines the proportion of weight loss from lean tissues. This proportion may be up to three times smaller in obese subjects than lean subjects. It can be regarded as an adaptation that depends on the composition of the initial reserves (see Fig. 10.3). This means that deterioration in body function is more rapid in lean subjects, and survival time shorter in lean subjects (approximately 2 months) compared to the obese (in whom it can be at least several months).

**Following trauma or shock**, some of the adaptive changes do not take place. Glucocorticoids and cytokines (see below) stimulate the ubiquitin–proteasome pathway in muscle, which is responsible for accelerated proteolysis in muscle in many catabolic illnesses. In starvation, there is a decrease in BMR, while in inflammatory and traumatic disease, there is often an increase in BMR. These changes all result in continuing gluconeogenesis with massive muscle breakdown, and further reduction in survival time.

**Regulation of metabolism**

Tissue metabolism is regulated by multiple coordinated processes. Some are rapid, involving
nerves, whilst others are slower, involving circulating substrates and hormones. Factors include:

- **Circulating substrate concentrations.** The uptake and metabolism of ketone bodies, which serve as the major fuel for the brain during prolonged starvation, are primarily determined by the circulatory concentration, which can increase up to 5 mmol/L or more. The liver is responsible for the production of ketone bodies, which is, in turn, controlled by the availability of fatty acids derived from adipose tissue. Substrates may also compete with each other for metabolism; e.g. glucose competes with non-esterified fatty acids for uptake and metabolism in muscle and heart (the glucose–fatty acid cycle), and this is independent of hormones.

- **Blood flow.** The delivery of substrates (and other signals) to tissues depends not only on their circulating concentration but also on the blood flow to tissues. In many tissues, there is coupling between metabolic activity and blood flow, with arterioles regulating blood flow to the tissue according to demand; e.g. blood flow to muscle increases during exercise.

- **Signals.** Hormones and other signals, such as cytokines (see below), regulate intracellular metabolism.

### Insulin/glucagon ratios in the fed and fasted state

**In the fed state,** insulin/glucagon ratios are high. Insulin promotes synthesis of glycogen, protein and fat, and inhibits lipolysis and gluconeogenesis.

**In the fasted state,** insulin/glucagon ratios are low. Glucagon acts mainly on the liver and has no action on muscle. It increases glycogenolysis and gluconeogenesis, as well as increasing ketone body production from fatty acids. It also stimulates lipolysis in adipose tissue. Catecholamines have a similar action to glucagon but also affect muscle metabolism. These agents both act via cyclic adenosine monophosphate (cAMP) to stimulate lipolysis, producing free fatty acids that can then act as a major source of energy.

### Proportion of lean to fat tissue

**During weight loss** uncomplicated by disease, the proportion of lean to fat tissue loss (or proportion of energy derived from protein metabolism) is greater in lean than overweight/obese individuals.

**During acute disease,** loss of lean tissue, which is associated with protein oxidation, can be particularly rapid. Hormones such as corticosteroids, pro-inflammatory cytokines and insulin resistance are all involved.

### Role of cytokines

The metabolic response to trauma, injury and inflammation depends on the balance between pro-inflammatory (e.g. tumour necrosis factor, TNF; interleukin-2, IL-2) and anti-inflammatory cytokines (e.g. IL-10), and the production of many of these cytokines is influenced by genetic polymorphisms. Since many chronic diseases, including atherosclerosis, have an inflammatory
component, these changes have wide-reaching metabolic implications.

Cytokines such as IL-1, IL-6 and TNF play a significant role in regulating metabolism. In acute diseases, they contribute to the catabolic process, glycogenolysis, and acute phase protein synthesis. TNF, which inhibits lipoprotein lipase, is one of a number of ‘cachexia factors’ in patients with cancer.

It is unclear how these cytokines interact with central feeding pathways to cause anorexia. However, in animal models of both cancer and inflammatory bowel disease, many peripheral and central mediators of appetite are involved. For example, neuropeptide Y levels in the hypothalamus are often inappropriately low, so there is a reduced drive to feed.

Clinical features

Patients are sometimes seen with loss of weight or malnutrition (failure to thrive in children) as the primary symptom. Mostly, however, malnourishment is only seen as an accompaniment of some other disease process, such as malignancy. Severe malnutrition is seen mainly with advanced organic disease or after surgical procedures followed by complications. Three key features that help in the detection of chronic protein–energy malnutrition (PEM) in adults are listed in Box 10.8.

Box 10.8

Keys to detecting chronic protein–energy malnutrition (PEM) in developed countries

1. Body mass index (BMI)
   - Probable chronic PEM: <18.5 kg/m²
   - Possible chronic PEM: 18.5–20 kg/m²
   - Little or no risk of chronic PEM: >20 kg/m²

   In patients with oedema or dehydration the BMI may be somewhat misleading.

2. Weight loss in previous 3–6 months
   - >10%: high risk of developing PEM
   - 5–10%: possible risk of developing PEM
   - <5%: low/no risk of developing PEM

3. Acute disease effect
   - Diseases that have resulted or are likely to result in no dietary intake for >5 days (e.g. prolonged unconsciousness, persistent swallowing problems after a stroke, or prolonged ileus after abdominal surgery): high risk of malnutrition
Other factors that may suggest PEM include:

• history of decreased food intake/loss of appetite
• clothes becoming loose-fitting (weight loss) and a general appearance indicating obvious wasting
• physical and psychosocial disturbances likely to have contributed to the weight loss.

The factors listed in **Box 10.8** act as a link between detection and management (see also **Fig. 10.5**, the Malnutrition Universal Screening Tool). If the underlying physical or psychosocial problems are not addressed adequately, treatment may not be successful.
PEM leads to a depression of the immunological defence mechanism, resulting in a decreased resistance to infection. It also detrimentally affects muscle strength and fatigue, reproductive function (e.g. in anorexia nervosa, which is common in adolescent girls; see pp. 927–928), wound healing and psychological function (depression, anxiety, hypochondriasis, loss of libido).

In children, growth failure is a key element in the diagnosis of PEM. WHO standards for optimal growth in children of 0–4 years have been adopted by developing and developed
countries. They aim to reflect optimal rather than prevailing growth in both developed and developing countries, since they involved a healthy pregnancy and children born to non-smoking, relatively affluent mothers who breast-fed their children exclusively or predominantly for the first 6 months of life. The general principles of management of severe PEM in children are similar in developed and developing countries but resources are required to manage the problems once they have been identified (see p. 194).

### Management

When malnutrition is obvious and the underlying disease cannot be corrected at once, some form of nutritional support is necessary (see also pp. 212 and 214). Nutrition should be given enterally if the gastrointestinal tract is functioning adequately. This can be done most easily by encouraging the patient to eat more often and by giving a high-calorie supplement. If this is not possible, a liquefied diet may be given intragastrically via a fine-bore tube or by a percutaneous endoscopic gastrostomy (PEG). If both of these measures fail, parenteral nutrition is given.

### Developing countries

The International Union of Nutritional Sciences, with support from the International Pediatric Association, launched a global Malnutrition Task Force in 2005 to ensure that an integrated system of prevention and treatment of malnutrition is actively supported.

In many areas of the world, people are on the verge of malnutrition due to extreme poverty. In addition, if events such as drought, war or changes in political climate occur, millions suffer from starvation.

### Clinical features

Although the basic condition of PEM is the same in all parts of the world, whatever the cause, malnutrition resulting from long periods of near-total starvation produces unique clinical appearances in children that are virtually never seen in high-income countries. The term ‘protein–energy malnutrition’ covers the spectrum of clinical conditions seen in adults and children. Children under 5 years may present with the following:

- **Kwashiorkor** occurs typically in a young child displaced from breast-feeding by a new baby. It is often precipitated by infections such as measles, malaria and diarrhoeal illnesses. The child is apathetic and lethargic with severe anorexia. There is generalized oedema with skin pigmentation and thickening (**Fig. 10.6B**). The hair is dry and sparse, and may become reddish or yellow in colour. The abdomen is distended owing to hepatomegaly and/or ascites. The serum albumin is always low. The exact cause is unknown, but theories related to diet (low in protein and high in carbohydrate) and free radical damage in the presence of inadequate antioxidant defences have been proposed.
• **Marasmus** is the childhood form of starvation, which is associated with obvious wasting. The child looks emaciated, and there is obvious muscle wasting and loss of body fat. There is no oedema. The hair is thin and dry (Fig. 10.6A). The child is not so apathetic or anorexic as with kwashiorkor. Diarrhoea is frequently present and signs of infection must be looked for carefully.

The **WHO classification of severe malnutrition (Box 10.9)** makes no distinction between kwashiorkor and marasmus because the approach to treatment is similar in both. The WHO classification of chronic under-nutrition in children is based on standard deviation (SD) scores. Thus, children with an SD score between −2 and −3 (between 3 and 2 SD scores below the median, corresponding to a value between 0.13 and 2.3 centiles) can be regarded as being at moderate risk of under-nutrition; below an SD score of −3, there is a risk of severe malnutrition. A low weight-for-height is a measure of thinness (wasting when pathological) and a low height-for-age is a measure of shortness (stunting when pathological). Those with oedema and clinical signs of severe malnutrition are classified as having oedematous malnutrition.

---

**Box 10.9**

**Classification of childhood malnutrition**
### Starvation in adults

Starvation in adults may lead to extreme loss of weight, depending on the severity and duration. They may crave food, are apathetic, and complain of cold and weakness with a loss of subcutaneous fat and muscle wasting. The WHO classification is based on BMI, with a value <18.5 kg/m² indicating malnutrition (severe malnutrition if <16.0 kg/m²).

Severely malnourished adults and children are very susceptible to respiratory and gastrointestinal infections, leading to an increased mortality in these groups.

### Investigations

These are not always practicable in certain settings in the developing world.

- **Blood tests** may demonstrate the following results:
  - Anaemia due to folate, iron and copper deficiency is often present, but the haematocrit may be high owing to dehydration.
  - Eosinophilia suggests parasitic infestation.
  - Electrolyte disturbances are common.
  - Malarial parasites should be sought.
  - Human immunodeficiency (HIV) tests should be performed.

- **Stools** should be examined for parasitic infestations.

- **Chest X-ray** may reveal tuberculosis, which is common and easily missed if a chest X-ray is not performed.

### Management

Management must involve the provision of protein and energy supplements and the control of infection. The approach to the treatment of children is described below. Adults do not usually suffer such severe malnutrition but the same general principles of treatment should be followed.

#### Resuscitation and stabilization

The severely ill child will require:
• correction of fluid and electrolyte abnormalities, avoiding intravenous therapy, if possible, because of the danger of fluid overload
• treatment of shock with oxygen
• treatment of hypoglycaemia (blood glucose <3 mmol/L), hypothermia (reduce heat loss, and provide additional heat if necessary) and infection (antibiotics) – these often co-exist.

The standard WHO oral hydration solution has a high sodium and low potassium content and is not suitable for severely malnourished children. Instead, the rehydration solution for malnutrition (ReSoMal) is recommended. It is commercially available but can also be produced by modification of the standard WHO oral hydration solution.

Infection is common (Box 10.10). Diarrhoea is often due to bacterial or protozoal overgrowth; metronidazole is very effective and is often given routinely. Parasites are also common and, as facilities for stool examination are usually not available, mebendazole 100 mg twice daily should be given for 3 days. In high-risk areas, antimalarial therapy is given. A recent study in Malawi suggests that the addition of antibiotics to therapeutic regimes for uncomplicated severe acute malnutrition in children less than 5 years of age is associated with a significant improvement in recovery and mortality.

---

**Box 10.10**

**Infections seen in PEM in developing countries**

- Diarrhoea
  - Bacteria
  - Protozoa
  - Helminths
- Malaria
- Tuberculosis
- HIV infection
- Measles
- Respiratory infections

---

Large doses of vitamin A are also given because deficiency of this vitamin is common. After the initial resuscitation, further stabilization over the next few days is undertaken, as indicated in **Box 10.11**.

---

**Box 10.11**

**Timeframe for the management of the child with severe malnutrition (10-step approach recommended by WHO)**
Re-feeding

This needs to be planned carefully. During the initial management of the acute situation, a balanced diet with sufficient protein and energy is given to maintain a steady state. Large increases in energy can lead to heart failure, circulatory collapse and death (re-feeding syndrome). Initial feeding involves the administration of feeds that are low in osmolarity and low in lactose. WHO recommendations are 100 kcal/kg per day; 1.0–1.5 g protein/kg per day; and 130 mL liquid/kg per day (100 mL/kg per day if the child has marked oedema). Attempts should be made to give the feeds slowly and frequently (e.g. 2-hourly during days 1–2; 3-hourly during days 3–5; and 4-hourly thereafter), although anorexia is often a problem and can be exacerbated by excessive feeding. If necessary, fluids and food should be given by nasogastric tube. The child is then gradually weaned to liquids and then solids by mouth. All severely malnourished children have vitamin and mineral deficiencies. Although anaemia is common, the WHO recommends giving iron only after the child develops a good appetite and starts gaining weight, because of concern about detrimental effects during the acute phase of illness (iron is a pro-oxidant). The child should be given daily micronutrient supplements for at least 2 weeks. These should include a multivitamin supplement with folic acid, zinc and copper.

Rehabilitation

Gradually, as the child improves, more energy can be given, and during rehabilitation, weight gain is achieved by providing extra energy and protein (‘catch-up weight gain’). Children who have been severely ill need constant attention right through the convalescent period, as home conditions are often poor and feeds are refused. Sensory stimulation and emotional support are major components of management during both the stabilization and the rehabilitation phases. The treatment of underlying chronic infective conditions, such as HIV, malaria and tuberculosis, is also necessary.
Care setting

There are not enough hospitals or therapeutic feeding centres to cope with the malnutrition problem (even acute malnutrition problems); this emphasizes the need for outpatient and community-based programmes, although these require investment and time to build to full capacity. The programmes may involve the use of ready-to-use therapeutic foods, such as energy-dense pastes with minerals and vitamins, without the need to add water, which could potentially contaminate the food.

Prognosis

Children with extreme malnutrition have a mortality of over 50%. By careful management, this can be reduced significantly to less than 10%, depending on the availability of facilities and trained staff. Treatment of underlying disease is essential. Brain development takes place in the first years of life, a time when severe PEM is frequently seen. There is evidence that intellectual impairment and behavioural abnormalities occur in severely affected children. Physical growth is also impaired. Probably both of these effects can be alleviated if it is possible to maintain a high standard of living with a good diet and freedom from infection over a long period.

Prevention

Prevention of PEM depends not only on the availability of adequate nutrients but also on the education of both governments and individuals in the importance of good nutrition and immunization (Box 10.12). Short-term programmes are useful for acute shortages of food, but long-term programmes involving improved agriculture are equally necessary. Bad feeding practices and infections are more prevalent than actual shortage of food in many areas of the world. However, good surveillance is necessary to avoid periods of famine.

Box 10.12

Prevention of protein–energy malnutrition–GOBIF (a WHO priority programme)

• Growth monitoring: the WHO has a simple growth chart that the mother keeps
• Oral rehydration, particularly for diarrhoea
• Breast-feeding supplemented by food after 6 months
• Immunization: against measles, tetanus, pertussis, diphtheria, polio and tuberculosis (see also Box 11.19)
• Family planning

Food supplements (and additional vitamins) should be given to ‘at-risk’ groups by adding
high-energy food (e.g. milk powder, meat concentrates) to the diet. Pregnancy and lactation are times of high energy requirement and supplements have been shown to be beneficial.

---

**Vitamins**

Deficiencies due to inadequate intake associated with PEM *(Box 10.13)* are commonly seen in the developing countries. This is not, however, invariable. For example, vitamin A deficiency is not seen in Jamaica, but is common in PEM in Hyderabad, India. In the West, deficiency of vitamins is less common but prominent in the specific groups shown in *Box 10.14*. The widespread use of vitamins as ‘tonics’ is unnecessary and should be discouraged. Toxicity from excess fat-soluble vitamins is occasionally seen.

*Values vary with age and sex. For women, values are generally the same or lower than for men, except during pregnancy and lactation, when they are generally higher than for men.*

*No RNI.*

*No official RNI in the UK because the amount varies, depending on the polyunsaturated fatty acid content of the diet; 15 mg is the value from the National Academy of Sciences, USA.*

*Thiamine requirements are related to energy metabolism.*
Some causes of vitamin deficiency in developed countries

**Decreased intake**
- Alcohol dependency: chiefly B vitamins (e.g. thiamine)
- Small bowel disease: chiefly folate, occasionally fat-soluble vitamins
- Vegans: vitamin D (if no exposure to sunlight), vitamin B$_{12}$
- Elderly with poor diet: chiefly vitamin D (if no exposure to sunlight), folate
- Anorexia from any cause: chiefly folate

**Decreased absorption**
- Ileal disease/resection: only vitamin B$_{12}$
- Liver and biliary tract disease: fat-soluble vitamins
- Intestinal bacterial overgrowth: vitamin B$_{12}$
- Oral antibiotics: vitamin K

**Miscellaneous**
- Long-term enteral or parenteral nutrition: usually vitamin supplements are given
- Renal disease: vitamin D
- Drug antagonists (e.g. methotrexate interfering with folate metabolism)

**Fat-Soluble Vitamins**

**Vitamin A**

Vitamin A (retinol) is part of the family of retinoids, which is present in food and the body as esters combined with long-chain fatty acids. The richest food source is liver, but it is also found in milk, butter, cheese, egg yolks and fish oils. Retinol or carotene is added to margarine in the UK and other countries.

Beta-carotene is the main carotenoid found in green vegetables, carrots and other yellow and red fruits. Other carotenoids, lycopene and lutein, are probably of little quantitative importance as dietary precursors of vitamin A.

Beta-carotene is cleaved in the intestinal mucosa by carotene dioxygenase, yielding retinaldehyde, which can be reduced to retinol. Between a quarter and a third of dietary vitamin A in the UK is derived from retinoids. Nutritionally, 6 µg of β-carotene is equivalent to 1 µg of preformed retinol; vitamin A activity in the diet is given as retinol equivalents.
Function

Retinol is stored in the liver and is transported in plasma bound to an α-globulin, retinol-binding protein (RBP). Vitamin A has several metabolic roles:

- Retinaldehyde in its cis form is found in the opsin proteins in the rods (rhodopsin) and cones (iodopsin) of the retina (see p. 1324). Light causes retinaldehyde to change to its trans isomer, and this leads to changes in membrane potentials that are transmitted to the brain.
- Retinol and retinoic acid are involved in the control of cell proliferation and differentiation.
- Retinyl phosphate is a co-factor in the synthesis of most glycoproteins containing mannose.

Vitamin A deficiency

Worldwide, vitamin A deficiency and xerophthalmia (see below) are the major causes of blindness in young children, despite intensive preventative programmes.

Xerophthalmia has been classified by the WHO (Box 10.15). Impaired adaptation, followed by night blindness, is the first effect. There is dryness and thickening of the conjunctiva and the cornea (xerophthalmia occurs as a result of keratinization). Bitot's spots – white plaques of keratinized epithelial cells – are found on the conjunctiva of young children with vitamin A deficiency. These spots can, however, be seen without vitamin A deficiency, possibly caused by exposure. Corneal softening, ulceration and dissolution (keratomalacia) eventually occur, superimposed infection is a frequent accompaniment and both lead to blindness (Fig. 10.7). In PEM, retinol-binding protein is reduced, along with other proteins. This suggests vitamin A deficiency, although body stores are not necessarily reduced.

(From WHO/UNICEF/IVACG 1988.)
Vitamin A in malnourished children

Vitamin A supplementation (single oral dose of 60 mg retinol palmitate) appears to improve morbidity and mortality from measles. It has also been suggested that similar supplementation reduces morbidity and/or mortality from diarrhoeal diseases and respiratory infections, and improves growth. Despite low circulating concentrations of vitamin A in HIV-infected individuals, supplementation of HIV-infected pregnant women does not appear to reduce the risk of mother-to-child transmission of HIV.

Diagnosis

In parts of the world where deficiency is common, diagnosis is made on the basis of the clinical features, and deficiency should always be suspected if any degree of malnutrition is present. Blood levels of vitamin A will usually be low, but the best guide to diagnosis is a response to replacement therapy.

Management

Urgent treatment with retinol palmitate 30 mg orally should be given on two successive days. In the presence of vomiting and diarrhoea, 30 mg of vitamin A is given intramuscularly. Associated malnutrition must be treated, and superadded bacterial infection should be treated with antibiotics. Referral for specialist ophthalmic treatment is necessary in severe cases.

Prevention

Most Western diets contain enough dairy products and green vegetables, but vitamin A is added to foodstuffs (e.g. margarine) in some countries. Vitamin A is not destroyed by cooking.

In some developing countries, vitamin A supplements are given at the time a child attends for measles vaccination. Food fortification programmes are another approach. Education of the population is necessary and people should be encouraged to grow their own vegetables. In particular, pregnant women and children should be encouraged to eat green vegetables and yellow fruits.
Other effects of vitamin A

In a chronically malnourished population, maternal repletion with vitamin A before, during and after pregnancy may improve lung function in the offspring at 9–13 years. It may also reduce maternal mortality. Administration of vitamin A to young children at risk of deficiency reduces mortality, although to a lesser extent than previously thought. The effect of β-carotene in cardiovascular and other diseases is discussed below in the section entitled ‘Dietary antioxidants’ (see p. 201). Retinoic acid and some synthetic retinoids are used in dermatology (see Box 31.10).

Possible adverse effects

• **High intakes of vitamin A.** Chronic ingestion of retinol can cause liver and bone damage, hair loss, double vision, vomiting, headaches and other abnormalities. Single doses of 300 mg in adults or 100 mg in children can be harmful.

• **Retinol is teratogenic.** The incidence of birth defects in infants is high with vitamin A intakes of >3 mg a day during pregnancy. In pregnancy, extra vitamin A or consumption of liver is not recommended in the UK. However, β-carotene is not toxic.

Vitamin D

Vitamin D is discussed in more detail in Chapter 19, where the most common manifestations of deficiency are discussed (rickets and osteomalacia). Vitamin D status is assessed by measurement of 25 hydroxyvitamin D in the serum. Vitamin D receptors are distributed widely in human tissues but their function in many non-musculoskeletal tissues still remains poorly understood. Vitamin D status has been linked to a wide range of diseases, including:

• cardiovascular disorders (ischaemic heart disease, heart failure, hypertension)
• respiratory disorders (chest infections)
• renal disorders (progression of renal disease)
• endocrine disorders (type 1 and type 2 diabetes)
• neuropsychiatric disorders (depression, cognitive deficits)
• cancer (e.g. prostate, breast, colon) and mortality from various causes.
• Multiple sclerosis (see p. 858)

It has therefore been suggested that vitamin D may have a role in global health, and not just the health of the musculoskeletal system. Studies of the relationship between vitamin D serum levels (25 hydroxyvitamin D) and the risk of the conditions listed above have led to different definitions of the optimal level of 25 hydroxyvitamin D for adequate status. This also implies that there are different requirements for vitamin D in different diseases. However, randomized controlled trials (RCTs) of vitamin D supplementation have not been as promising in averting some of these conditions as might have been anticipated from the observational relationships. Reduced circulating concentrations of vitamin D can result not only from lack of exposure to
sunlight and a poor diet, but also from inflammation, smoking and obesity.

**Vitamin K**

Vitamin K is found as phylloquinone (vitamin K₁) in green, leafy vegetables, dairy products, rapeseed and soya bean oils. Intestinal bacteria can synthesize the other major form of vitamin K, menaquinone (vitamin K₂), in the terminal ileum and colon. Vitamin K is absorbed in a similar manner to other fat-soluble substances in the upper small gut. Some menaquinones must also be absorbed, as this is the major form found in the human liver.

**Function**

Vitamin K is a co-factor that is necessary for the production not only of blood clotting factors (II, VII, IX and X, and other proteins involved in coagulation; see p. 573), but also of proteins that are necessary for the formation of bone.

Vitamin K is a co-factor for the post-translational carboxylation of specific protein-bound glutamate residues in γ-carboxyglutamate (Gla). Gla residues bind calcium ions to phospholipid templates, and this action on factors II, VII, IX and X, and on proteins C and S, is required for coagulation to take place.

Bone osteoblasts contain three vitamin K-dependent proteins: osteocalcin, matrix Gla protein and protein S, which have a role in bone matrix formation. Osteocalcin contains three Gla residues, which bind tightly to the hydroxyapatite matrix, depending on the degree of carboxylation; this leads to bone mineralization. There is, however, no convincing evidence that vitamin K deficiency or antagonism affects bone other than rapidly growing bone.

**Vitamin K deficiency**

Vitamin K deficiency results in inadequate synthesis of clotting factors (see p. 573), which leads to an increase in the prothrombin time and haemorrhage. It has also been linked to bone health, but there is inadequate evidence to support the routine use of vitamin K to prevent osteoporosis and reduce fracture risk. Deficiency occurs in the newborn, in cholestatic jaundice, and with concomitant use of vitamin K antagonists.

**The newborn**

Deficiency occurs in the newborn owing to:

- poor placental transfer of vitamin K
- the fact that there is little vitamin K in breast milk
- the lack of hepatic stores of menaquinone (no intestinal bacteria in the neonate).

Deficiency leads to a haemorrhagic disease of the newborn, which can be prevented with prophylactic vitamin K. Vitamin K (phytomenadione 1 mg, i.m.) is given to all neonates after the risks have been discussed with parents and consent has been obtained.
**Cholestatic jaundice**

When bile flow into the intestine is interrupted, malabsorption of vitamin K occurs, as no bile salts are available to facilitate absorption and the prothrombin time increases. This can be corrected by giving 10 mg of phytomenadione intramuscularly. (Note that an increased prothrombin time caused by liver disease does not respond to vitamin K injection, there being no shortage of vitamin K – just poor liver function.) In patients with chronic cholestasis (e.g. primary biliary cholangitis), oral therapy with a water-soluble preparation, menadiol sodium phosphate 10 mg daily, is used.

**Concomitant vitamin K antagonists**

Oral anticoagulants, such as warfarin, antagonize vitamin K (see pp. 578–580). Antibacterial drugs also interfere with the bacterial synthesis of vitamin K.

**Vitamin E**

Vitamin E includes eight naturally occurring compounds that may be divided into tocopherols and tocotrienols. The most active compound and the most widely available in food is the natural isomer d-d-α-tocopherol (or RRR-α-tocopherol), which accounts for 90% of vitamin E in the human body. Vegetables and seed oils, including soya bean, saffron, sunflower, cereals and nuts, are the main sources. Animal products are poor sources of the vitamin. Vitamin E is absorbed with fat, transported in the blood largely in LDLs.

An individual's vitamin E requirement depends on the intake of polyunsaturated fatty acids (PUFAs). Since this varies widely, no daily requirement is given in the UK. The requirement stated in the USA is approximately 7–10 mg/day, but average diets contain much more than this. If PUFAs are taken in large amounts, more vitamin E is required.

**Function**

The biological activity of vitamin E results principally from its antioxidant properties. In biological membranes, it contributes to membrane stability. It protects cellular structures against damage from a number of highly reactive oxygen species, including hydrogen peroxide, superoxide and other oxygen radicals. Vitamin E may also affect cell proliferation and growth.

**Vitamin E deficiency**

The first deficiency to be demonstrated was a haemolytic anaemia described in premature infants. Infant formulations now contain vitamin E.

Deficiency is seen only in children with abetalipoproteinaemia (see p. 402) and in patients on long-term parenteral nutrition. The severe neurological deficit (gross ataxia) can be prevented with vitamin E injections.

Plasma or serum levels of α-tocopherol can be measured and should be corrected for the level of plasma lipids by expressing the value as milligrams per milligram of plasma lipid.
**Epidemiological data and clinical trials**

Animals fed an atherogenic diet supplemented with α-tocopherol develop far fewer new atheromatous lesions than those fed an atherogenic diet alone; there may be regression of existing lesions.

There is also evidence for vitamin E intake and blood α-tocopherol levels as an independent risk factor for the development of ischaemic heart disease in healthy, well-nourished individuals eating a Western diet. This has been shown in comparisons of different communities in the WHO ‘MONICA’ observational study.

Randomized trials involving vitamin E supplementation have produced conflicting results, possibly due to factors such as short duration of treatment, use of suboptimal doses or lack of concurrent administration of vitamin C. There are very few trials to assess the role of vitamin E in prevention of peripheral vascular disease and cancer.

**Water-Soluble Vitamins**

Water-soluble vitamins are non-toxic and relatively cheap; they can therefore be given in large amounts if a deficiency is possible. The daily requirements for water-soluble vitamins are given in *Box 10.13* (on p. 195).

**Thiamine (vitamin B₁)**

**Function**

Thiamine diphosphate, often called thiamine pyrophosphate (TPP), is an essential co-factor, particularly in carbohydrate metabolism.

TPP is involved in the oxidative decarboxylation of acetyl coenzyme A (CoA) in mitochondria. In formation of acetyl CoA (from pyruvate) and in the Krebs cycle, TPP is the key enzyme for the decarboxylation of α-ketoglutarate to succinyl CoA. TPP is also the co-factor for transketolase, a key enzyme in the hexose monophosphate shunt.

Thiamine is found in many foodstuffs, including cereals, grains, beans and nuts, as well as pork and duck. It is often added to food (e.g. in cereals) in developed countries. The dietary requirement (see *Box 10.13*) depends on energy intake, more being required if the diet is high in carbohydrates.

Following absorption, thiamine is found in all body tissues, the majority being in the liver. Body stores are small and signs of deficiency quickly develop with inadequate intake.

There is no evidence that a high oral intake is dangerous but ataxia has been reported after high parenteral therapy.

**Thiamine deficiency**

Thiamine deficiency is seen:
• As beriberi, where the only staple food consumed is polished rice.
• In chronic alcohol-dependent patients who are consuming virtually no food at all.
• In starved patients (e.g. with carcinoma of the stomach), and in severe prolonged hyperemesis gravidarum, anorexia nervosa and prolonged total starvation in healthy subjects (e.g. fasts for political reasons). It can also occur in patients given parenteral nutrition with little or no thiamine, as large doses of glucose increase requirements for thiamine and can precipitate deficiency (e.g. during re-feeding).

**Beriberi**

This is now confined to the poorest areas of South-east Asia. It can be prevented by eating under-milled or parboiled rice, or by fortification of rice with thiamine. The prevention of beriberi needs a general increase in overall food consumption so that the staple diet is varied and includes legumes and pulses, which contain a large amount of thiamine. There are two main clinical types of beriberi, which, surprisingly, only rarely occur together.

• **Dry beriberi** usually presents insidiously with a symmetrical polyneuropathy. The initial symptoms are heaviness and stiffness of the legs, followed by weakness, numbness, and pins and needles. The ankle jerk reflexes are lost and eventually all the signs of polyneuropathy that may involve the trunk and arms are found (see p. 885). Cerebral involvement occurs, producing the picture of the Wernicke–Korsakoff syndrome (p. 885). In endemic areas, mild symptoms and signs may be present for years without unduly affecting the patient.

• **Wet beriberi** causes oedema. Initially, this is of the legs, but it can extend to involve the whole body, with ascites and pleural effusions. The peripheral oedema may mask the accompanying features of dry beriberi.

  Thiamine deficiency impairs pyruvate dehydrogenase with accumulation of lactate and pyruvate, producing peripheral vasodilatation and eventually oedema. The heart muscle is also affected and heart failure occurs, causing a further increase in the oedema. Initially, there are warm extremities, a full, fast, bounding pulse and a raised venous pressure (‘high-output state’), but eventually heart failure advances and a poor cardiac output ensues. The electrocardiogram may show conduction defects.

  **Infantile beriberi** occurs, usually acutely, in breast-fed babies at approximately 3 months of age. The mothers show no signs of thiamine deficiency but presumably their body stores must be virtually nil. The infant becomes anorexic, develops oedema and has some degree of aphonia. Tachycardia and tachypnoea develop and, unless treatment is instituted, death occurs quickly.

**Diagnosis**

In endemic areas, the diagnosis of beriberi should always be suspected; if it is in doubt, treatment with thiamine should be instituted. A rapid disappearance of oedema after thiamine (50 mg i.m.) is diagnostic. Other causes of oedema must be considered (e.g. renal or liver
disease), and the polyneuropathy is indistinguishable from that due to other causes. The diagnosis is confirmed by measurement of the circulating thiamine concentration or transketolase activity in red cells using fresh heparinized blood.

**Management**

Thiamine 50 mg i.m. is given for 3 days, followed by 50 mg of thiamine daily by mouth. The response in wet beriberi is seen in hours, providing a dramatic improvement, but in dry beriberi improvement is often slow to occur. In most cases, all the B vitamins are given because of multiple deficiency. Infantile beriberi is treated by giving thiamine to the mother, which is then passed on to the infant via the breast milk.

**Thiamine deficiency in people with alcohol dependence or acute illness**

In the developed world, alcohol-dependent people and those with severe acute illness receiving high-carbohydrate infusions without vitamins are the only major groups to suffer from thiamine deficiency. Rarely, they develop wet beriberi, which must be distinguished from alcoholic cardiomyopathy. More usually, however, thiamine deficiency presents with polyneuropathy or with the *Wernicke–Korsakoff syndrome*.

This syndrome, which consists of dementia, ataxia, varying ophthalmoplegia and nystagmus (see p. 885), presents acutely and should be suspected in all heavy drinkers. If treated promptly it is reversible; if left, it becomes irreversible. It is a major cause of dementia in the USA.

**Urgent treatment** with thiamine 250 mg i.m. or i.v. infusion once daily is given for 3 days, often combined with other B-complex vitamins. Anaphylaxis can occur. Thiamine must always be given before any intravenous glucose infusion.

**Riboflavin**

Riboflavin is widely distributed throughout all plant and animal cells. Good sources are dairy products, offal and leafy vegetables. Riboflavin is not destroyed appreciably by cooking but is destroyed by sunlight. It is a flavo-protein that is a co-factor for many oxidative reactions in the cell.

There is no definite deficiency, although many communities have low dietary intakes. Studies in volunteers taking a low-riboflavin diet have produced:

• angular stomatitis or cheilosis (fissuring at the corners of the mouth)
• a red, inflamed tongue
• seborrhoeic dermatitis, particularly involving the face (around the nose) and the scrotum or vulva.

 Conjunctivitis with vascularization of the cornea and opacity of the lens has also been described. It is probable, however, that many of the above features are due to multiple deficiencies rather than lack of riboflavin itself.
Riboflavin 5 mg daily can be tried for the above conditions, usually given as the vitamin B complex.

**Niacin**

This is the generic name for the two chemical forms, nicotinic acid and nicotinamide, the latter being found in the two pyridine nucleotides, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP). Both act as hydrogen acceptors in many oxidative reactions, and in their reduced forms (NADH and NADPH) act as hydrogen donors in reductive reactions. Many oxidative steps in the production of energy require NAD and NADP.

Niacin is found in many foodstuffs, including plants, meat (particularly offal) and fish. Niacin is lost when bran is removed from cereals, but is added to processed cereals and white bread in many countries.

Niacin can be synthesized in humans from tryptophan, 60 mg of tryptophan being converted to 1 mg of niacin. The amount of niacin in food is given as the ‘niacin equivalent’, which is equal to the amount of niacin plus one-sixtieth of the tryptophan content. Eggs and cheese contain tryptophan.

Kynureninase and kynurenine hydroxylase, key enzymes in the conversion of tryptophan to nicotinic acid, are both B₆ and riboflavin-dependent, and deficiency of these B vitamins can also produce pellagra.

**Pellagra**

This is rare but is found in people who eat virtually only maize: for example, in parts of Africa. Maize contains niacin in the form of niacytin, which is biologically unavailable and has a low content of tryptophan. In Central America, pellagra has always been rare because maize (for the cooking of tortillas) is soaked overnight in calcium hydroxide, which releases niacin. Many of the features of pellagra *(Fig. 10.8)* can be explained purely by niacin deficiency, but some are probably due to multiple deficiencies, including deficiencies of proteins and of other vitamins.
Clinical features

The classical features are dermatitis, diarrhoea and dementia. Although this is an easily remembered triad, not all features are always present and the mental changes are not a true dementia.

- **Dermatitis.** In the areas of skin exposed to sunlight, there is redness initially, followed by cracks with occasional ulceration. Chronic thickening, dryness and pigmentation develop. The lesions are always symmetrical and often affect the dorsal surfaces of the hands. The perianal skin and vulva are frequently involved. Casal’s necklace or collar is the term given to the skin lesion around the neck, which is confined to this area by the clothes worn.

- **Diarrhoea.** This is often a feature but constipation is occasionally seen. Other gastrointestinal manifestations include a painful, red, raw tongue, glossitis and angular stomatitis. Recurring mouth infections occur.

- **Dementia.** This occurs in chronic disease. In milder cases, there are symptoms of depression, apathy and sometimes thought disorders. Tremor and an encephalopathy frequently occur. Hallucinations and acute psychosis are also seen with more severe cases.

**Pellagra may also occur in the following circumstances:**

- **Isoniazid therapy.** This can lead to a deficiency of vitamin B$_6$, which is needed for the synthesis of nicotinamide from tryptophan. Vitamin B$_6$ is now given concomitantly with isoniazid.

- **Hartnup’s disease,** a rare inborn error in which basic amino acids, including tryptophan, are not absorbed by the gut. There is also loss of this amino acid in the urine.
• Generalized malabsorption (rare).
• Alcohol-dependent patients who eat little.
• Very-low-protein diets given for renal disease or taken as a food fad.
• Carcinoid syndrome and phaeochromocytomas. In these disorders, tryptophan metabolism is diverted away from the formation of nicotinamide to form amines.

**Diagnosis and management**

In endemic areas, diagnosis and management are based on the clinical features, remembering that other vitamin deficiencies can produce similar changes (e.g. angular stomatitis). Nicotinamide (approximately 300 mg daily by mouth) is given, with a maintenance dose of 50 mg daily, and produces a dramatic improvement in the skin and diarrhoea. Mostly, however, vitamin B complex is given, as other deficiencies are often present.

An increase in the protein content of the diet, and treatment of malnutrition and other vitamin deficiencies, are essential.

**Vitamin B<sub>6</sub>**

Vitamin B<sub>6</sub> exists as pyridoxine, pyridoxal and pyridoxamine, and is found widely in plant and animal foodstuffs. Pyridoxal phosphate is a co-factor in the metabolism of many amino acids. Dietary deficiency is extremely rare. Some drugs (e.g. isoniazid, hydralazine and penicillamine) interact with pyridoxal phosphate, producing B<sub>6</sub> deficiency. The polyneuropathy occurring after isoniazid usually responds to vitamin B<sub>6</sub>.

Sideroblastic anaemia may respond to vitamin B<sub>6</sub> (see p. 526).

A polyneuropathy has occurred after high doses (>200 mg) given over many months. Vitamin B<sub>6</sub> is used for premenstrual tension; a daily dose of 10 mg should not be exceeded.

**Biotin and pantothenic acid**

Biotin is involved in a number of carboxylase reactions. It occurs in many foodstuffs and the dietary requirement is small. Deficiency is extremely rare and is confined to a few people who consume raw eggs, which contain an antagonist (avidin) to biotin. It has also been reported in patients receiving long-term parenteral nutrition without adequate amounts of biotin. It causes a dermatitis that responds to biotin replacements.

Pantothenic acid is widely distributed in all foods and deficiency in humans has not been described.

**Vitamin C**

Ascorbic acid is a powerful reducing agent that controls the redox potential within cells. It is involved in the hydroxylation of proline to hydroxyproline, which is necessary for the formation of collagen. The failure of this biochemical pathway in vitamin C deficiency
accounts for virtually all of the clinical effects seen.

Humans, along with a few other animals (e.g. primates and the guinea-pig), are unusual in not being able to synthesize ascorbic acid from glucose.

Vitamin C is present in all fresh fruit and vegetables. Unfortunately, ascorbic acid is easily leached out of vegetables when they are placed in water and it is also oxidized to dehydro-ascorbic acid during cooking or exposure to copper or alkalis. Potatoes are a good source, as many people eat a lot of them, but vitamin C is lost during storage.

It has been suggested that ascorbic acid in high dosage (1–2 g daily) will prevent the common cold. While there is some scientific support for this, clinical trials have shown no significant effect. Vitamin C supplements have also been advocated to prevent atherosclerosis and cancer, but again a clear benefit has not been demonstrated.

**Vitamin C deficiency** is seen mainly in infants fed boiled milk and in the elderly and single people who do not eat vegetables. In the UK, it is also seen in Asians eating only rice and chapattis and also in food faddists.

### Scurvy

In adults, the early symptoms of vitamin C deficiency may be non-specific, with weakness and muscle pain. Other features are shown in **Box 10.16**. Parafollicular haemorrhages and corkscrew hairs (**Fig. 10.9**) occur. In infantile scurvy, there is irritability, painful legs, anaemia and characteristic subperiosteal haemorrhages, particularly into the ends of long bones.

### Box 10.16

**Clinical features of vitamin C deficiency (scurvy)**

- Keratosis of hair follicles with ‘corkscrew’ hair
- Perifollicular haemorrhages
- Swollen, spongy gums with bleeding and superadded infection, loosening of teeth
- Spontaneous bruising
- Spontaneous haemorrhage
- Anaemia
- Failure of wound healing
**Diagnosis**

The anaemia is usually hypochromic but, occasionally, a normochromic or megaloblastic anaemia is seen. The type of anaemia depends on whether iron deficiency (owing to decreased absorption or loss due to haemorrhage) or folate deficiency (folate being largely found in green vegetables) is present.

Plasma ascorbic acid is very low in obvious deficiency and a vitamin C level of <11 µmol/L (0.2 mg/100 mL) indicates vitamin C deficiency. The leucocyte-platelet layer (buffy coat) of centrifuged blood corresponds to vitamin C concentrations in other tissues. The normal level of leucocyte ascorbate is 1.1–2.8 pmol/10^6 cells.

**Management**

Initially, the patient is given 250 mg of ascorbic acid daily and encouraged to eat fresh fruit and vegetables. Subsequently, 40 mg daily will maintain a normal exchangeable body pool of about 900 mg (5.1 mmol).

**Prevention**

Orange juice should be given to bottle-fed infants. The intake of breast-fed infants depends on the mother’s diet. In the elderly, eating adequate fruit and vegetables is the best way to avoid scurvy. Careful surveillance of the elderly, particularly those who live alone, is necessary. Ascorbic acid supplements should be necessary only occasionally.

**Vitamin B_{12} and folate**

These are dealt with on page 527 and daily requirements are shown in *Box 10.13* on p. 195.

**Folate**

In many developed countries, up to 15% of the population have a partial deficiency of 5,10-methylene tetrahydrofolate reductase, a key folate-metabolizing enzyme. This is due to a point
mutation and is associated with an increase in neural tube defects and hyperhomocysteinaemia, which has been linked to cardiovascular disease. Autoantibodies against folate receptors have been found in serum from women who have had a pregnancy complicated by neural tube defects. However, the role of this in the pathogenesis is unclear.

In the USA and some other countries, enriched cereals are fortified with 1.4 mg/kg grain of folic acid to increase daily intake.

**Dietary Antioxidants**

Free radicals are generated during inflammatory processes, radiotherapy, smoking, and in the course of a wide range of diseases. They may cause uncontrolled damage of multiple cellular components, the most sensitive of which are unsaturated lipids, proteins and DNA, and they also disrupt the normal replication process. They have been implicated as a cause of a wide range of diseases, including malignant, acute inflammatory and traumatic diseases, cardiovascular disease, neurodegenerative conditions such as Alzheimer's disease, senile macular degeneration, and cataract. Defence against uncontrolled damage by free radicals is provided by antioxidant enzymes (e.g. catalase, superoxide dismutase) and antioxidants, which may be endogenous (e.g. glutathione) or exogenous (e.g. vitamins C and E, carotenoids). A possible causal link between lack of antioxidants and cardiovascular disease has emerged from epidemiological studies, although several RCTs have not confirmed this.

---

**Epidemiology**

**Dietary intake**

- A high intake of fruits and vegetables has been linked to a reduced risk of heart disease, cerebrovascular disease and total cardiovascular morbidity and mortality.
- A high intake of nuts (rich in vitamin E) and dietary components, such as red wine, onions and apples (rich in flavonoids), which are strong scavengers of free radicals, has also been linked to a reduced risk of cardiovascular disease.
- The seasonal variation in cardiovascular disease, which is higher in winter, has been related to a decreased intake of fresh fruit and vegetables at that time of year.
- The decline in cardiovascular disease in the USA since the 1950s has been associated with a simultaneous increase in the intake of fresh fruit and vegetables.

**Status of antioxidant nutrients**

The level of antioxidant nutrients in the circulation has been reported to be inversely related to cardiovascular morbidity and mortality, the extent of atherosclerosis as assessed by intra-arterial ultrasound, and clinical signs of ischaemic heart disease. The tissue content of lycopene, a marker of vegetable intake, has been reported to be low in patients with myocardial infarction.
Antioxidants, especially vitamin E, have been shown to prevent the initiation and progression of atherosclerotic disease in animals. They also reduce the oxidation of LDL in the arterial wall in vitro. Oxidation of LDL is an initial event in the atherosclerotic process (see pp. 992–993). However, these epidemiological studies show an association rather than a causal link, and RCTs comparing the antioxidant against a control group are necessary.

The results of RCTs (see also p. 26) have been formally evaluated through a series of systematic reviews and meta-analyses.

• For **primary or secondary prevention** of cardiovascular disease, intervention with β-carotene, α-tocopherol (vitamin E) and ascorbic acid (vitamin C) has demonstrated no significant benefit.

• Vitamin E or β-carotene given in, for example, stroke and fatal and non-fatal myocardial infarction has also not yielded benefits.

• There is a report of increased risk of intracerebral and subarachnoid haemorrhage in healthy individuals receiving carotene and α-tocopherol.

• A meta-analysis has shown a small but significant overall increased risk of cardiovascular death and all-cause mortality in individuals treated with β-carotene (compared to the control group).

• There is an increased risk of developing lung cancer when large doses of β-carotene are administered to subjects with a history of heavy smoking.

• Although administration of antioxidant nutrients has been proposed in a wide range of acute (e.g. critical illness, pancreatitis) and chronic diseases, the evidence base from RCTs is generally not strong.

• In some cases, improvement in indices of free radical damage has been demonstrated (e.g. in acute inflammatory conditions), but with little evidence of clinical benefit.

Epidemiological studies are also confounded by other associated variables, such as eating a low-fat diet or undertaking more exercise. The latter may be more valuable in the causal pathway than the intake of antioxidants. Diets rich in fresh fruit and vegetables also contain a range of antioxidants that were not tested in the clinical trials. Therefore, the results of large-scale RCTs using various combinations and doses of antioxidant nutrients are awaited. In the meantime, the policy of encouraging ‘healthy’ behaviour, which includes increased physical activity and a varied diet rich in fresh fruit and vegetables, and nuts, is still generally recommended both for the population as a whole and for those at risk of cardiovascular disease.

**Homocysteine, Cardiovascular Disease and B Vitamins**

The circulating concentration of the amino acid homocysteine is an independent risk factor for cardiovascular disease. A high concentration is related to ischaemic heart disease, stroke, thrombosis, pulmonary embolism, coronary artery stenosis and heart failure. The strength of the association is similar to that in smoking or hyperlipidaemia.
Proposed mechanisms, based on experimental evidence, by which homocysteine detrimentally affects vascular function, include:

- the direct damaging effects of homocysteine on endothelial cells of blood vessels
- an increase in blood vessel stiffness
- an increase in blood coagulation.

Homocysteine is not found in food, but results from metabolism within the body, which depends on folic acid, vitamin B$_{12}$, and pyridoxine (vitamin B$_{6}$) (Fig. 10.10). Deficiency of one or more of these vitamins is common in the elderly, which would increase the concentration of homocysteine. If an elevated homocysteine concentration were causally linked to cardiovascular disease, then it should be possible to lower the risk by administering one or more of these vitamins to decrease the homocysteine concentration. However, several studies suggest that lowering homocysteine concentrations in this way does not reduce the risk of cardiovascular disease.

Minerals

A number of minerals have been shown to be essential in animals, and an increasing number of deficiency syndromes are becoming recognized in humans. Long-term total parenteral nutrition allowed trace element deficiency to be studied in controlled conditions; now trace elements are always added to long-term parenteral nutrition regimens. It is highly probable that trace-element deficiency is also a frequent accompaniment of all PEM states, but this is difficult to study because of multiple deficiencies. Sodium, potassium, magnesium and chloride are discussed in Chapter 9. Reference nutrient intake (RNI) values are shown in Box 10.17. However, in disease, the requirements of specific nutrients may increase (e.g. sodium, potassium, magnesium and zinc in patients with persistent diarrhoea or other gastrointestinal fluid losses) or decrease (e.g. phosphate, potassium and sodium in chronic kidney disease).

*UK value; a substantially higher value is recommended in the USA.

In the UK, most flour is fortified.

Iron

Iron deficiency (see also pp. 524–526) is common worldwide, affecting both developing and developed countries. It is particularly prevalent in women of reproductive age. Dietary iron overload is seen in South African men who cook and brew in iron pots.

Copper

Copper deficiency

Menkes' kinky hair syndrome is a rare condition caused by malabsorption of copper. The Menkes' disease gene (ATP7A) encodes a copper-transporting ATPase and has a homology to the gene in Wilson's disease. Infants with this sex-linked recessive abnormality develop growth failure, mental retardation, bone lesions and brittle hair. Anaemia and neutropenia also occur. This condition, which serves as a model for copper deficiency, supports the idea that some of the clinical features seen in PEM are due to copper deficiency. Breast and cow's milk are low in copper, and supplementation is occasionally necessary when first treating PEM.
Copper toxicity
This occurs in Wilson's disease; see page 479.

Zinc
Zinc is involved in many metabolic pathways, often acting as a coenzyme; it is essential for the synthesis of RNA and DNA. In young children in developing countries, death attributable to zinc deficiency is lower than previously thought. One study found significant improvements when extra zinc was provided with several other micronutrients.

Zinc deficiency
Acrodermatitis enteropathica is an inherited disorder caused by malabsorption of zinc. Infants develop growth retardation, severe diarrhoea, hair loss and a skin rash, which can occur anywhere on the body but is most often found around the mouth, genitalia and hands (a similar rash occurs in adults suffering from zinc deficiency due to other causes; see below). There are also associated Candida and bacterial infections (Fig. 10.11). This condition provides a model for zinc deficiency. Zinc supplementation results in a complete cure. Zinc deficiency probably also plays a role in PEM and in many diseases in children in the developing world. Zinc supplementation has been demonstrated as being of some benefit in, for example, the prevention of diarrhoeal diseases and acute respiratory infections; it also improves growth.

Levels of zinc have also been shown to be low in some patients with malabsorption or skin disease, and in patients with the acquired immunodeficiency syndrome (AIDS), but its exact role in these situations is disputed. Zinc has low toxicity, but high zinc levels from water stored in galvanized containers interfere with iron and copper absorption. Conversely, administration of copper or iron to treat deficiencies such as iron deficiency anaemia can precipitate zinc deficiency. Wound healing is impaired with moderate zinc deficiency and is
improved by zinc supplements. Impaired taste and smell, hair loss and night blindness are also features of severe zinc deficiency.

**Iodine**

Iodine exists in foodstuffs as inorganic iodides, which are efficiently absorbed. Iodine is a constituent of the thyroid hormones (see pp. 1200–1201).

**Iodine deficiency**

Many areas throughout the world lack iodine in the soil, and so iodine deficiency, which impairs brain development, is a WHO priority. Two billion people worldwide (one-third of whom are children) have insufficient iodine intake. Endemic goitre *(Fig. 10.12)* occurs in remote areas where the daily intake is below 70 µg, and in those parts 1–5% of babies are born with congenital hypothyroidism (with severe stunting, learning difficulty and a goitre). In these areas, iodized oil should be given intramuscularly to all reproductive women every 3–5 years. Salt iodization is now practised in many countries and is a simple, cost-effective way to prevent deficiency.

![Goitre due to iodine deficiency](image)

*FIGURE 10.12 Goitre due to iodine deficiency.* (From Dhillon RS, East CA 2013 Ear, Nose and Throat and Head and Neck Surgery 4th Edn, Elsevier, with permission.)

**Fluoride**

In areas where the level of fluoride in drinking water is less than 1 p.p.m. (0.7–1.2 mg/L), dental caries is relatively more prevalent. Fluoridation of the water provides 1–2 mg daily, resulting in a reduction of about 50% of tooth decay in children. There is little fluoride in food. Fluoride-containing toothpaste may add up to 2 mg/day.

Excessive fluoride intake in areas where the water fluoride level is above 3 mg/L can result in fluorosis, in which there is infiltration into the enamel of the teeth, producing pitting and discoloration.
**Selenium**

Clinical deficiency of selenium is rare, except in areas of China where Keshan disease, a selenium-responsive cardiomyopathy, occurs. Selenium deficiency may also cause a myopathy. Interactions between selenium and viruses have also been implicated. Toxicity has been described with very high intakes.

**Calcium**

Calcium absorption (see also p. 708) from the gastrointestinal tract is vitamin D-dependent. Some 99% of body calcium is in the skeleton.

Increased calcium is required in pregnancy and lactation, when dietary intake must be increased. Calcium deficiency is usually due to vitamin D deficiency.

**Phosphate**

Phosphates (see also p. 171) are present in all natural foods, and dietary deficiency has not been described. Patients taking large amounts of aluminium hydroxide can, however, develop phosphate deficiency owing to binding in the gut lumen. It can also be seen in total parenteral nutrition. Symptoms include anorexia, weakness and osteoporosis.

**Other trace elements**

The possible significance of chromium, cobalt, manganese, molybdenum and nickel is shown in *Box 10.18*.

Nutrition and Ageing

Many animal studies have shown that life expectancy can be extended by restricting food intake. It is, however, not known whether the ageing process in humans can be altered by nutrition.

The ageing process

The process of ageing is not well understood. While wear and tear may play a role, it is an insufficient explanation for the causation of ageing. The ‘programmed’ theories depend on inbuilt biological clocks that regulate lifespan, and involve genes that are responsible for controlling signals that influence various body systems. The ‘error’ theories involve environmental stressors that induce damage (e.g. mitochondrial DNA damage or cross-linking).

The search for a single cause of ageing, such as a single gene defect, has been replaced by the view that ageing is a complex multifactorial process that involves an interaction between genetic, environmental and stochastic (random damage to essential molecules) causes. The following theories have been suggested.

Molecular theories

• Genetic regulation. Ageing results, for example, from changes in expression of genes that regulate both development and ageing. An insulin-like signalling pathway has been linked to the lifespan of worms, flies and mice (activation of a transcription factor in response to reduced insulin-like signalling prolongs lifespan).

• Epigenetic regulation. Epigenetic modification, including DNA methylation and histone modification, can help explain why individuals with similar genetic backgrounds can age very differently.

• Codon restriction. Inadequate messenger RNA (mRNA) translation results from inadequate decoding of codons in mRNA.

• Error catastrophe. Errors in gene expression give rise to abnormal proteins.
• **Somatic mutation.** There is cumulative molecular damage mainly to genetic material.

• **Dysdifferentiation.** Cumulative random molecular damage detrimentally affects gene expression.

  Mutations in genes encoding lamin A are found in fibroblasts of elderly people and in progeria syndromes.

**Cellular theories**

• **Cellular senescence–telomere.** An increase in senescent cells is caused by:
  
  – **Loss of telomeres,** which is known to occur with ageing (with each cell division, a small amount of DNA is necessarily lost at each end of the chromosome). Activation of the telomerase enzyme regenerates telomeres, prevents senescence (replicative senescence) and immortalizes cell cultures. Cancer cells are known to activate telomerase. Accelerated telomerase shortening occurs in progerias, such as **Werner syndrome.** One study has also found that telomere length in leucocytes predicts coronary artery disease in middle-aged men at high risk, and these individuals might benefit from statin treatment.
  
  – **Damage** due to a variety of other factors, including DNA damage (stress-induced senescence).

• **Free radical.** Production of free radicals takes place during oxidative metabolism, which damages fat, protein and DNA.

• **Wear and tear.** There is cumulative damage from normal injury/stress, which is unable to repair itself.

• **Apoptosis.** Programmed cell death (see p. 105) is caused by genetic events.

**System theories**

These theories involve loss in the function of neuroendocrine or immune systems with consequent age-related physiological changes and an increase in autoimmunity.

  **Whole-body metabolism and energy expenditure theory** proposes that there is a fixed limit to the cumulative energy expenditure and metabolism during a lifetime; if this limit is reached quickly, the lifespan is short. Energy restriction in rodents reduces energy expenditure and prolongs lifespan, but there is a lack of studies in primates or humans.

**Evolutionary theories**

• **Cumulative mutation.** Mutations that accumulate during a lifetime act in older age rather than during the active reproductive period (for which there is evolutionary selection), producing pathology and senescence. The theory was initially based on the observation that in Huntington's disease, which is due to a dominant lethal mutation that typically presents itself between 35 and 55 years, allows affected individuals to reproduce prior to their clinical diagnosis.

• **Disposable soma.** The somatic body is maintained to ensure reproductive success, after
which it is disposable. Factors that may enhance reproductive success may have detrimental effects on ageing; a possible example is androgen secretion, which may be beneficial to reproduction but potentially detrimental, with development of prostatic cancer and cardiovascular disease in later life.

Nutritional components of theories of ageing

Several of the theories described above have strong nutritional components. **Disability and dependency** in older humans are, at least partly, due to poor nutrition, and correction of deficiencies or nutrient imbalances can prevent the decline in function from falling below the disability threshold (**Fig. 10.13**). In this way, some loss of function may be prevented or reversed, especially if other measures – such as physical activity, which increases muscle mass and strength – are undertaken.

**FIGURE 10.13** Nutrition and ageing. Nutrition is a contributory cause of the variability in function during the lifespan. Appropriate nutrition may improve function, or delay deterioration below the threshold of disability and dependence.

Early origins of health and disease in older adults

A low birth weight (and/or length) is associated with reduced height, as well as reduced mass and fat-free mass in adult life. These relationships are independent of genetic factors; the smaller of identical twins becomes a shorter and lighter adult.

Relationships have also been reported between growth of the fetus and a variety of diseases and risk factors for disease in adults and older people. These include cardiovascular disease (especially ischaemic heart disease), hypertension, diabetes, and even obesity and fat distribution. However, the strength of association for some of these conditions is weak. Animal studies involving dietary modifications (e.g. protein and zinc, even within the normal range)
during pregnancy or in early postnatal life have clearly demonstrated effects, such as hypertension. The effects can not only persist through the lifetime of the offspring, but also be passed through to their offspring.

The extent to which these findings apply to humans is uncertain and the mechanisms are poorly understood. Since relationships have been reported between cardiovascular disease in old age and growth in the first few years of life, as well as starvation during puberty, it is likely that cumulative environmental stresses, including nutritional stress, from the time of implantation of the fertilized egg, to fetal and postnatal growth and development, and into adult life, summate to produce an overall disease risk (see Fig. 10.13). Although high birth weight and length are associated with a reduced risk of cardiovascular disease in later life, they may also be associated with an increased risk of cancer.

**Nutritional requirements in the elderly**

These are qualitatively similar to the requirements of younger adults; the diet should contain approximately the same proportions of nutrients, and essential nutrients are still needed. However, the RNIs stated earlier (see Boxes 10.13 and 10.17) are intended for healthy people without disease; specific requirements in disease, which is common in older people, are less well defined. Furthermore, the extent to which muscle loss is due to ageing, malnutrition and disease continues to be debated, as do the boundaries between sarcopenia, cachexia, malnutrition and frailty. **Sarcopenia** is defined as loss of skeletal muscle bulk, accompanied by decreased strength; unlike cachexia, it occurs without an underlying illness. Sarcopenia leads to disability with an increase in falls.

Maintenance of physical activity continues to be necessary for overall health, regardless of age. However, energy expenditure by the elderly is less, so they have a lower energy requirement. For people aged 60 and above, irrespective of age, the daily energy requirement has been set at approximately $1.5 \times \text{BMR}$. Because they have reduced fat-free mass – from an average of 60 kg to 50 kg in men, and from 40 kg to 35 kg in women – their BMR is reduced.

Nutritional deficits in the elderly are common and may be due to many factors, such as dental problems, lack of cooking skills (particularly in widowers), depression and lack of motivation. Significant malnourishment in developed countries is usually secondary to social problems or disease. In elderly people who are in institutions, multiple nutrient deficiencies are common. Vitamin D supplements (colecalciferol 20 µg (800 units) daily) may be required because of poor diet, and elderly people often do not go into the sunlight. Owing to the high prevalence of osteoporosis in elderly people, an increased daily calcium intake (1–1.5 g/day) is often recommended.

**Further reading**

Obesity

Obesity is almost invariable in developed countries and almost all people accumulate some fat as they get older. The WHO acknowledges that obesity (BMI >30 kg/m²) is a worldwide problem that also affects many developing countries. Obesity implies an excess storage of fat and this can most easily be detected by looking at the undressed patient. Not all obese people eat more than the average person but all obviously eat more than they need.

The present obesity epidemic is mainly due to changes in lifestyle behaviour (although genetic factors may be involved in some individuals). There has been a trebling in the prevalence of obesity over the last three decades in the UK, as well as a vast increase in developing countries. The growing obesity problem in humans has affected children, adults and older people. Clinical and public health interventions require a multi-level approach: for example, by altering the cumulative environmental experience during the lifespan. Strategies to prevent and treat obesity in children can influence obesity in adults, and this in turn influences obesity in old age. Ultimately, all depend on changing energy balance through effects on food intake and/or energy expenditure.

Most patients suffer from simple obesity, but in certain conditions, obesity is an associated feature (Box 10.19). Even in the latter situation, the intake of calories must have exceeded energy expenditure over a prolonged period of time. Hormonal imbalance is often incriminated in women (e.g. after the menopause or when taking contraceptive pills), but most weight gain in such cases is usually small and due to water retention.

Box 10.19

Conditions in which obesity is an associated feature

- Genetic syndromes associated with hypogonadism (e.g. Prader–Willi, Laurence–Moon–Biedl)
- Hypothyroidism
- Cushing syndrome
Pathophysiology

Genetic and environmental factors

These have always been difficult to separate in the study of obesity but there is little doubt that the recent obesity ‘epidemic’, which has developed over a few decades, is predominantly due to changes in lifestyle (various environmental factors) and unlikely to be caused by rapid changes in the gene pool over this period of time. This is consistent with the view that evolution during times of limited food resources has tended to defend more against under-nutrition than over-nutrition. However, observational studies in both monozygotic and dizygotic twins, reared together or apart, suggest that strong genetic influences account for the difference in BMI later in life, and that the influence of the childhood environment is weaker. These observations also showed that weight gain did not occur in all pairs of twins, suggesting that environmental factors operate.

A search for genetic factors led to the identification of a putative gene, first in the obese (ob ob) mouse and now in humans. The ob gene was shown to be expressed solely in both white and brown adipose tissue. The ob gene is found on chromosome 7 and produces a 16 kDa protein called leptin. In the ob ob mouse, a mutation in the ob gene leads to production of a non-functioning protein. Administration of normal leptin to these obese mice reduces food intake and corrects the obesity. A similar situation has been described in a very rare genetic condition that causes obesity in humans, in which leptin is not expressed.

In massively obese subjects, leptin mRNA in subcutaneous adipose tissue is 80% higher than in controls. Plasma levels of leptin are also very high, correlating with the BMI. Weight loss due to food restriction decreases plasma levels of leptin. However, in contrast to the ob ob mouse, the leptin structure is normal, and abnormalities in leptin are not the prime cause of human obesity.

Leptin secreted from fat cells was thought to act as a feedback mechanism between the adipose tissue and the brain, acting as a ‘lipostat’ (adipostat), and controlling fat stores by regulating hunger and satiety (see below). However, many other signals are involved and the human genome map has identified hundreds of genes that correlate with the presence of obesity. It is also interesting that obesity is largely restricted to humans and animals that are either domesticated or living in zoos.

Food intake

Many factors related to the home environment, such as finance and the availability of sweets and snacks, will affect food intake. Some individuals eat more during periods of heavy exercise or during pregnancy, and are unable to return to their former eating habits. The
increase in obesity in social class 5 can usually be related to the type of food consumed (i.e. food containing sugar and fat). Measures to reduce the sugar content in popular foods and drinks are being introduced in various countries. Psychological factors and the way in which food is presented may override complex biochemical interactions.

It has been shown that obese patients eat more than they admit to eating, and over the years, a very small daily excess of intake over expenditure can lead to a large accumulation of fat. For example, a 44 kJ (10.5 kcal) daily excess would lead to a 10 kg weight gain over 20 years.

**Control of appetite**

Appetite is the desire to eat and this usually initiates food intake. Following a meal, satiation occurs. This depends on gastric and duodenal distension and the release of many substances peripherally and centrally.

Following a meal, cholecystokinin (CCK), bombesin, glucagon-like peptide 1 (GLP-1), enterostatin and somatostatin are released from the small intestine, and glucagon and insulin from the pancreas. All of these hormones have been implicated in the control of satiety. Centrally, the hypothalamus – particularly the lateral hypothalamic area and paraventricular and arcuate nuclei – plays a key role in integrating signals involved in appetite and body weight regulation *(Fig. 10.14)*.
Peripheral signals (1st order in Fig. 10.14)

- **Peripheral appetite-suppressing signals.** Leptin and insulin act centrally to activate the **appetite-suppressing pathway** (while also inhibiting the appetite-stimulating pathway). Since these hormones circulate in proportion to adipose tissue mass, they can be regarded as long-term signals, although they probably also modulate short-term signals (insulin also responds acutely to meal ingestion). **Peptide YY (PYY)** is produced by the L cells of the large bowel and distal small bowel in proportion to the energy ingested. The release of this rapidly responsive (short-acting) signal begins shortly after food intake, suggesting that the initial response involves neural pathways, before ingested nutrients reach the site of PYY production. PYY is thought to reduce appetite, at least partly through inhibition of the **appetite-stimulating pathway (NPY/AgRP-expressing neurones)**. There are a large number of other peripheral appetite-suppressing signals, including GLP-1 and oxyntomodulin, which, like PYY, are produced by the gut in a nutrient-dependent manner.

- **Peripheral appetite-stimulating signals.** Ghrelin is a 28-amino-acetylated peptide produced by the oxytic cells of the fundus of the stomach. It is the first known gastrointestinal tract peptide that stimulates appetite by activating the central appetite-stimulating pathway. The circulatory concentration is high before a meal and is reduced rapidly by ingestion of a meal or glucose (compare PYY, which increases after a meal). It may also act as a long-term
signal, as its circulating concentration in weight-stable individuals is inversely related to BMI over a wide range (compare insulin and leptin, which are positively related to BMI; see below). Ghrelin is also increased in several situations in which there is a negative energy balance, such as long-term exercise, very-low-calorie diets, anorexia nervosa, and both cancer and cardiac cachexia (an exception is vertical banded gastric bypass surgery, where its concentration is low rather than high). The peptide, obestatin, produced by the same gene that encodes ghrelin, counteracts the increase in food intake induced by ghrelin.

Central pathways (2nd order in Fig. 10.14)

There are two main pathways in the arcuate nucleus:

• The central appetite-stimulating (orexigenic) pathway in the ventromedial part of the arcuate nucleus, which expresses neuropeptide Y (NPY) and agouti pathway-related protein (AgRP). Animal studies suggest that this pathway also decreases energy expenditure.

• The central appetite-suppressing pathway (anorexigenic pathway or leptin–melanocortin pathway) in the dorsolateral part of the arcuate nucleus, which expresses pro-opiomelanocortin/cocaine-and-amfetamine-regulated transcript (POMC/CART). In this pathway, α-melanocyte-stimulating hormone (α-MSH), formed by cleavage of POMC by prohormone convertase (PC1), exerts its appetite-suppressing effect via the melanocortin-4 receptors (Mc4R) in areas of the brain that regulate food intake and autonomic activity. Animal studies suggest that this pathway also increases energy expenditure.

These pathways interact with each other and feed into the lateral hypothalamus, which communicates with other parts of the brain, and influence the autonomic nervous system and ingestive behaviour.

These central pathways are in turn influenced by a variety of peripheral signals, which can also be classified as appetite-stimulating or appetite-suppressing.

Other factors

The single gene mutations affecting the appetite-suppressing pathway in humans, e.g. leptin, leptin receptor, POMC, Mc4R, PC1 and SIM1, are rare and recessive, with the exception of Mc4R, which is common and dominant with incomplete penetrance. It appears that the Mc4R mutation accounts for 2–6% of human obesity. Affected individuals are obese without disturbances in pituitary function or resting energy expenditure, although children tend to be tall. However, these mutations are of little significance, as obesity is predominantly polygenic in origin (the human obesity gene map has already identified several hundreds of candidate genes).

The endocannabinoid system is also involved in both central and peripheral regulation of food intake and control of energy balance. There are two receptors: endocannabinoid (CB1) in the brain and CB2 in the periphery. CB1 receptors are located in the cerebral cortex, cerebellum and hippocampus.

The control of appetite is extremely complex. To take just one signal, leptin, as an example,
there can be leptin resistance, in which obese individuals have high circulating leptin but appetite is not reduced. In contrast, in acute starvation, leptin concentrations decrease to lower levels than could be expected from the prevailing adipose tissue mass. It is known that cytokines, such as TNF and IL-2, which are elevated in a wide range of inflammatory and traumatic conditions, also suppress appetite, although the exact pathways involved are not entirely clear. Finally, a range of transmitters in the central nervous system appear to affect appetite:

- appetite inhibitors: dopamine, serotonin, γ-aminobutyric acid
- appetite stimulators, e.g. opioids.

**Energy expenditure**

**Basal metabolic rate**

Basal metabolic rate (BMR) in obese subjects is higher than in lean subjects, which is not surprising since obesity is associated with an increase in lean body mass.

**Physical activity**

Obese patients tend to expend more energy during physical activity, as they have a larger mass to move. On the other hand, many obese patients decrease their amount of physical activity. The energy expended on walking at 3 miles/hour is only 15.5 kJ/min (3.7 kcal/min); therefore, a mild to moderate increase in physical activity plays only a small part in losing weight. Nevertheless, because increased body fat develops insidiously over many years, any change in energy balance is helpful.

**Thermogenesis**

About 10% of ingested energy is dissipated as heat and is unconnected with physical activity. This dietary-induced thermogenesis has been reported to be lower in obese and post-obese subjects than in lean subjects. This would tend to favour energy deposition in obesity and those predisposed to obesity. However, other reports have identified no difference in dietary-induced thermogenesis between lean and obese subjects.

When stimulated by cold or food, brown adipose tissue in animals dissipates the energy derived from ingested food into heat. This can be a major component of overall energy balance in small mammals but the effect is likely to be very small and of doubtful clinical significance in adult humans, even though brown adipose tissue is found in humans. The principal receptors mediating catecholamine-stimulated lipolysis in brown adipose tissue, and to a lesser extent at other sites, are the β₃-adrenergic receptors. Drugs with β₃-adrenergic activities have been developed but side-effects have limited their use.

**Clinical features**

Most patients recognize their own problems, although often they are unaware of the main foods that cause obesity. Many symptoms are related to psychological problems or social pressures,
such as the woman who cannot find fashionable clothes to wear.

The degree of obesity can be assessed by comparing the patient with tables of ideal weight for height, calculating the BMI (Box 10.20) and measuring skinfold thickness. The latter should be measured over the middle of the triceps muscle; normal values are 20 mm in a man and 30 mm in a woman. A central distribution of body fat (a waist/hip circumference ratio of >1.0 in men and >0.9 in women) is associated with a higher risk of morbidity and mortality than a more peripheral distribution of body fat (waist/hip ratio <0.85 in men and <0.75 in women). This is because fat located centrally, especially inside the abdomen, is more sensitive to lipolytic stimuli, with the result that the abnormalities in circulating lipids are more severe.

**Box 10.20**

**Box 10.21** shows the conditions and complications that are associated with obesity. The relationship between cardiovascular disease (hypertension or ischaemic heart disease), hyperlipidaemia, smoking, physical exercise and obesity is complex. Difficulties arise in interpreting mortality figures because of the number of factors involved. Many studies do not differentiate between the types of physical exercise taken nor do they take into account the cuff-size artefact in the measurement of blood pressure (an artefact will occur if a large cuff is not used in patients with a large arm). Nevertheless, obesity almost certainly plays a part in all of these diseases and should be treated. An exception is that stopping smoking, even if accompanied by weight gain, is more beneficial than any of the other factors. Physical fitness is also helpful, and there is some evidence to suggest that a fit obese person may have a similar cardiovascular risk to a leaner, unfit person, or even a lower risk.

**Box 10.21**

**Conditions and complications associated with obesity**

Osteoarthritis of knees and hips
Varicose veins
Hiatus hernia
Gallstones
Postoperative problems
Back strain
Accident proneness
Obstructive sleep apnoea
Hypertension
Breathlessness
Ischaemic heart disease
Stroke
Diabetes mellitus (type 2)
Hyperlipidaemia
Menstrual abnormalities
Increased morbidity and mortality
Increased cancer risk
Heart failure
Non-alcoholic fatty liver disease

Morbidity and mortality
Obese patients are at risk of early death, mainly from diabetes, coronary heart disease and cerebrovascular disease. The greater the obesity, the higher are the morbidity and mortality rates. For example, men who are 10% overweight have a 13% increased risk of death, while the increase in mortality for those 20% overweight is 25%. The rise is less in women, and in men over 65, obesity is not an independent risk factor. Weight reduction reduces this mortality and therefore should be strongly encouraged. The benefits are probably greater in more obese subjects (Box 10.22).

Box 10.22
Potential benefits from loss of 10 kg in 100 kg patients with co-morbidities

Mortality
• 20–25% fall in total mortality
• 30–40% fall in diabetes-related deaths
• 40–50% fall in obesity-related cancer deaths

**Blood pressure**

• Fall of about 10 mmHg (systolic and diastolic)

**Diabetes**

• Reduction in risk of developing diabetes by >50%
• 30–50% fall in fasting blood glucose
• 15% fall in HbA₁c

**Serum lipids**

• 10% fall in total cholesterol
• 15% fall in LDL cholesterol
• 30% fall in triglycerides
• 8% increase in HDL cholesterol

HbA₁c, haemoglobin A₁c; HDL, high-density lipoprotein; LDL, low-density lipoprotein.

**Metabolic syndrome**

There are two classification systems, which are shown in Box 10.23. The differences are as follows:

• A large waist is an absolute requirement for the International Diabetes Federation (IDF) but not for the Adult Treatment Panel 3 National Cholesterol Education Programme (ATP III NCEP).
• The IDF criteria use lower cut-off values for waist circumference (close to values for people with a BMI of 25 kg/m²) and lower fasting blood glucose concentrations.

ATP III, Adult Treatment Panel 3; HDL, high-density lipoprotein; IDF, International Diabetes Federation; NCEP, National Cholesterol Education Programme.

This means that the prevalence of metabolic syndrome will be higher using the IDF criteria, and that the IDF criteria will identify at-risk patients at an earlier stage. This could lead to further investigations following on from the initial screening, and earlier institution of preventative as well as therapeutic measures.

Overweight/central obesity and insulin resistance, which causes glucose and lipid disturbances including non-alcoholic fatty liver disease, seem to form the basis of many features of the metabolic syndrome. Early treatment of obesity and the metabolic syndrome can prevent the development of clinical diabetes and its complications.

The metabolic syndrome is a combination of risk factors (Box 10.23). Its overall role in the prediction of the risk of cardiovascular disease has been questioned, as the sum of the combined risk factors involved in the syndrome does not offer more than the individual factors added together.

### Management

#### Dietary control

This largely depends on a reduction in calorie intake. The most common diets allow a daily intake of approximately 4200 kJ (1000 kcal), although this may need to be nearer 6300 kJ (1500 kcal) for someone engaged in physical work. Very-low-calorie diets are also advocated by some, usually over shorter periods of time, but unless they are accompanied by changes in lifestyle, weight regain is likely. Patients must realize that prolonged dieting is necessary for large amounts of fat to be lost. Furthermore, a permanent change in eating habits is required to maintain the new low weight. It is relatively easy for most people to lose the first few kilograms but long-term success in moderate obesity is poor (no more than 10%). Most obese people oscillate in weight; they often regain the lost weight but many manage to lose weight again. This ‘cycling’ in body weight may play a role in the development of coronary artery
Many dietary regimens aim to produce a weight loss of approximately 1 kg/week. Weight loss will be greater initially owing to accompanying protein and glycogen breakdown and consequent water loss. After 3–4 weeks, further weight loss may be very small because only adipose tissue is broken down and there is less accompanying water loss.

Patients must understand the principles of energy intake and expenditure, and the best results are obtained in educated, well-motivated patients. Constant supervision by healthcare professionals or close relatives, or through membership of a slimming club, helps to encourage compliance. It is essential to establish realistic aims. A 10% weight loss, which is regarded by some as a ‘success’ (see Box 10.22), is a realistic initial aim.

An increase in exercise will increase energy expenditure and should be encouraged – provided there is no contraindication – since weight control is usually not achieved without exercise. The effects of exercise are complex and not entirely understood. However, exercise alone will usually produce little long-term benefit. On the other hand, there is evidence to suggest that, in combination with dietary therapy, it can prevent weight being regained. In addition, regular exercise (30 min daily) will improve general health.

The diet should contain adequate amounts of protein, vitamins and trace elements (Box 10.24).

---

**Box 10.24**

**Constituents of a diet for weight loss**

- A total of 4200 kJ (1000 kcal) per day is allowed, made up of >50 g protein, approximately 100 g of carbohydrate and 40 g of fat
- Carbohydrate should be in the form of complex carbohydrates, such as vegetables and fruit, rather than simple sugars
- Alcohol should be discouraged (contains 29 kJ/g (7 kcal/g)); it can be substituted for other foods in the diet but it often reduces willpower
- With a varied diet, vitamin and mineral intake will be adequate and supplements are not necessary.

---

A balanced diet, attractively presented, is of much greater value and is safer than any of the slimming regimens often advertised in magazines.

A wide range of diets are available, including low-fat or low-carbohydrate diets, and some suit certain individuals better than others. The following general statements can be made about them:

- All low-calorie diets produce loss of body weight and fat, irrespective of dietary composition. Short-term weight loss is faster on low-carbohydrate diets, as a result of greater loss of body water, which is regained after the end of dietary therapy.
• Very-low-fat diets are often low in vitamins E and B\textsubscript{12}, and in zinc. Very-low-carbohydrate diets may be nutritionally inadequate and may lead to deficiencies.
• Low-fat diets decrease LDL triglycerides and increase HDL, whereas low-carbohydrate diets produce a greater decrease in HDL and triglyceride, with no change in LDL.
• There are some potential long-term concerns with low-carbohydrate diets (high in fat and protein), including increased risk of osteoporosis, renal stones and atheroma (due to high intake of saturated fat, high trans fat and cholesterol, and the lack of fruits, vegetables and whole grains), but long-term studies are lacking.
• Low-energy-density diets, often bulky and rich in fibre and complex carbohydrates, may be more satiating but they are often less palatable than high-energy-dense diets, which may affect long-term compliance.
• Liquids, such as soft drinks, appear to be less satiating than solid foods.
• A study has shown that Mediterranean and low-carbohydrate diets are as effective as a low-fat diet for weight loss.

**Behavioural modification**

The aim of behavioural modification is to encourage the patient to take personal responsibility for changing lifestyle, which will determine dietary habits and physical activity. Family therapy may also be useful, especially when it involves obese children, but can be time-consuming and expensive. Cognitive behavioural therapy is even more time-consuming and expensive.

**Drug therapy**

Drugs can be used in the short term (e.g. up to 3 months and then reviewed), as an adjunct to the dietary regimen, but they do not substitute for strict dieting. The pancreatic lipase inhibitor, orlistat, was the only licensed drug for obesity in the UK in 2015.

Centrally acting drugs are as follows:

• Drugs acting on both serotoninergic and noradrenergic pathways, e.g. sibutramine (now withdrawn in Europe due to side-effects). Other drugs are being evaluated.

• **Cannabinoid-1 receptor blockers**, e.g. rimonabant (now withdrawn due to depression/suicide risk), acting on the endocannabinoid system.

• **Drugs acting on the noradrenergic pathways**. These do suppress appetite but all have been withdrawn, at least in the UK, because of cardiovascular side-effects.

  **Peripherally acting** drugs are as follows:

• **Orlistat** is an inhibitor of pancreatic and gastric lipases. It reduces dietary fat absorption and aids weight loss. Weight regain occurs after the drug is stopped. It has been used continuously in a large-scale trial for up to 2 years. Patients complain of diarrhoea during treatment and, to avoid this, take a low-fat diet, resulting in weight loss.

• **GLP-1** suppresses appetite; injections have been used to treat obesity (see Fig. 10.14) and
type 2 diabetes mellitus (see p. 1254).

A systematic review of long-term pharmacotherapy concluded that there was a paucity of long-term studies with anti-obesity agents, and that in weight loss trials of 1 year's duration, these agents appear to be only modestly effective in promoting weight loss (about 3 or 4 kg greater weight loss, respectively, than the control group). Other randomized trials show that a combination of lifestyle modification and pharmacotherapy produces greater weight loss than either treatment alone, but the withdrawal of several anti-obesity drugs suggests that a pharmacotherapeutic magic bullet to treat obesity without substantial short-term and long-term effects is not yet available; the search continues. Alternative forms of treatment should be considered (unless obesity and its risks are accepted as part of modern society).

**Surgical management (bariatric surgery, metabolic surgery)**

Surgery is now performed laparoscopically in patients with morbid obesity (BMI >40 kg/m²), or in patients with a BMI >35 kg/m² and obesity-related complications, after conventional medical treatments have failed. It can be used as a first-line option for individuals with a BMI >50 kg/m². Fitness for surgery should be checked, especially in older people. Some centres may insert a balloon into the stomach to initiate weight loss prior to bariatric surgery for morbid obesity. A variety of gastrointestinal surgical procedures have been used, which fall into three main groups (*Fig. 10.15*):

- **Restrictive procedures**, which restrict the ability to eat (e.g. adjustable gastric banding, vertical banded gastroplasty and sleeve gastropasty).

- **Malabsorptive procedures**, which reduce the ability to absorb nutrients (e.g. biliopancreatic diversion and Roux-en-Y gastric bypass). The malabsorptive procedures cause nutrient deficiencies, malnutrition and, in some cases, anastomotic leaks and the dumping syndrome (e.g. with the duodenal switch).

- **Restrictive plus malabsorptive procedures** (e.g. duodenal switch, Roux-en-Y gastric bypass, intragastric balloon).
FIGURE 10.15 Examples of surgical procedures to treat morbid obesity. A. Restrictive procedure: gastric banding with a subcutaneous port attached to the anterior abdominal wall so that fluid can be injected into the adjustable band around the upper stomach. B. Restrictive plus malabsorptive procedure: Roux-en-Y gastric bypass, in which food bypasses through a small stomach pouch and bypasses the proximal small bowel. C. Gastric sleeve.

The procedures all have advantages and disadvantages, and there is controversy about the procedure of choice for specific groups of patients. The restrictive procedures are more straightforward than the complex bypass procedures. The adjustable gastric banding procedure is attractive in concept, especially since it can be undertaken laparoscopically with a lower perioperative mortality (<0.3%) than the other procedures (approximately 1%); it can, however, be associated with erosion and slippage of the band, as well problems with the port, making repeat operations a frequent requirement (>10% of cases). The sleeve gastrectomy is associated with heartburn and greater risk of weight regain, but a biliary pancreatic diversion (duodenal switch) can be added at a later time.

There is a need to monitor nutrient status carefully with blood tests and to provide supplements of vitamins and minerals (including iron and calcium), as nutrient deficiencies are common. Weight loss following the combined restrictive and malabsorptive procedures tends to be greater than with either procedure alone.

A systematic analysis of several bariatric surgical procedures concluded that, in comparison to non-surgical treatments, they produced significantly more weight loss (23–37 kg), which was maintained up to 8 years and associated with improvement in quality of life and co-
morbidities. There is now evidence showing that the risk of myocardial infarction, stroke, cardiovascular events and mortality is reduced by about half compared to non-surgical controls over a follow-up period of 2–15 years. Although fertility is improved after bariatric surgery, women are advised to delay pregnancy for a year or more after rapid and substantial weight loss, while the safety of pregnancy is being elucidated. A recent study has shown a reduction in risk of gestational diabetes and earlier than expected birth but the benefits and risks of bariatric surgery still need further study. The commissioning of specialist obesity services should be multidisciplinary and should not focus on the surgical treatment only.

**Liposuction**, the removal of large amounts of fat by suction (liposuction), does not deal with the underlying problem and weight regain frequently occurs. There appears to be no reduction in cardiovascular risk factors with the procedure.

### Prevention

Preventing obesity must always be the goal because most obese people find it difficult to maintain any weight loss they have managed to achieve. All health professionals must be aware of the dangers of obesity and encourage children, and young as well as older adults, from gaining too much weight. A small gain each year over a long period produces an obese individual for whom treatment is difficult. Public health policies should consider the creation of public places to encourage physical activity and fitness, education about the benefits of losing weight or not gaining it, through healthy eating and physical activity, and changes in food composition (alternatives to high-fat, high-energy-dense foods and sugar reduction).

Since the present obesity epidemic has resulted from lifestyle changes, it is appropriate to promote lifestyle changes, not only as the first-line therapy for most overweight and obese individuals, but also in the prevention of overweight and obesity. Lifestyle modification would involve changes in the amount of time watching television and using computers, use of bicycle paths, dietary changes and educational activities for patients and public, parents and children. To prevent long-term weight gain after any of the therapies discussed above, each therapy should be part of a package that involves lifestyle modification.

Nutritional Support

Support in the hospital patient

Nutritional support is recognized as being necessary in many hospitalized patients. The pathophysiology and hallmarks of malnutrition have been described earlier (see pp. 189–191); here, the forms of nutritional support that are available are discussed, along with special nutritional requirements in some diseases.

Principles

Some form of nutritional supplementation is required in those patients who cannot eat, should not eat, will not eat or cannot eat enough. All patients should be screened for malnutrition on admission and the findings linked to a care plan, preferably under the supervision of a trained multidisciplinary team, including a registered dietician. Plans are discussed with patients and consent is taken for any invasive procedure (e.g. nasogastric tube, parenteral nutrition). If the patient is unable to give consent, the healthcare team should act in the patient's best interest, taking into account any previously expressed wishes of the patient and views of the family. It is usually necessary to provide nutritional support for:

• all severely malnourished patients on admission to hospital
• moderately malnourished patients who, because of their physical illness, are not expected to
eat for more than 5 days
• normally nourished patients expected not to eat for more than 5 days or expected to eat less
  than half their intake for more than 8–10 days.

Enteral rather than parenteral nutrition should be used if the gastrointestinal tract is
functioning normally.

In the re-feeding syndrome, the shifts of water and electrolytes that occur during parenteral
and enteral nutrition can be life-threatening. Carbohydrate intake stimulates insulin release,
which leads to cellular uptake of phosphate, potassium and magnesium. Complications
include hypophosphataemia, hypokalaemia, hypomagnesaemia and fluid overload because of sodium
retention (decreased renal excretion of sodium and water). Biochemical abnormalities can
result in cardiac arrhythmias and respiratory insufficiency, and are associated with a raised
mortality. Any electrolyte deficiency should be replaced and monitored, and patients who have
eaten little or nothing for more than 5 days should initially receive no more than 50% of their
energy requirements (National Institute for Health and Care Excellence (NICE) guidelines).
Patients at risk of the re-feeding syndrome should be given high potency vitamins daily for
10 days and oral or enteral thiamine 50 mg 4 times daily for 10 days, along with multivitamins.

Nutritional requirements for adults

The exact nutrient requirements in many disease states are not clearly defined and vary with the
stage and severity of disease, as well as nutritional status. The optimal protein and energy
intakes needed to produce the best clinical outcomes in acute critical illness continue to be
debated. The following general guidance is provided for specific nutrients or groups of
nutrients:

• **Fluid.** Typical requirements are approximately 2–3 L/day (>60 years = 30 mL/kg, 18–
  60 years = 35 mL/kg). Requirements are increased in patients with large-output fistulae,
  nasogastric aspirates, diarrhoea and fever. Requirements are reduced in patients with
  oedema, hepatic failure, renal failure (oliguric and not dialysed) and brain oedema.

• **Energy.** Typical requirements are approximately 7.5–10.0 MJ/day (1800–2400 kcal/day).
  Disease increases resting energy expenditure but decreases physical activity. Extra energy is
given for repletion and reduced energy for obesity.

• **Protein.** Typical requirements are 9–15 g N/day (56–94 g protein/day) or 0.15–0.25 g N/kg
  per day (0.94–1.56 g protein/kg per day). Extra protein may be needed in severely catabolic
  conditions, such as extensive burns, sepsis and major trauma.

• **Major minerals.** Typical requirements for sodium and potassium are 60–100 mmol/day (1.0–
  1.5 mmol/kg). Requirements are increased in patients with gastrointestinal effluents. The
  excretion of these minerals in various effluents can provide an indication of the additional
  requirements (see Box 9.12). Requirements may be low in patients with fluid overload (or
  those with hypernatraemia and hyperkalaemia). The requirements for calcium and magnesium
  are higher in enteral than in parenteral nutrition because only a proportion of these minerals is
  absorbed by the gut.
• **Trace elements.** For trace elements such as iodine, fluoride and selenium, which are well absorbed, the requirements are similar in enteral and parenteral nutrition. For other trace elements, such as iron, zinc, manganese and chromium, the requirements in parenteral nutrition are substantially lower than in enteral nutrition (Fig. 10.16).

![Recommended i.v. intake](image)

**FIGURE 10.16  Trace elements. Recommended intravenous intake in absolute values and as a percentage of recommended oral intake. *Trace elements for which there is too little information to establish a recommended value for dietary oral intake; the midpoint of estimated safe and adequate oral intake is shown.**

• **Vitamins.** Many vitamins are given in greater quantities in patients receiving parenteral nutrition than in those receiving enteral nutrition (Fig. 10.17). This is because patients on parenteral nutrition may have increased requirements, partly because of severe disease, partly because they may already have depleted pools of vitamins, and partly because some vitamins degrade during storage. Vitamin K is usually absent from parenteral nutrition regimens and therefore it may need to be administered separately.
Enteral nutrition

In enteral nutrition, feeds can be given by various routes:

- By mouth (food can be supplemented with solid or liquid supplements with multiple benefits).
- By fine-bore nasogastric tube *(Box 10.25).*

---

**Box 10.25**

Enteral feeding via nasogastric tube

Explain the procedure to the patient and obtain consent.

**Procedure**

- Insert a fine-bore tube intranasally with a wire stylet.
- Confirm the position of the tube in the stomach by aspiration of gastric contents (check pH).
- Check by X-ray if aspiration is unsuccessful or pH $<$ 5.5 (pH $<$ 5 in some centres) is not
definitive. Care should be taken in patients on strong acid suppressants such as proton pump inhibitors.

**Problems**

- No satisfactory way of keeping nasogastric tubes in place (up to 60% come out).

**Main complications**

- Regurgitation and aspiration into bronchus.
- Blockage of the nasogastric tube.
- Gastrointestinal side-effects, the most common being diarrhoea.
- Metabolic complications, including hyperglycaemia and hypokalaemia, as well as low levels of magnesium, calcium and phosphate.

- By percutaneous endoscopic gastrostomy (PEG). This is useful for patients who need enteral nutrition for a prolonged period (e.g. >30 days), such as those with swallowing problems following a head injury, or elderly people after a stroke. A catheter is placed percutaneously into the stomach under endoscopic control (*Fig. 10.18*).
• By needle catheter jejunostomy. In this technique, a fine catheter is inserted into the jejunum at laparotomy and brought out through the abdominal wall.

**Diet formulation**
A polymeric diet with whole protein and fat can be used (*Box 10.26*), except in patients with severely impaired gastrointestinal function, who may require a pre-digested (i.e. semi-elemental/elemental) diet. In these patients, the nitrogen source is purified low-molecular-weight peptides or amino acid mixtures, the fat sometimes being given partly as medium-chain triglycerides (MCTs).

---

**Box 10.26**

*Standard enteric diet, providing 8.4 MJ/day (= 2000 kcal/day)*

**Energy**
• Carbohydrate as glucose polymers (49–53% of total energy). Fat as triglycerides (30–35% of total energy)
Nitrogen

- Whole protein (10–14 g of nitrogen/day). Additional electrolytes, vitamins and trace elements

Features

- Ratio of energy to nitrogen kJ : g = 620 : 1 (kcal : g = 150 : 1). Osmolality = 285–300 mOsm/kg

Management of enteral nutrition

Daily amounts of fluid vary between 1.5 and 2.5 L, but small amounts are started in patients with suspected poor gastric emptying and severe malnutrition (to avoid the re-feeding syndrome).

Hypercatabolic patients require a high supply of nitrogen (0.25–0.35 g/kg daily) and often will not achieve positive nitrogen balance until the primary injury is resolved.

The success of enteral feeding depends on careful supervision of the patient, with monitoring of weight, biochemistry and diet charts.

Parenteral nutrition

This should only be used if the enteral route cannot be used. The need for major improvements in the practice of parenteral nutrition in UK hospitals has been emphasized by the National Confidential Enquiry into Patient Outcome and Death (NCEPOD). This included a requirement for improvements at every level: assessment, monitoring and follow-up, including appropriate care of lines to avoid catheter-related sepsis and documentation.

Peripheral parenteral nutrition

Specially formulated mixtures for peripheral use are available; these have a low osmolality (<800 mosmol/L) and contain lipid emulsions. Heparin and corticosteroids can be added to the infusion and local application of glyceryl trinitrate patches reduces the occurrence of thrombophlebitis and prolongs catheter life.

- A peripheral cannula can be inserted into a mid-arm vein (20 cm) and can be left for up to 5 days.

- A longer (60 cm), peripherally inserted central catheter (PICC) placed into an antecubital fossa vein has its distal end lying in a central vein; here, there is less risk of thrombophlebitis and hyperosmolar solutions can be given. With careful management, PICCs can be used for up to a month or so.

Peripheral parenteral nutrition is often preferred initially, allowing time to consider the necessity for insertion of a central venous catheter.
**Parenteral nutrition via a central venous catheter**

A silicone catheter is placed into a central vein, usually adopting an infraclavicular approach to the subclavian vein (Box 10.27). The skin-entry site should be dressed carefully and not disturbed unless there is a suggestion of catheter-related sepsis.

---

**Box 10.27**

**Central catheter placement for parenteral nutrition**

This should be performed only by experienced clinicians under aseptic conditions in an operating theatre.

- Explain the procedure to the patient and obtain consent.
- Place the patient supine with 5° of head-down tilt to avoid air embolism.
- Infiltrate the skin below the midpoint of the right clavicle with 1–2% lidocaine and make a 1 cm skin incision.
- Insert a 20-gauge needle on a syringe beneath the clavicle and first rib, angling it towards the tip of a finger held in the suprasternal notch.
- When blood is aspirated freely, use the needle as a guide to insert the cannula through the skin incision and into the subclavian vein.
- Advance the catheter so that its tip lies in the distal part of the superior vena cava.
- Create a skin tunnel under local anaesthetic using an introducer inserted through a point about 10 cm below and medial to the incision and passed upwards to the incision.
- Pass the proximal end of the catheter (with hub removed) backwards through the introducer so that it emerges 10 cm below the clavicle; suture it to the chest wall.
- Now suture the original infraclavicular entry incision.

Complications of catheter placement include central vein thrombosis, pneumothorax and embolism, but one of the most common problems is catheter-related sepsis. Organisms, mainly staphylococci, enter along the side of the catheter, leading to septicaemia. Sepsis can be prevented by ensuring careful and sterile placement of the catheter, not removing the dressing over the catheter entry site, and not giving other substances (e.g. blood products, antibiotics) via the central vein catheter.

Sepsis should be suspected if the patient develops fever and leucocytosis. In two-thirds of cases, organisms can be grown from the catheter tip after removal. Treatment involves removal of the catheter and appropriate systemic antibiotics.

**Nutrients**

With parenteral nutrition, it is possible to provide sufficient nitrogen for protein synthesis and calories to meet energy requirements. Electrolytes, vitamins and trace elements are also necessary. All of these substances are infused simultaneously.
Nitrogen source
Most patients receive at least 11–15 g N/day, in the form of synthetic L-amino acids.

Energy source
Energy is supplied by glucose, with additional calories provided by a fat emulsion. Fat infusions give a greater number of calories in a smaller volume than can be provided by carbohydrate. Fat infusions are not hypertonic and they also prevent essential fatty acid deficiency, which has been reported in long-term parenteral nutritional regimens without fat emulsions. It causes a scaly skin, hair loss and a delay in healing.

Electrolytes, vitamins and trace elements
Initially, the electrolyte status should be monitored on a daily basis and electrolyte solutions given as appropriate. Fat- and water-soluble vitamins and minerals, including trace elements, should be given routinely (see Figs 10.16 and 10.17).

Management of parenteral nutrition
Peripheral parenteral nutrition is administered via 3 L bags over 24 hours, the constituents being premixed under sterile conditions by the pharmacy. Box 10.28 shows the composition that provides 9 g of nitrogen and 7206 kJ (1700 kcal) in 24 hours.

<table>
<thead>
<tr>
<th>Box 10.28</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Examples of parenteral nutrition regimens</strong></td>
</tr>
</tbody>
</table>

**Peripheral**

**Nitrogen**
- L-amino acids 9 g/L: 1 L

**Energy**
- Glucose 20%: 1 L
- Lipid 20%: 0.5 L
- Trace elements, electrolytes, water-soluble and fat-soluble vitamins, heparin 1000 U/L and hydrocortisone 100 mg; insulin is added if required. Nitrogen 9 g, non-protein calories 7206 kJ (1700 kcal)

**Central**

**Nitrogen**
- L-amino acids 14 g/L: 1 L

**Energy**
- Glucose 50%: 0.5 L
• Glucose 20%: 0.5 L
• + Lipid 10% as either Intralipid or Lipofundin: 0.5 L; fractionated soya oil 100 g/L, soya oil 50 g, medium-chain triglycerides 50 g/L
• + Electrolytes, water-soluble and fat-soluble vitamins, trace elements; heparin and insulin may be added if required. Nitrogen 14 g, non-protein calories 9305 kJ (2250 kcal)

*All mixed in 3-L bags and infused over 24 h.

For a **central venous parenteral nutrition regimen**, most hospitals now use premixed 3 L bags. A standard parenteral nutrition regimen that provides 14 g of nitrogen 9305 kJ (2250 kcal) over 24 hours is also given in **Box 10.28**.

Monitoring includes:

- **Blood tests**. Plasma electrolytes and glucose are checked daily (at least initially); full blood count, liver biochemistry and function, calcium and phosphate twice weekly; and magnesium, zinc and triglycerides weekly.

- **Nutritional status**. Weight and skinfold thickness are monitored on a weekly basis if appropriate callipers are available. Daily weight changes reflect changes in fluid balance.

- **Nitrogen balance assessment** (see p. 186). This requires complete collections of urine.

### Complications

- **Mechanical**: insertional trauma and catheter-related (see above).

- **Metabolic**: e.g. hyperglycaemia (insulin therapy is usually necessary), fluid and electrolyte disturbances, hypercalcaemia, nutrient deficiencies (if inadequately provided).

- **Organ or tissue dysfunction**: e.g. abnormal liver dysfunction, respiratory distress and metabolic bone disease.

- **Others**: e.g. rare allergic reactions to lipid, and psychological disturbances.

### Support in the home patient

In both high- and low-income countries, there is considerably more under-nutrition in the community than in hospital. However, the principles of care are very similar: detection of malnutrition and the underlying risk factors; treatment of underlying disease processes and disabilities; correction of specific nutrient deficiencies; and provision of appropriate nutritional support. This typically begins with dietary advice, and may involve the provision of ‘meals on wheels’ by social services. A systematic review of the use of nutritional supplements in the community came to the following conclusions:

- Supplements are generally of more value in **patients with a BMI <20 kg/m² and children with growth failure** (weight for height <85% of ideal) than in those with better
anthropometric indices. They are likely to be of little or no value in patients with little weight loss and a BMI >20 kg/m². The supplemental energy intake in such subjects largely replaces oral food intake.

• Supplements may be of value in **weight-losing patients** (e.g. >10% weight loss compared to pre-illness) with a BMI >20 kg/m², and in **children with deteriorating growth performance** without chronic protein–energy under-nutrition.

• The functional benefits vary according to the patient group. In patients with **chronic obstructive airways disease**, the observed functional benefits were increases in respiratory muscle strength, handgrip strength, and walking distance/duration of exercise. In the **elderly**, the benefits were reduction in number of falls, or increase in activities of daily living, and reduction in pressure ulcer surface area. In patients with **HIV/AIDS**, there were changes in immunological function and improved cognition. Patients with **liver disease** experienced a lower incidence of severe infections and had a lower frequency of hospitalization.

• **Acceptability and compliance** are likely to be better when a choice of supplements (of type, flavour, consistency) and the schedule are decided in conjunction with the patient and/or carer. Adjustments to these may be necessary when there is a change in patterns of daily activities, disease status, and ‘taste fatigue’ with prolonged use of the same supplement.

• Nutritional **counselling and monitoring** are recommended before and after the start of supplements (see below).

Some patients receive enteral tube feeding or parenteral nutrition at home. At any one point in time in developed countries, enteral tube feeding occurs more frequently at home than in hospital.

**Home enteral nutrition**

In adults, the most common reason for starting home tube feeding is for swallowing difficulties. This involves patients with neurological disorders, such as motor neurone disease, multiple sclerosis and Parkinson's disease, but the most common single diagnosis is cerebrovascular disease. Approximately 2% of patients who have had a stroke in the UK receive home enteral tube feeding (HETF). However, in a British Nutrition survey of patients with these disorders (apart from Parkinson's), only 15% in total were able to return to oral feeding after 1 year.

The swallowing capabilities of patients should be assessed regularly in order to avoid unnecessary tube feeding. The patients and/or carers should have adequate training, contacts with appropriate health professions, and a reliable delivery service for feeds and ancillary equipment. They should also be clear about how to manage simple problems associated with the feeding tube, which is usually a gastrostomy tube rather than a nasogastric tube.

**Home parenteral nutrition**

Home parenteral nutrition is practised much less frequently, and usually comes under the supervision of specialist centres. The potential value of intestinal transplantation in patients with long-term intestinal failure is still being assessed.
Food Allergy and Food Intolerance

Many people ascribe their various symptoms to food, and many such sufferers are seen and started on exclusion diets. The scientific evidence that food does harm is weak, in most instances, although adverse reactions to food certainly exist. These can be divided into those that involve immune mechanisms (food allergy) and those that do not (food intolerance).

Food allergy

Food allergy, which is estimated to affect up to 5–7% of young children and 1–2% of adults (with a rising prevalence), may be mediated by immunoglobulin E (IgE) or not mediated by IgE (T cell-mediated). The IgE-mediated reactions tend to occur early after a food challenge (within minutes to an hour). Adults tend to be allergic to fish, shellfish and peanuts, while children tend to be allergic to cow's milk, egg white, wheat and soy. Peanuts are very allergenic and peanut allergy persists throughout life. The following conditions can result from food allergy:

- **Acute hypersensitivity.** An example is urticaria, vomiting or diarrhoea after eating nuts, strawberries or shellfish. These IgE-mediated reactions do not usually produce clinical problems, as the patients have already learned to avoid the suspected food. Inadvertent ingestion of the incriminating food can sometimes occur, leading to angioneurotic oedema (see pp. 1356–1357).

- **Eczema and asthma.** These tend to affect young children; they are often due to egg and are IgE-mediated.
• **Rhinitis and asthma.** These have been produced by foods such as milk and chocolate, mainly in atopic subjects.

• **Chronic urticaria.** This has been treated successfully by an exclusion diet.

• **Food-sensitive enteropathy.** This may manifest itself as coeliac disease (gluten (wheat) sensitive enteropathy) and cow's milk enteropathy (in infants); it is T cell-mediated.

### Food intolerance

• **Migraine.** This sometimes follows the intake of foods such as chocolate, cheese and alcohol, which are rich in certain amines, such as tyramine. Patients on monoamine oxidase inhibitors, which are involved in the metabolism of these amines, are particularly vulnerable.

• **Irritable bowel syndrome.** In some patients, this seems to be related to ingestion of certain food items, such as wheat, but the mechanisms are not clearly defined.

• **Chinese restaurant syndrome.** Monosodium glutamate, a flavour enhancer used in cooking Chinese food, may produce dizziness, faintness, nausea, sweating and chest pains.

• **Lactose intolerance.** Patients develop abdominal bloating and diarrhoea following ingestion of lactose, which is present in milk (see p. 395). This is probably the most common form of food intolerance worldwide, and may be genetic in origin.

• **Phenylketonuria.** This can also be classified as a form of food intolerance; it is due to lack of phenylalanine hydroxylase, which is necessary for the metabolism of phenylalanine present in dietary protein.

A number of other inborn errors of metabolism can also be regarded as forms of food intolerance.

Food intolerance may be caused by a constituent of food (e.g. the histamine in mackerel or canned food, or the tyramine in cheeses); by chemical mediators released by food (e.g. histamine may be released by tomatoes or strawberries); or by toxic chemicals found in food (e.g. the food additive tartrazine). Many other additives and compounds with certain E numbers have been implicated as causing reactions but the evidence is poor.

There is little or no evidence to suggest that diseases such as arthritis, behavioural and affective disorders, and Crohn's disease are due to ingestion of a particular food. Multiple vague symptoms, such as tiredness or malaise, are also not caused by food allergy. Most of the patients in this group are suffering from a psychiatric disorder (see pp. 901–902).

### Management

• The history may help to delineate the causative agent, particularly when the effects are immediate.

• Skin-prick testing with allergen and measurement in the serum of antigen or antibodies have not correlated with symptoms and are usually misleading. Although widely advertised, ‘fringe’ techniques, such as hair analysis, are of no value.
• Diagnostic exclusion diets are sometimes used but are time-consuming. They can occasionally be of value in identifying a particular food that is causing problems.

• Dietary challenge consists of the food and the test being given sublingually or by inhalation in an attempt to reproduce the symptoms. Again, this may be helpful in a few cases.

• Most people who have acute reactions to food realize it and stop eating the food; they do not require medical attention. In the remainder of patients, a small minority seem to be helped by modifying their diet but there is no good scientific evidence to support these exclusion diets. A recent study showed that the introduction of peanuts decreased the frequency of peanut allergy in children at high risk of developing this allergy, and modulated immune responses to peanuts.

• Increasing evidence suggests that many children with milk and egg allergies are able to tolerate the food when heat-modified, and this may speed up resolution of the allergy.

• There is no good evidence to recommend that pregnant or breast-feeding women should change their diet to prevent allergies in infants at high risk or normal risk.

Further reading

Alcohol

Although alcohol is not a nutrient, it is consumed in large quantities all over the world. In many countries, alcohol consumption is becoming a major medical and social problem (see pp. 920–922). It increases morbidity and mortality in a variety of ways, including effects on heart disease, stroke, cancers, liver and neurological/psychiatric problems, and is associated with nutritional deficiencies and abnormal metabolism of drugs.
Ethanol (ethyl alcohol) is oxidized, in the steps shown in Box 10.29, to acetaldehyde. Acetaldehyde is then converted to acetate, 90% in the liver mitochondria. Acetate is released into the blood and oxidized by peripheral tissues to carbon dioxide and water.

**Box 10.29**

The main pathways of ethanol oxidization

**Alcohol dehydrogenase**

\[ \text{CH}_3\text{CH}_2\text{OH} + \text{NAD}^+ \xrightarrow{\text{ADH}} \text{CH}_3\text{CHO} + \text{NADH} + \text{H}^+ \] \hspace{1cm} [1]

**Liver microsomal enzyme oxidizing system (MEOS)**

- Includes the specific P450 enzyme, CYP2EI, which is induced by ethanol

\[ \text{CH}_3\text{CH}_2\text{OH} + \text{NADPH} + \text{H}^+ + \text{O}_2 \xrightarrow{\text{MEOS}} \text{CH}_3\text{CHO} + \text{NADP} + 2\text{H}_2\text{O} \] \hspace{1cm} [2]

Alcohol dehydrogenases are found in many tissues and it has been suggested that enzymes present in the gastric mucosa may contribute substantially to ethanol metabolism.

Ethanol itself produces 29.3 kJ/g (7 kcal/g), but many alcoholic drinks also contain sugar, which increases their calorific value. For example, 1 pint of beer provides about 1045 kJ (250 kcal), so heavy drinkers will be unable to lose weight if they continue to drink.

**Effects of excess alcohol consumption**

Excess consumption of alcohol leads to two major problems, both of which can be present in the same patient:

- alcohol dependence syndrome (see pp. 921–922)
- physical damage to various tissues.

Each unit of alcohol (defined as 10 mL (7.9 g) of pure ethanol) corresponds to about half a pint of normal beer, one single measure of spirit or half a glass of wine) *(Fig. 10.19)*. An intake of less than 21 units per week in men and 14 units per week in women is generally considered to be safe, but recent UK guidelines suggest 14 units for women and men. All the long-term effects of excess alcohol consumption are due to excess ethanol, irrespective of the type of alcoholic beverage; that is, beer and spirits are no different in their long-term effects. Short-term effects, such as hangovers, depend on additional substances, particularly other alcohols such as isoamyl alcohol, which are known as congeners. Brandy and bourbon contain the highest percentage of congeners.
The amount of alcohol that produces damage varies and not everyone who drinks heavily will suffer physical damage. For example, only 20% of people who drink heavily develop cirrhosis of the liver. The effect of alcohol on different organs of the body is not the same; in some patients, the liver is affected; in others, the brain or muscle. The differences may be genetically determined.

Thiamin deficiency contributes to neurological (confusion, Wernicke–Korsakoff syndrome; see p. 885) and some of the non-neurological manifestations (cardiomyopathy). The susceptibility of different organs to damage is variable and the figures given in Box 10.30 are provided only as a guide to sensible drinking. Heavy drinkers who persist for many years are at greater risk than heavy sporadic drinkers.

### Box 10.30

**Guide to sensible alcohol drinking**

#### Daily maximum

- 3 units for men; 2 units for women

#### To help achieve this

- Use a standard measure
- Do not drink during the daytime
- Have alcohol-free days each week

#### Remember

- Health can be damaged without being ‘drunk’. Regular heavy intake is more harmful than occasional binges
- Do not drink to ‘drown your sorrows’
- In the UK, the drink-before-driving limit of alcohol in the blood is 800 mg/L (80 mg%)
• 4–5 units are sufficient to put the blood alcohol level over the legal driving limit in a 70 kg man (less in a lighter person)

Liver disease
In general, the effects of a given intake of alcohol seem to be worse in women. The following figures are for men and should be reduced by about 30% for women:

- **High risk**: 160 g ethanol per day (20 single drinks)
- **Medium risk**: 80 g ethanol per day (10 single drinks)
- **Little risk**: 40 g ethanol per day (5 single drinks).

Alcohol consumption in pregnancy
Women are advised not to drink alcohol at all during pregnancy because consumption of even small amounts of alcohol can lead to ‘small babies’ and may also increase the risk of miscarriage. The fetal alcohol syndrome is characterized by mental retardation, dysmorphic features and growth impairment; it occurs in fetuses of alcohol-dependent women.

A summary of the physical effects of alcohol is given in Box 10.31. Details of these diseases are discussed in the relevant chapters. The effects of alcohol withdrawal are discussed on page 922.

Infection and Infectious Disease

Introduction

‘Infection’ is defined as the process of pathogenic organisms invading and multiplying in or on a host's tissues. The term should be reserved for situations in which this results in harm, rather than when an infectious agent simply colonizes the host without ill effect. The delicate balance between colonizing pathogenic and non-pathogenic organisms in health is increasingly being recognized in studies of the human microbiome. Infectious diseases remain one of the main causes of morbidity and mortality in humans, particularly in developing areas, where they are associated with poverty and overcrowding.

In the developed world, increasing prosperity, hygiene, universal immunization and antibiotics have reduced the prevalence of infectious disease. Increasingly, however, antibiotic-resistant, and difficult-to-treat, strains of microorganisms are being isolated, and diseases such as human immunodeficiency virus (HIV) infection, variant Creutzfeldt–Jakob disease (vCJD), avian and pandemic H1N1 influenza, and Middle East respiratory syndrome (MERS) have emerged. There is increased global mobility, both enforced (as a result of war, civil unrest and natural disaster) and voluntary (for tourism and economic benefit). This has aided the spread of infectious disease and allowed previously localized pathogens, such as dengue, West Nile virus and chikungunya, to establish themselves across much wider territories. An increase in the movement of livestock and animals has enabled the spread of zoonotic diseases like monkeypox, while changes in farming and food-processing methods have contributed to an increase in the incidence of food- and water-borne diseases. Deteriorating social conditions in the inner city areas of our major conurbations have facilitated the resurgence of tuberculosis and other infections. Prisons and refugee camps, where large numbers of people are forced to live in close proximity, often in poor conditions, continue to provide a breeding ground for devastating epidemics of infectious disease. There are ongoing concerns about the deliberate release of infectious agents, such as smallpox or anthrax, by terrorist groups or national governments.

In the developing world, successes such as the eradication of smallpox have been balanced or outweighed by the new plagues. Communicable, maternal, neonatal and nutritional conditions were responsible for 23% of deaths worldwide in 2012. Although, increasingly, the leading causes of deaths are non-communicable diseases, lower respiratory tract infections, HIV and diarrhoeal diseases still account for 11% of all deaths (Box 11.1). In low-income countries, these infections remain common causes of mortality, malaria and tuberculosis being the sixth and eighth most common causes of death, respectively. In 2012, 8.6 million people developed tuberculosis, 1.3 million died and there were 450 000 cases of multidrug-resistant tuberculosis; approximately 2.7 million people caught malaria with 627 000 deaths; and 42.1 million were treated for schistosomiasis. Some 240 million people are chronically infected with a hepatitis virus (either hepatitis B or C virus) and 35 million people are living with HIV or the acquired immunodeficiency syndrome (AIDS, or advanced HIV), with 2.1 million new HIV infections in 2013 (70% in sub-Saharan Africa). Infections are often multiple and there is
synergy between different infections (e.g. tuberculosis and HIV) and other factors such as malnutrition. Many of the infectious diseases affecting developing countries are preventable or treatable, but continue to thrive owing to lack of money and political will. The surveillance of infectious diseases is generally poor in such countries, resulting in a slow response to emerging problems. It seems likely that the emergence of highly resistant Gram-negative pathogens will disproportionately affect the poor and vulnerable.

(Data from World Health Organization, [www.who.int](http://www.who.int))

The World Health Organization (WHO) set eight Millennium Development Goals (MDGs; see p. 43), meant to be achieved by 2015; these included combating HIV/AIDS, malaria and other diseases. Subsequently, new HIV infections fell by 33% between 2001 and 2012, and approximately 10 million people in low- and middle-income countries are now receiving antiretroviral therapy. Of the 97 countries with ongoing malaria transmission in 2013, 20 were classified as being in the pre-elimination or elimination phase. Whilst a lot has been achieved by public/private partnerships, such as the Global Fund, and other governmental, nongovernmental and charitable funders, it is clear that there is still much to be done and it is likely that many countries will not achieve all of the goals.

The impact of global warming on the spread and incidence of infection remains uncertain. Both natural climatic events and the gradual global change in weather conditions can affect the spread and transmission of infectious diseases. Changes in temperature directly influence the behaviour of insect vectors, while changes in rainfall have an effect on water-borne disease. Climate change also triggers population movement and migration, indirectly affecting infection
Infectious agents

The causative agents of infectious diseases can be divided into four groups.

**Prions** are the most recently recognized and the simplest infectious agents, consisting of a single protein molecule. They contain no nucleic acid and therefore no genetic information; their ability to propagate within a host relies on inducing the conversion of endogenous prion protein PrPc into an abnormal protease-resistant isoform referred to as PrPSc or PrPRes.

**Viruses** contain both protein and nucleic acid, and so carry the genetic information for their own reproduction. However, they lack the apparatus to replicate autonomously, relying instead on ‘hijacking’ the cellular machinery of the host. They are small (usually less than 250 nanometres (nm) in diameter) and each virus possesses only one species of nucleic acid (either RNA or DNA).

**Bacteria** are usually, though not always, larger than viruses. Unlike the latter, they have both DNA and RNA, with the genome encoded by DNA. They are enclosed by a cell membrane, and even bacteria that have adopted an intracellular existence remain enclosed within their own cell wall. Bacteria are capable of fully autonomous reproduction and the majority are not dependent on host cells.

**Eukaryotes** are the most sophisticated infectious organisms, displaying sub-cellular compartmentalization. Different cellular functions are restricted to specific organelles: for example, photosynthesis takes place in the chloroplasts, DNA transcription in the nucleus and respiration in the mitochondria. Eukaryotic pathogens include unicellular protozoa, fungi (which can be unicellular or filamentous) and multicellular parasitic worms.

Other higher classes, notably the insects and the arachnids, also contain species that can parasitize humans and cause disease; these are discussed in more detail on page 316.

Host–organism interactions

Each of us is colonized by huge numbers of microorganisms (10^{14} bacteria, plus viruses, fungi, protozoa and worms), with which we coexist. The relationship with some of these organisms is symbiotic, in which both partners benefit, while other organisms are commensals, living on the host without causing harm. Infection and illness may be due to these normally harmless commensals and symbiotes evading the body's defences and penetrating into abnormal sites. Alternatively, disease may be caused by exposure to exogenous pathogenic organisms that are not part of our normal flora.

The symptoms and signs of infection are a result of the interaction between host and pathogen. In some cases, such as the early stages of influenza, symptoms are almost entirely due to killing of host cells by the invading organism. Usually, however, the harmful effects of infection are caused by a combination of direct microbial pathogenicity and the body's response to infection. In meningococcal septicaemia, for example, much of the tissue damage is caused by cytokines released in an attempt to fight the bacteria. The molecular mechanisms underlying host–pathogen interactions are discussed in more detail on pages 227–229.
Sources of infection

The endogenous skin and bowel commensals can cause disease in the host, either because they have been transferred to an inappropriate site (e.g. bowel coliforms causing urinary tract infection) or because host immunity has been attenuated (e.g. candidiasis in an immunocompromised host). Many infections are acquired from other people, who may be symptomatic themselves or be asymptomatic carriers. Some bacteria, like the meningococcus, are common transient commensals but cause invasive disease in a small minority of those colonized. Infection with other organisms, such as the hepatitis B virus, can be followed in some cases by an asymptomatic but potentially infectious carrier state.

**Zoonoses** are infections that can be transmitted from wild or domestic animals to humans. Infection can be acquired in a number of ways: direct contact with the animal, ingestion of meat or animal products, contact with animal urine or faeces, aerosol inhalation, via an arthropod vector or by inoculation of saliva in a bite wound. Many zoonoses can also be transmitted from person to person. Some zoonoses are listed in **Box 11.2**.

**Bacteria**

- Gastroenteritis: *Escherichia coli*, *Salmonella enteritidis* and others, *Campylobacter jejuni*
- Leptospirosis: *Leptospira interrogans*
- Brucellosis: *Brucella abortus*, *Brucella melitensis*
- Anthrax: *Bacillus anthracis*
- Lyme disease: *Borrelia burgdorferi*
- Cat-scratch disease: *Bartonella henselae*
- Plague: *Yersinia pestis*
- Typhus: *Various Rickettsiae spp.*
- Ornithosis (psittacosis): *Chlamydia psittaci*
- Other: *Toxoplasmosis*, *Trichinosis*, *Toxocariasis*, *Cutaneous larva migrans*, *Leishmaniasis*
Most microorganisms do not have a vertebrate or arthropod host but are free-living in the environment. The vast majority of these environmental organisms are non-pathogenic but a few can cause human disease (Box 11.3). Person-to-person transmission of these infections is rare. Some parasites may have a stage of their life cycle that is environmental (e.g. the free-living larval stage of *Strongyloides stercoralis* and the hookworms), even though the adult worm requires a vertebrate host. Other pathogens can survive for periods in water or soil and be transmitted from host to host via this route (see below); these should not be confused with true environmental organisms.

**Box 11.3**

Routes of transmission

**Endogenous infection**
The body's own endogenous flora can cause infection if the organism gains access to a usually sterile site. This can happen by simple mechanical transfer, such as when colonic bacteria enter the female urinary tract. The non-specific host defences may be breached, for example, by cutting or scratching the skin and allowing surface commensals to gain access to deeper tissues; this is frequently the aetiology of cellulitis. There may be more serious defects in host immunity owing to disease or chemotherapy, allowing normally harmless skin and bowel flora to produce invasive disease.

**Air-borne spread**
Many respiratory tract pathogens are spread from person to person by aerosol or droplet transmission. Secretions containing the infectious agent are coughed, sneezed or breathed out and are then inhaled by a new victim. Some enteric viral infections may also be spread by aerosols of faeces or vomit. Environmental pathogens, such as *Legionella pneumophila*, and zoonoses, such as ornithosis, are also acquired by aerosol inhalation, while rabies virus may be inhaled in the dust from bat droppings.

**Faeco-oral spread**
Transmission of organisms by the faeco-oral route occur by direct transfer (usually in small children), by contamination of clothing or household items (usually in institutions or conditions of poor hygiene) or, most commonly, via contaminated food or water. Human and animal faecal pathogens get into the food supply at any stage. Raw sewage is used as fertilizer in many parts of the world, contaminating growing vegetables and fruit. Poor personal hygiene can result in contamination during production, packaging, preparation or serving of foodstuffs. In the Western world, the centralization of the food supply and increased processing of food have allowed the potential for relatively minor episodes of contamination to cause widely disseminated outbreaks of food-borne infection.

Water-borne faeco-oral spread is usually the result of inadequate access to clean water and safe sewage disposal, and is common throughout the developing world. Worldwide, 1.1 billion people have no access to clean water and 2.6 billion do not have basic sanitation.

**Vector-borne disease**
Many tropical infections, including malaria, are spread from person to person or from animal to person by an arthropod vector. Vector-borne diseases are also found in temperate climates but are relatively uncommon. In most cases, part of the parasite life cycle takes place within the body of the arthropod and each parasite species requires a specific vector. Simple mechanical transfer of infective organisms from one host to another can occur but is rare. Some vector-borne diseases are shown in *Box 11.4*.

Direct person-to-person spread

Organisms can be passed on directly in a number of ways. Sexually transmitted infections are dealt with on pages 317–331. Skin infections such as ringworm, and ectoparasites such as scabies and head lice, can be spread by simple skin-to-skin contact. Other organisms are passed on by transmission from blood (or, occasionally, some other body fluid) to blood. Blood-to-blood transmission can occur during sexual contact; from mother to infant, either transplacentally or in the peripartum; between intravenous drug users sharing any part of their injecting equipment; when infected medical or other (e.g. tattoo needles) equipment is reused; if contaminated blood or blood products are transfused; or in any sporting or accidental contact when blood is spilled. Ingestion of infected breast milk is another route of person-to-person spread for some infections (e.g. HIV).

Indirect person-to-person spread
Many organisms can be spread from person to person indirectly by contamination of fomites (e.g. door handles), which are subsequently touched by another person. Common examples include respiratory viruses, such as influenza, and healthcare-associated pathogens, such as meticillin-resistant *Staphylococcus aureus* (MRSA) and the spores of *Clostridium difficile*. This is sometimes an overlooked route of transmission; minimization requires, for example, hand-washing immediately after sneezing or coughing and when moving from ward to ward in a hospital, and optimal cleaning regimens in institutions.

**Direct inoculation**

Infection can occur when pathogenic organisms breach the normal mechanical defences by direct inoculation. Some of the circumstances in which this can occur are covered under endogenous infection and blood-to-blood transmission above. Some environmental organisms may be inoculated by accident; this is a common mode of transmission of tetanus and certain fungal infections. Rabies virus may be inoculated by the bite of an infected animal.

**Consumption of infected material**

Although many food-related zoonotic infections are due to contamination of food with animal faeces (and are thus, strictly speaking, faeco-oral), several diseases are transmitted directly in animal products. These include some strains of *Salmonella* (eggs, chicken meat), brucellosis (unpasteurized milk), *E. coli*, and the prion diseases kuru and vCJD (neural tissue).

**Prevention and control**

Methods of preventing infection depend on the source and route of transmission.

- **Infection control measures.** Poor infection control practice in hospitals and other healthcare environments can cause the transfer of infection from person to person. It is essential for all healthcare workers to wash or clean their hands before and after patient contact; whenever necessary, they should wear gloves, aprons and other protective equipment. This is particularly necessary when they are performing invasive procedures or manipulating indwelling devices. Care should also be taken with contact with a patient known to be colonized or infected with a resistant organism (e.g. carbapenemase-producing *Klebsiella pneumoniae*) or a communicable pathogen with high mortality (e.g. Ebola), or a patient who has diarrhoea (e.g. *Clostridium difficile* infection).

- **Eradication of reservoir.** In a few diseases, for which humans are the only natural reservoir of infection, it may be possible to eliminate disease by an intensive programme of case-finding, treatment and immunization. This has been achieved in the case of smallpox. If there is an animal or environmental reservoir, complete eradication is unlikely, but local control methods may decrease the risk of human infection (e.g. killing of rodents to control plague, leptospirosis and other diseases).
  
  – For **arthropod–vector-borne infections.** It may be possible to destroy the vector species (which may be practical in certain circumstances) or to take measures to avoid being
bitten (e.g. insect repellent sprays, impregnated bed nets).
– For **food-borne infections**. Improvements in food handling and preparation result in less contamination during processing, transport or preparation. Organisms intrinsically present in food can be killed by appropriate preparation and cooking. Improved surveillance and regulation of the food industry, as well as better health education for the public, are necessary.
– For **faeco-oral infections**. Improvements in water supply and sanitation (recognized in the Millennium Development Goals) could dramatically decrease the prevalence of faeco-oral infections.
– For **blood-borne infections**. Blood transfer may be prevented, e.g. in blood transfusions and contaminated medical equipment. Donated blood is routinely tested for infection in most developed countries.
– For **infections spread by air-borne and direct contact**. Some air-borne respiratory infections and some infections spread by direct contact can be controlled by isolating patients. This is often difficult, but isolation is useful in patients with severe immunodeficiency to protect them from infection.

• **Immunization** (see pp. 245–246).

**Healthcare-associated infections**

The burden of morbidity, mortality and cost attributed to healthcare-associated infection (HCAI) has been highlighted in many developed countries. Although data from low-income countries are lacking, the impact of HCAI is likely to be even greater. *Clostridium difficile*, *Staph. aureus* (especially MRSA), vancomycin-resistant enterococci and the increasingly difficult-to-treat, multiresistant, Gram-negative organisms are all strongly associated with healthcare contact and are a growing problem in hospitals worldwide. In 2011, the number of inpatients with an HCAI in acute hospitals in England decreased to 6.4%, compared to 8.2% in 2006, the most frequent infections affecting the respiratory tract, urinary tract and surgical sites. Over a similar period, there have also been notable declines in the incidences of, and mortality caused by, MRSA bloodstream and *C. difficile* infections. These have been due to higher standards of basic infection control, including rapid isolation of patients, hospital cleaning and universal MRSA screening (and decolonization therapy, if positive) on entry to acute hospitals and prior to surgery.

**HCAI control measures**

• The **care bundle approach** is used: a set (typically 3–5) of, ideally, highly evidence-based, simple actions that healthcare professionals should always take to minimize the risk of a negative outcome. As an example, see the *Matching Michigan* approach to reducing infections associated with central intravenous catheters (‘Further reading’).

Other infection control measures that health workers should focus on to reduce the risk of HCAI include:
• **Hand hygiene.** Before and after all patient contacts, and after contact with body fluids, mucous membranes, non-intact skin or fomites in the patient's environment, soap and water (rather than an alcohol-based rub) should be used after visible contamination of hands and when patients are vomiting or have diarrhoea, even if gloves are used.

• **Personal protective equipment.** Gloves should be worn for all invasive procedures, including venesection, and contact with sterile sites, mucous membranes, bodily fluids or non-intact skin. Disposable plastic aprons should be used when there is a risk of contamination of clothing or skin; if there is a risk of extensive contamination, surgical gowns should be worn.

• **Aseptic technique.** This should be adopted for all invasive procedures, when using and manipulating invasive devices, and when in contact with all wounds.

• **Urinary catheters.** Insert these only when it is essential to do so and remove them as soon as possible. Ensure that a clear care plan is in place for longer-term catheters.

• **Vascular access devices.** Insert a vascular catheter only when there is a clear plan to use it; check the device daily and remove as soon as possible. Use 2% chlorhexidine gluconate in 70% isopropyl alcohol for skin decontamination prior to insertion and to clean the access port or hub prior to use. Ensure that a clear care plan is in place for medium- or long-term devices.

### Classification of outbreaks

The type of outbreak has a bearing on the public health measures that need to be instituted for its control.

• **Person-to-person** is where infection is passed from one infected individual to another and outbreaks of infection are separated by the incubation period.

• **Point source** is where there is a single source of infection, e.g. food eaten at a social function. All those infected will develop symptoms at the same time, around the expected incubation period.

• **Common source** is where there is a single source of infection but infection is spread over a period of time, e.g. a symptomatic carrier of infection working with food preparation. Many people will be exposed over a long period of time.

• **Epidemic** is when there is an increased and unusually widespread infection in the community, causing waves of infection. Epidemics spread through communities and affect all people who have no active immunity to that infection.

• **Pandemic** is an epidemic, as defined above, occurring worldwide or over a very wide geographical area and crossing international boundaries, usually affecting a large number of people.

Some infectious diseases should be notified to the public health authorities, so that they are aware of cases and outbreaks and can respond accordingly. Diseases that are notifiable in England and Wales are listed in Box 11.5.

Principles and Basic Mechanisms

The majority of microorganisms cause no harm and some play a role in the normal functioning of the mouth, vagina and intestinal tract. However, many microorganisms have the potential to produce disease. This results from inoculation into damaged tissues, tissue invasion, a variety of virulence factors, or toxin production.

Specificity

Microorganisms are often highly specific with respect to the organ or tissue they infect (see p. 220). For example, a number of viruses are hepatotropic, such as those responsible for hepatitis A, B, C and E and for yellow fever. This predilection for specific sites in the body relates partly to the presence of appropriate receptors on different cell types and partly to the immediate environment in which the organism finds itself; for example, anaerobic organisms colonize the anaerobic colon, whereas aerobic organisms are generally found in the mouth, pharynx and proximal intestinal tract. Other organisms that show selectivity include:

- Streptococcus pneumoniae (respiratory tract)
- Escherichia coli (urinary and alimentary tract).

Even within a species of bacterium such as E. coli, there are clear differences between strains with regard to their ability to cause gastrointestinal disease (see p. 274), which, in turn, differ from uropathogenic E. coli, which are responsible for urinary tract infection.

Within an organ, a pathogen may show selectivity for a particular cell type. In the intestine, for example, rotavirus predominantly invades and destroys intestinal epithelial cells on the upper portion of the villus, whereas reovirus selectively enters the body through the specialized epithelial cells, known as M cells, which cover the Peyer's patches (see p. 393).

Pathogenesis

Figure 11.1 summarizes some of the steps that occur during the pathogenesis of infection. In addition, pathogens have developed a variety of mechanisms to evade host defences. For example, some pathogens produce toxins directed at phagocytes – Staphylococcus aureus (α-toxin), Streptococcus pyogenes (streptolysin) and Clostridium perfringens (α-toxin) – while others, such as Salmonella spp. and Listeria monocytogenes, can survive within macrophages. Several pathogens possess a capsule that protects against complement activation (e.g. Strep. pneumoniae). Antigenic variation is an additional mechanism for evading host defences that is
recognized in viruses (antigenic shift and drift in influenza), bacteria (flagella of Salmonella and gonococcal pili) and protozoa (surface glycoprotein changes in Trypanosoma).

**FIGURE 11.1** The pathogenesis of infection.
Epithelial attachment

Many bacteria attach to the epithelial substratum by specific organelles called pili (or fimbriae) that contain a surface lectin (or lectins) – a protein or glycoprotein that recognizes specific sugar residues on the host cell. This family of molecules is known as adhesins (see pp. 94–95). Following attachment, some bacteria, such as species of coagulase-negative staphylococci, produce an extracellular slime layer and recruit additional bacteria, which cluster together to form a biofilm. These biofilms can be difficult to eradicate and are a frequent cause of medical device-associated infections that affect prosthetic joints and heart valves, as well as indwelling catheters. Many viruses and protozoa (e.g. Plasmodium spp., Entamoeba histolytica) attach to specific epithelial target-cell receptors. Other parasites, such as hookworm, have specific attachment organs (buccal plates) that firmly grip the intestinal epithelium.

Colonization

Following epithelial attachment, pathogens may remain either on the surface epithelium or within the lumen of the organ they have colonized. Tissue invasion may follow. Invasion may result in:

• an intracellular location for the pathogen (e.g. viruses, Mycobacterium spp., Toxoplasma gondii, Plasmodium spp.)
• an extracellular location for the pathogen (e.g. pneumococci, E. coli, Entamoeba histolytica)
• invasion directly into the blood or lymph circulation (e.g. schistosome schistosomula and trypanosomes).

Once the pathogen is firmly established in its target tissue, a series of events follows that usually culminates in damage to the host.

Tissue dysfunction or damage

Microorganisms produce disease by a number of well-defined mechanisms, as described below.

Cell lysis

The presence of replicating viruses within a cell may interfere with host-cell metabolism, such that the cell dies – so-called cytolytic or cytocidal infection.

Exotoxins and endotoxins

• **Exotoxins** have many diverse activities, including inhibition of protein synthesis (diphtheria toxin), neurotoxicity (Clostridium tetani and C. botulinum) and enterotoxicity, which results in intestinal secretion of water and electrolytes (E. coli, Vibrio cholerae). Colonization and secretion in many classical diarrhoeal diseases are the result of virulence-associated genes that encode protein secretion systems (**Fig. 11.2**).
**Endotoxin** is a lipopolysaccharide (LPS) in the cell wall of Gram-negative bacteria. It is responsible for many of the features of septic shock (see pp. 1154–1155), namely: hypotension, fever, intravascular coagulation and, at high doses, death. The effects of endotoxin are mediated predominantly by release of tumour necrosis factor.

The clinical expression of disease caused by *Staphylococcus aureus* varies according to site, invasion and toxin production and is summarized in **Box 11.6**. Furthermore, host susceptibility to infection may be linked to genetic or acquired defects in host immunity that may complicate intercurrent infection, injury, ageing and metabolic disturbances (**Box 11.7**).

Host response to infection

Natural defences
The natural host defences to infection are those of an intact surface epithelium with local production of secretions, antimicrobial enzymes (e.g. lysozyme in the eye) and, in the stomach, gastric acidity. The latter is reduced by proton-pump inhibitors, increasing the risk of some gastroenteritic infections, including *C. difficile* infection. The mucociliary escalator of the large airways is unique to the lung but is destroyed by smoking.

Immunological defences
Antibody- and cell-mediated immune mechanisms play a vital role in combating infection. All organisms can initiate secondary immunological mechanisms, such as complement activation, immune complex formation and antibody-mediated cytolysis of cells. The immunological response to infection is described on page 121.

Metabolic and immunological consequences

Fever
Body temperature is controlled by the thermoregulatory centre in the anterior hypothalamus in
the floor of the third ventricle. Body temperature is maintained at 36.8°C in health, with a diurnal variation of ± 0.5°C. Gram-negative bacteria contain LPS and peptidoglycan, which is also a component of Gram-positive bacterial cell walls. Toll-like receptors (TLRs; see p. 127) on monocytes and dendritic cells recognize these lipopolysaccharides and generate signals, leading to the formation of inflammatory cytokines, such as interleukin (IL)-1, IL-6, IL-12, tumour necrosis factor alpha (TNF-α) and many others. These cytokines act on the thermoregulatory centre by increasing prostaglandin (PGE₂) synthesis. The antipyretic effect of salicylates is brought about, at least in part, through their inhibitory effects on prostaglandin synthase.

Fever production has a positive effect on the course of infection. However, for every 1°C rise in temperature, there is a 13% increase in resting metabolic rate and oxygen consumption. Fever, therefore, leads to increased energy requirements at a time when anorexia leads to decreased food intake. The normal compensatory mechanisms in starvation (e.g. mobilization of fat stores) are inhibited in acute infections. This leads to an increase in skeletal muscle breakdown, releasing amino acids, which, via gluconeogenesis, are used to provide energy.

The inflammatory response

The inflammatory response is a fundamental biological response to a variety of stimuli, including microorganisms or their products, such as endotoxin, which acts on monocytes and macrophages. Non-phagocytic cells (lymphocytes, natural killer cells) are also involved. The release of cytokines, notably TNF-α, IL-1, IL-6 and interferon-γ, leads to the release of a cascade of other mediators involved in inflammation and tissue remodelling, such as interleukins, prostaglandins, leukotrienes and corticotropin.

The biological behaviour of the pathogen and the consequent host response are responsible for the clinical expression of disease that often allows clinical recognition. The incubation period following exposure can be helpful (e.g. 14–21 days for chickenpox). The site and distribution of a rash may be diagnostic (e.g. shingles), while symptoms of cough, sputum and pleuritic pain point to lobar pneumonia. Fever and meningismus characterize classical meningitis. Infection may remain localized or become disseminated and give rise to septic shock and disturbances of protein metabolism and acid–base balance.

Further reading

**Clinical Approach to the Patient with a Suspected Infection**
Fever is often regarded as the cardinal feature of infection, but not all febrile illnesses are infections and not all infections present with a fever. Fever is usually intermittent, may not be present at the time of presentation and occurs less commonly in elderly patients. Infection can also present with hypothermia (temperature <36°C), which is a poor prognostic sign.

The three critical points in the assessment and management of a patient with infection or sepsis are:

- **Physiological assessment** (severity of illness), which is predominantly based on systematic examination of key physiological markers at initial presentation

- **Diagnostic assessment**, which is predominantly based on history-taking, examination and review of those diagnostic tests available at presentation and subsequently performed (see below)

- **Management**, based on linkage of the above physiological and diagnostic assessments to key interventions; antibiotics and, when required, intravenous fluids, oxygen, infection source control (e.g. drainage of an abscess) and advanced physiological support.

A detailed history can be taken first in a physiologically stable patient but may need to be delayed until after a patient is stabilized in a case of sepsis.

**Physiological assessment**

Patients should initially be assessed according to the airway, breathing, circulation, disability and extremities (ABCDE) approach (see p. 1156). A succinct history can be taken as this is done. In particular, evidence suggesting sepsis or septic shock should be sought, according to the definitions:

- **Sepsis** is defined as life-threatening organ dysfunction caused by dysregulated host response to infection.

- **Septic shock** is defined as sepsis that has circulatory, cellular and metabolic abnormalities that are associated with a greater risk of mortality than sepsis alone.

- **Hypoperfusion** is diagnosed if one or more of the following is present after the administration of at least 30 mL/kg body weight intravenous fluids or the patient has a serum lactate >4 mmol/L:
  - systolic blood pressure of <90 mmHg
  - mean arterial pressure (MAP) of <65 mmHg
  - fall of >40 mmHg in the patient's usual systolic blood pressure that persists.

**Diagnostic assessment**

History-taking and examination should aim to identify the site(s) of infection and also the likely causative organism(s).
A detailed history is taken with specific questions about symptoms (see p. 221) and epidemiological risk factors for infection. The latter are based on sources of infection and routes of transmission (see p. 223).

- **Symptoms.**
- **Travel history.** Some diseases are more prevalent in certain geographical locations.
- **Food and water history.** Include systemic, as well as gastroenteric, infections.
- **Occupational history.** Healthcare workers may be exposed to certain infections by, for example, air-borne (e.g. chickenpox), person-to-person (e.g. MRSA) and needlestick injury (e.g. blood-borne viruses) routes of transmission.
- **Animal contact.** Domestic, farm and wild animals can all be responsible.
- **Sexual activity.** As well as the traditional sexually transmitted infections, HIV, hepatitis B and, occasionally, other blood-borne infections can be transmitted sexually. Some enteric infections are more common among men having sex with men.
- **Intravenous drug use.** As well as blood-borne viruses, drug injectors are susceptible to a variety of bacterial and fungal infections due to inoculation. Other needle exposures, such as tattooing, body piercing and receipt of blood products (especially outside the UK), are also risk factors for blood-borne viruses.
- **Leisure activities.** Certain pastimes may predispose to water-borne infections or zoonoses.
- **Vaccination history.** Patients who have not received certain childhood (e.g. measles) or pre-travel (e.g. typhoid) vaccines are at higher risk if exposed.

**Clinical examination**

A thorough examination covering all systems is required. Skin rashes (Fig. 11.3) and lymphadenopathy are common features of infectious diseases and the ears, eyes, mouth and throat should also be inspected. Infections commonly associated with a rash are listed in Box 11.8. Rectal, vaginal and penile examination is required in sexually transmitted infections. The fever pattern may occasionally be helpful: for example the tertian fever of falciparum malaria.
Skin rashes and lymphadenopathy are common non-specific features of infectious diseases.

Box 11.8
Infections commonly associated with a rash

Macular/maculopapular
- Measles
- Rubella
- Enteroviruses
- Human herpesvirus 6
- Epstein–Barr virus
- Cytomegalovirus
- Human erythrovirus (parvovirus) B19
- Human immunodeficiency virus (HIV)
- Dengue
- Typhoid
- Secondary syphilis
- Rickettsial spotted fevers

Vesicular
- Chickenpox (varicella zoster virus)
- Shingles (varicella zoster virus)
- Herpes simplex virus
- Hand, foot and mouth disease (Coxsackie virus, enterovirus 71)
- Herpangina (Coxsackie virus)
Petechial/haemorrhagic
• Meningococcal septicaemia
• Any septicaemia with disseminated intravascular coagulation (DIC)
• Rickettsiae
• Viruses (see Box 11.33)

Erythematous
• Scarlet fever
• Lyme disease (erythema chronicum migrans)
• Toxic shock syndrome
• Human erythrovirus (parvovirus) B19

Urticarial
• *Toxocara*
• *Strongyloides*
• *Schistosoma*
• Cutaneous larva migrans

Others
• Tick typhus (eschar)
• Primary syphilis (chancre)
• Anthrax (ulcerating papule)

Investigations
In some infections, such as chickenpox, the clinical presentation is so distinctive that no investigations are normally necessary to confirm the diagnosis. Many cases require further tests to determine the cause and site of the infection.

**General investigations (to assess health and identify organ(s) involved)**
These will vary depending on circumstances:

• **Blood tests.** Routine blood count, erythrocyte sedimentation rate (ESR) (or plasma viscosity) and C-reactive protein (CRP), liver biochemistry and function, urea and electrolytes, and serum lactate. CRP is a non-specific marker of inflammation and is raised in many different infections; it is more useful in monitoring response to treatment than in making a diagnosis *(Box 11.9).* The exact role of procalcitonin in the diagnostic and prognostic assessment of bacterial infections is controversial; it may have a useful role in antibiotic stewardship (see pp. 234–235), particularly for respiratory tract infections and in the critical care environment, by detecting when it is safe to stop antibiotic therapy.

- **Imaging.** X-ray, ultrasound, echocardiography, computed tomography (CT) and magnetic resonance imaging (MRI) are used to identify and localize infections. Positron emission tomography (PET) and single photon emission tomography (SPECT) have proved useful in localizing infection, especially when combined with CT scanning. However, the sensitivity and specificity of these tests in diagnosing infection have yet to be determined and their use remains limited. Biopsy or aspiration of tissue for microbiological examination is facilitated by ultrasound or CT guidance.

- **Radionuclide scanning** after injection of indium- or technetium-labelled white cells (previously harvested from the patient) occasionally helps to localize infection. It is most effective when the peripheral white cell count is raised and is of particular value in localizing occult abscesses.
Microbiological investigations (to identify causative organism)

Diagnostic services range from simple microscopy to molecular probes. It is often helpful to discuss the clinical problem with a microbiologist to ensure that appropriate tests are performed and that specimens are collected and transported correctly.

Direct tests

Some microbiological tests rely on direct examination of a tissue specimen (e.g. blood, cerebrospinal fluid (CSF) or urine) for the presence of microorganisms: for example, microscopy and electron microscopy. Other direct tests identify specific microbial components, such as nucleic acids, cell wall molecules and other antigens. Specific genes from many pathogenic microorganisms have been cloned and sequenced.

Nucleic acid detection

Nucleic acid probes can be designed to detect these sequences, identifying pathogen-specific nucleic acid in body fluids or tissue. The use of nucleic acid amplification techniques (NAATs) such as the polymerase chain reaction (PCR) has increased the power of these tests to detect very small quantities of microbial material. Such techniques not only are exquisitely sensitive, but also may enable quantitation (e.g. viral load testing) and sub-speciation (e.g. at the genotype level). However, the ability to detect tiny amounts of nucleic acid in a sample means that there is a significant potential for false-positive results due to contamination. This is less likely when looking for viral nucleic acid and it is in the area of virology that NAAT tests are most widely used. Bacterial identification has been introduced to clinical practice with PCR tools for amplifying bacterial ribosome 16S subunits. This allows ‘screening’ of clinical samples for a wide range of organisms, but because of the risk of contamination results must be interpreted in the light of clinical findings.

Culture

Culture techniques can be applied to a wide variety of bacteria, fungi and viruses. However, some organisms are difficult to grow and may require special culture media and conditions. Viruses are particularly difficult (and in many cases impossible) to culture in the laboratory. Increasingly, traditional culture techniques are combined with subsequent molecular tests, such as Matrix-assisted laser desorption ionization time-of-flight (MALDTI-TOF) and PCR, to reduce the time to identification of pathogens, including, for example, whether a pathogen produces an extended-spectrum beta lactamase (ESBL) or carbapenemase (associated with multidrug resistance in Gram-negative bacteria).

Specimens to be sent for microscopy and culture (Box 11.10) are as follows:

• Blood and urine should routinely be sent for bacterial culture if infection is suspected in hospitalized patients, regardless of whether fever is present at the time.

• CSF, sputum and biopsy specimens are sent if clinically indicated.

• Special culture techniques are required for fungi, mycobacteria and some other bacteria...
such as *Brucella* spp., and the laboratory must be informed.

- **Faecal culture** for viruses is not helpful in the investigation of gastroenteritis; the viruses responsible do not grow in routine tissue culture. Antigen or nucleic acid detection techniques (see below) are more appropriate, especially in the investigation of an outbreak of diarrhoea and vomiting (e.g. norovirus). Protozoa are a cause of diarrhoea in returning travellers, immunocompromised patients, toddlers and men having sex with men, farm workers and in any cases of prolonged unexplained diarrhoea. Detection of a specific clostridial toxin is a more reliable test for diarrhoea caused by *C. difficile* than culture of the organism itself. Routine stool culture is costly and is frequently unnecessary.

NAAT, nuclear acid amplification test; PCR, polymerase chain reaction; STI, sexually transmitted infection; TB, tuberculosis.

**Immunodiagnostic tests**

These can be divided into two types:

- tests that detect *microbial components*, using a polyvalent antiserum or a monoclonal antibody
- tests that detect an *antibody response* to infection (serological tests).

These investigations are valuable in the identification of organisms that are difficult to culture, especially viruses and fungi, and can also be helpful when antibiotics have been administered before samples were obtained. Elevated antibody titres on a single occasion
(especially of immunoglobulin (Ig) G) are rarely diagnostic and it may be difficult to distinguish between past and acute infection. Paired serological tests a few weeks apart, or specific assays for IgM antibodies (indicating an acute infection), are more helpful. Avidity testing may also enable distinction between recent infection (low-avidity antibodies) and historical infection (high-avidity antibodies). Numerous serological tests are available; they should only be used in light of the clinical picture.

Management of sepsis

Many infections, particularly those caused by viruses, are self-limiting and require no treatment. Patients who have sepsis, however, require immediate antibiotic and supportive therapies and commencement of investigations within 1 hour, as every hour delay increases the mortality by 8%.

Acute medical units (AMU) have a key role to play in early sepsis management. All patients must be assessed for sepsis and a clear clinical pathway defined. A qSOFA (see p. 1154) is a useful bedside assessment. This should include initiation of all investigations necessary to confirm or exclude organ dysfunction and include criteria for escalation/de-escalation of care.

The ‘Sepsis Six’ (or equivalent) can be used as a delivery method for early sepsis care (see algorithm on p. 221).

The ‘Sepsis Six’ recommendations are:

• **High-flow oxygen.** This is given via a facemask with a reservoir bag titrated to pulse oximetry readings or arterial blood gas results.

• **Blood cultures** (before antibiotic therapy; see above). **Source control** should be established as soon as possible (e.g. drainage of an abscess or removal of an infected intravenous access device).

• **Intravenous antibiotics.** These should be given within 1 hour (see below)

• **Intravenous fluid resuscitation**, e.g. 30 mL/kg of crystalloid (0.9% saline) for adult patients with evidence of end-organ dysfunction (see above). Septic shock is diagnosed if hypoperfusion persists after this fluid challenge.

• **Haemoglobin and serial lactate measurement.** Transfuse blood when the haemoglobin concentration is <70 g/L, aiming for a target range of 70–90 g/L in adults; **mortality** correlates with serum lactate (<2 mmol/L = 15%; 2–4 mmol/L = 25%; >4 mmol/L = 38%).

• **Hourly urine output measurement.** Aim for a urine output of >0.5 mL/kg per hour.

Patients initially managed on an acute medical unit (AMU) should achieve the following physiological goals by 6 h:

• MAP ≥65 mmHg

• urine output >0.5 mL/kg per hour

• other evidence of improving end-organ dysfunction (e.g. improved oxygen saturations, declining lactate).
Patients who fail to achieve these goals are referred to the critical care unit (see pp. 1156–1161) for advanced physiological support.

The choice of antibiotic should be governed by:

• the physiological assessment of the patient (see above)
• the likely cause of the infection (i.e. diagnostic assessment).

It is always preferable to have a definite microbial diagnosis before starting treatment, so that an antibiotic with the most appropriate site of action and narrowest spectrum of activity can be chosen. However, some patients are too unwell to wait for the results (which, in the case of culture, may take days). In diseases such as meningitis or severe sepsis, a delay in treatment may be fatal and broad-spectrum intravenous therapy must be started on an empirical basis. Ideally, appropriate samples for culture should be taken before the first dose of antibiotic, but therapy should not be delayed in potentially life-threatening infection to obtain, for example, a urine specimen. For patients who are physiologically stable, specific therapy is often deferred pending results.

Special circumstances

Returning travellers

A detailed travel itinerary, including any flight stopovers, should be taken from anyone who is unwell after arriving from another country. Previous travel should also be covered, as some infections may be chronic or recurrent. It is necessary to find out not just which countries were visited but also the type of environment; a stay in a remote jungle village carries different health risks from a holiday in an air-conditioned coastal holiday resort. Food and water consumption, bathing and swimming habits, animal and insect contact, and contact with human illness all need to be established. Enquiry should be made about sexual contacts, drug use and medical treatment (especially parenteral). In some parts of the world, over 90% of professional sex workers are HIV-positive and hepatitis B and C are very common in parts of Africa and Asia. Special tests may be needed, depending on the epidemiological risks and clinical signs, and malaria films are mandatory in anyone who is unwell after being in a malarious area. Some of the more common causes of a febrile illness in returning travellers are listed in Box 11.11.

Immunocompromised patients

Advances in medical treatment over the past three decades have led to a huge increase in the number of patients living with immunodeficiency states. Cancer chemotherapy, the use of immunosuppressive drugs and the worldwide AIDS epidemic have all contributed to this. The presentation may be very atypical in the immunocompromised patient with few, if any, localizing signs or symptoms. Infection can be due to organisms that are not usually pathogenic, including environmental bacteria and fungi. The normal physiological responses to infection (e.g. fever, neutrophilia) may be diminished or absent. The onset of symptoms may be sudden and the course of the illness fulminant. A high index of suspicion for infections in people who are known to be immunosuppressed is required. Common causes of infection in immunocompromised patients are shown in Box 11.12. For neutropenic sepsis, see pages 604–

Injecting drug users

Parenteral drug use is associated with a variety of local and systemic infections. HIV, HBV and HCV infections can all be transmitted if injecting equipment is shared. Abscesses and soft tissue infections at the site of injection are common, especially in the groin, and may involve adjacent vascular and bony structures. Systemic infections are also common; they are most frequently caused by Staph. aureus and group A streptococci but a wide variety of other bacterial and fungal pathogens may be implicated.

Highly transmissible infections

Relatively few patients with infectious disease present a serious risk to healthcare workers and other contacts. However, the appearance of diseases like the ‘new’ strains of influenza (such as H5N1 avian influenza and pandemic H1N1), the occasional importation of zoonoses like Lassa fever and Ebola (see p. 267), and concerns about the bioterrorist use of agents such as smallpox mean that there is still the potential for unexpected outbreaks of life-threatening
disease. During the worldwide outbreak of severe acute respiratory syndrome (SARS) in 2003, scrupulous infection control procedures reduced the spread of infection. However, in the ‘inter-epidemic’ period, it is difficult to maintain the same level of alert. Healthcare workers should remain vigilant because the early symptoms of many of these diseases are non-specific. In Africa, many healthcare workers are developing multidrug-resistant tuberculosis from contact with HIV patients.

**Pyrexia of unknown origin**

History, clinical examination and simple investigation will reveal the cause of a fever in most patients. In a small number, however, no diagnosis is apparent, despite continuing symptoms. The term pyrexia (or fever) of unknown origin (PUO) is sometimes used to describe this problem. Various definitions have been suggested for PUO; a useful one is ‘a fever persisting for >2 weeks, with no clear diagnosis despite intelligent and intensive investigation’. Patients who are known to have HIV or other immunosuppressive conditions are normally excluded from the definition of PUO, as the investigation and management of these patients are different.

Successful diagnosis of the cause of PUO depends on knowledge of the likely and possible aetiologies. These have been documented in a number of studies and are summarized in **Box 11.13**.

### Box 11.13

**Causes of pyrexia of unknown origin**

**Infection (20–40%)**

- Pyogenic abscess
- Tuberculosis
- Infective endocarditis
- Toxoplasmosis
- Epstein–Barr virus infection
- Cytomegalovirus infection
- Primary HIV infection
- Brucellosis
- Lyme disease

**Malignant disease (10–30%)**

- Lymphoma
- Leukaemia
- Renal cell carcinoma
• Hepatocellular carcinoma

**Vasculitides (15–20%)**

• Adult Still's disease
• Systemic lupus erythematosus
• Granulomatosis with polyangiitis
• Giant cell arteritis
• Polymyalgia rheumatica

**Miscellaneous (10–25%)**

• Drug fevers
• Thyrotoxicosis
• Inflammatory bowel disease
• Sarcoidosis
• Granulomatous hepatitis
• Factitious fever
• Familial Mediterranean fever

**Undiagnosed (5–25%)**

A detailed history and examination is essential, taking into account the possible causes, and the examination should be repeated on a regular basis in case new signs appear. Investigative findings to date should be reviewed, obvious omissions amended and abnormalities followed up. Confirmation should be sought that the patient does have objective evidence of a raised temperature; this may require admission to hospital if the patient is not already under observation. Some people have an exaggerated circadian temperature variation (usually peaking in the evening), which is not pathological.

The range of tests available is discussed above. Obviously, investigation is guided by particular abnormalities on examination or initial test results, but in some cases ‘blind’ investigation is necessary. Some investigations, especially cultures, should be repeated regularly and serial monitoring of inflammatory markers such as CRP allows assessment of progress.

Ultrasound, echocardiography, CT, MRI, PET and labelled white-cell scanning can all help in establishing a diagnosis if used appropriately; the temptation to scan all patients with PUO from head to toe as a first measure should be avoided. Biopsy of the bone marrow (and, less frequently, liver) may be useful, even in the absence of obvious abnormalities, and temporal artery biopsy is helpful to confirm temporal arteritis in the elderly (see p. 701). Bronchoscopy can be used to obtain samples for microbiological and histological examination if sputum specimens are not adequate. Molecular and serological tests have greatly improved the diagnosis of infectious causes of PUO, but these tests should only be ordered and interpreted in
the context of the clinical findings and epidemiology.

Management

Management of a patient with a persistent fever is aimed at the underlying cause; if possible, only symptomatic treatment should be given until a diagnosis is made. Blind antibiotic therapy may make diagnosis of an occult infection more difficult and empirical steroid therapy may mask an inflammatory response without treating the underlying cause. In a few patients, no cause of fever is found despite many months of investigation and follow-up. In most of these individuals, the symptoms do eventually settle spontaneously, and if no definite cause has been identified after 2 years, the long-term prognosis is good.

Antimicrobial Chemotherapy

Principles of use and antibiotic stewardship

Antibiotics have undoubtedly reduced the morbidity and mortality associated with life-threatening infections, major surgery and other interventions, such as chemotherapy for cancer. Unnecessary prescribing has resulted in patient harm and mortality through adverse effects such as *C. difficile* infection, as well as the ongoing evolution and spread of antibiotic-resistant pathogens. Antibiotic resistance is now a major worldwide problem and ‘total resistance’ has been described.

In particular, some Gram-negative bacteria, such as *E. coli* and *K. pneumoniae*, have developed an extended spectrum of antibiotic resistance, with some strains, such as those that produce New Delhi metallo-beta-lactamase-1 (NDM-1), now almost untreatable. In 2013, the Centers for Disease Control and Prevention estimated that there were over 2 million infections caused by resistant bacteria and fungi in the United States each year, with more than 23 000 deaths. In northern India, a recent study showed that 5% of clinical *E. coli* isolates from a tertiary hospital were NDM-1 producers. These bacteria typically infect vulnerable patient groups and retain sensitivity only to very few less familiar and infrequently used antibiotics, such as colistimethate (polymixin E) and tigecycline. These are now often used in combination when treating these infections, but have been associated with serious adverse effects or poorer
patient outcomes; mortality associated with highly resistant infections is considerable.

Antibiotics increase the natural selection of resistant pathogens that are innately resistant. They also allow genetic mutations under an antibiotic resistance pressure and bacteria to acquire that code for resistance. They also facilitate person-to-person spread of resistant organisms by damaging the human microbiome that protects mucosal surfaces against colonization and subsequent infection. Good antibiotic stewardship, in the form of promotion of the appropriate use of antibiotics, the adoption of antibiotic guidelines, epidemiological surveillance of resistant pathogens and prescribing, and education and feedback to prescribers, has helped reduce resistance spread.

The core principle of antibiotic stewardship is that broad-spectrum antibiotics, which, in general, are more likely to cause *C. difficile* infection and contribute to resistance, should only be prescribed for life-, limb- or sight-threatening infections when the underlying microbial diagnosis is unclear. Neither should antibiotics be prescribed for self-limiting or viral infections.

In physiologically stable patients who are deemed to need an antibiotic or those with a clear microbiological diagnosis, the antibiotic with the narrowest spectrum that is effective should be chosen. Nevertheless, there were increases of 4% and 12% in antibiotic prescribing by general practitioners and hospitals, respectively, between 2010 and 2013.

The principles of the UK’s *Start Smart and then Focus* antibiotic stewardship campaign are described below.

**‘Start smart’**

- Do not start antibiotics in the absence of clinical evidence of bacterial infection.
- Take a thorough allergy history.
- Use local guidelines to initiate prompt and effective antibiotic treatment within 1 h of diagnosis (or as soon as possible) if there is evidence/suspicion of life-threatening bacterial infection.
- Document, on the drug chart and in the notes, the exact clinical indication, duration or review/stop date, route and dose.
- Obtain (appropriate) cultures first.
- Prescribe single-dose antibiotics for surgical prophylaxis within the 60 min prior to surgical incision or tourniquet inflation where antibiotics have been shown to be effective.

**‘Then focus’**

- Review the clinical diagnosis and the continuing need for antibiotics by 48 h and make a clear plan of action – the ‘Antimicrobial Prescribing Decision’.
- Remember that the five antimicrobial prescribing decision options are:
  - stop
  - switch from intravenous to oral antibiotics;
  - change to a more appropriate antibiotic
Mechanisms of action and resistance to antimicrobial agents

Antibiotics act at different sites of the bacterium, either inhibiting essential steps in metabolism or assembly, or destroying vital components such as the cell wall.

Resistance to an antibiotic can be the result of:

- impaired or altered permeability of the bacterial cell envelope, e.g. penicillins in Gram-negative bacteria
- active expulsion from the cell by membrane efflux systems
- alteration of the target site (e.g. single point mutations in E. coli or a penicillin-binding protein in Strep. pneumoniae, leading to acquired resistance; see below)
- over-production of the target site
- specific enzymes that inactivate the drug before or after cell entry (e.g. β-lactamases)
- development of a novel metabolic bypass pathway.

The development or acquisition of resistance to an antibiotic by bacteria involves either a mutation at a single point in a gene or transfer of genetic material from another organism (Fig. 11.4). Larger fragments of DNA may be introduced into a bacterium either by transfer of ‘naked’ DNA or via a bacteriophage (a virus) DNA vector. Both the former (transformation) and the latter (transduction) are dependent on integration of this new DNA into the recipient chromosomal DNA. This requires a high degree of homology between the donor and recipient chromosomal DNA.
Finally, antibiotic resistance can be transferred from one bacterium to another by conjugation, when extrachromosomal DNA (a plasmid) containing the resistance factor (R factor) is passed from one cell into another during direct contact. Transfer of such R factor plasmids can occur between unrelated bacterial strains and involve large amounts of DNA and often codes for multiple antibiotic resistance: for example, as for the fluoroquinolones.

Transformation is probably the least clinically relevant mechanism, whereas transduction and R factor transfer are usually responsible for the sudden emergence of multiple antibiotic resistances in a single bacterium. Increasing resistance to many antibiotics has developed (Box 11.14).

### Empirical ‘blind’ therapy

Most antibiotic prescribing, especially in the community, is empirical. Even in hospital practice, microbiological documentation of the nature of an infection and the susceptibility of the pathogen is generally not available for a day or two. Initial choice of therapy relies on a clinical diagnosis and, in turn, a presumptive microbiological diagnosis. Such ‘blind therapy’ is directed at the most likely pathogen(s) responsible for a particular syndrome such as meningitis, urinary tract infection or pneumonia. Examples of ‘blind therapy’ for these three conditions are ceftriaxone, trimethoprim and amoxicillin (with or without a macrolide), respectively. Initial therapy in the severely ill patient is often broad-spectrum in order to cover the range of possible pathogens but should be targeted once microbiological information becomes available. There is little firm evidence that bactericidal drugs (penicillins, cephalosporins, aminoglycosides) are more effective than bacteriostatic drugs (tetracyclines), but it is generally considered better to use the former in the treatment of bacterial endocarditis and in patients in whom host defence mechanisms are compromised, particularly in those with neutropenia. In patients with less severe infections, a narrower-spectrum agent can be used from the outset while awaiting culture results, as the potential consequences of initial inadequate coverage are less serious.

### Combination therapy

Combinations of drugs are occasionally required for reasons other than providing broad-spectrum cover. Tuberculosis is initially treated with three or four agents to avoid the emergence of resistance. Synergistic inhibition is achieved by using penicillin and gentamicin
in enterococcal endocarditis, or gentamicin and ceftazidime in life-threatening *Pseudomonas* infection. In general, combinations should be avoided because of the increased risk of adverse effects, including damage to the human microbiome, and drug interactions, but may need to be employed more in order to prevent or treat antibiotic-resistant infections.

**Pharmacokinetic factors**

To be successful, sufficient antibiotic must penetrate to the site of the infection. Knowledge of the standard pharmacokinetic considerations of absorption, distribution, metabolism and excretion for the various drugs is required. Difficult sites include the brain, eye and prostate, while loculated abscesses are inaccessible to most agents and therefore often require radiological or surgical drainage (i.e. source control).

Many mild to moderate infections can be treated effectively with oral antibiotics, provided that the patient is compliant. Parenteral administration is indicated in the severely ill patient to ensure rapid high and/or consistent blood and tissue concentrations of drug. Some antibiotics can only be administered parenterally, such as the aminoglycosides and extended-spectrum cephalosporins. Parenteral therapy is also required if the patient is unable to swallow or if gastrointestinal absorption is unreliable.

**Dose and duration of therapy**

These will vary according to the nature, severity and response to therapy. The need to clear the infection completely must be balanced against the undesired effects of prolonged antibiotic therapy (e.g. promotion of antimicrobial resistance, drug toxicity, superinfection with organisms such as *Candida* spp. or *C. difficile*, and cost). For many infections, 5–7 days of treatment is adequate, while for some (e.g. uncomplicated urinary tract infections and some forms of bacterial gastroenteritis) 1–3 days is enough. However, other infections require much longer: bacterial endocarditis normally needs 4–6 weeks, bone and prosthetic joint infections often need 6–12 weeks, and mycobacterial infections require months or even years of therapy. In a few conditions such as HIV or chronic hepatitis B infection, treatment is suppressive rather than curative, so lifelong antimicrobial treatment is needed. Even within a course of treatment, it may be possible to simplify or streamline therapy – for example, change from intravenous to oral, or from broad-spectrum to narrow-spectrum – as the patient improves.

**Renal and hepatic insufficiency**

Patients with renal impairment may require a reduction in dose or an increase in dosing interval in order to avoid the toxic accumulation of antibiotic. This applies to the β-lactams and especially the aminoglycosides and vancomycin. In those with hepatic insufficiency, dose reduction is often required for agents that rely on extensive hepatic metabolism for excretion. A full list of such drugs can be found in the national formularies (e.g. the *British National Formulary*, or BNF).

**Therapeutic drug monitoring**
To ensure therapeutic yet non-toxic drug concentrations, serum concentrations of drugs such as the aminoglycosides and vancomycin should be monitored, especially in those with impaired or changing renal function. Therapeutic drug monitoring of antibiotics not usually monitored, such as the β-lactams, may be necessary to optimize therapy in the fight against antibiotic resistance. Specific monitoring algorithms are available in national formularies but local guidelines should be followed when available.

**Antibiotic chemoprophylaxis**

The value of antibiotic chemoprophylaxis has been questioned, as there are relatively few controlled trials to prove efficacy (see pp. 1020–1021). The evidence for chemoprophylaxis against infective endocarditis is an example. National Institute for Health and Care Excellence (NICE) guidelines recognize that procedures can cause bacteraemia but without a significant risk of infective endocarditis. Even patients at ‘high risk’, such as those with previous infectious endocarditis, prosthetic heart valves and surgical shunts, do not always require prophylaxis *(Box 11.15)*. However, there are a number of indications for which the prophylactic use of antibiotics is still advised. These include surgical procedures where the risk of infection is high (colon surgery) or the consequences of infection are serious (post-splenectomy sepsis). The choice of agent(s) is determined by the likely infectious risk and the established efficacy and safety of the regimen. Antibiotic prophylaxis for the vast majority of surgical or radiological procedures should not extend for more than 24 hours post procedure and, for most operations, a single dose at induction is all that is required.

*Box 11.15*

**Outpatient parenteral antibiotic therapy**

Outpatient parenteral antibiotic therapy (OPAT) is an increasingly employed and safe approach to administering intravenous antibiotics, either in an outpatient clinic or at home, to clinically stable patients who require intravenous therapy. A wide range of acute and chronic infections can be managed in this way, including skin and soft tissue infections, bone/joint infections,
pyelonephritis, endocarditis, organ and tissue abscesses, and multidrug-resistant tuberculosis. Usually, OPAT is either administered once daily by bolus or infusion (depending on the agent) using an antibiotic with a long half-life (e.g. teicoplanin, daptomycin, ertapenem), or given continuously by an elastomeric device (e.g. flucloxacillin, piperacillin/tazobactam), or is self-, carer- or nurse-administered at home. Careful patient selection and subsequent supervision and monitoring are mandatory.

Antibacterial drugs

β-Lactams (penicillins, cephalosporins, monobactams and carbapenems)

Penicillins

Structure. The β-lactams share a common ring structure (Fig. 11.5). Changes to the side-chain of benzylpenicillin (penicillin G) render the phenoxymethyl derivative (penicillin V) resistant to gastric acid and allow it to be orally absorbed. The presence of an amino group in the phenyl radical of benzylpenicillin increases its antimicrobial spectrum to include many Gram-negative and Gram-positive organisms. More extensive modification of the side-chain (e.g. as in flucloxacillin) renders the drug insensitive to bacterial penicillinase. This is useful in treating infections caused by penicillinase (β-lactamase)-producing staphylococci.

![The structure of penicillins.](image)

Mechanism of action. The β-lactams block bacterial cell-wall mucopeptide formation by binding to and inactivating specific penicillin-binding proteins (PBPs), which are peptidases involved in the final stages of cell-wall assembly and division. Meticillin-resistant Staph. aureus (MRSA; see p. 270) produces a low-affinity PBP that retains its peptidase activity, even in the presence of high concentrations of meticillin. Many bacteria are able to produce penicillinases and β-lactamases, which inactivate antibiotics of this class. The emergence of
Gram-negative organisms producing extended-spectrum β-lactamases (ESBLs) and carbapenemases has rendered some bacteria potentially resistant to all β-lactam antibiotics and often to other classes of antibiotics as well.

**Indications for use.** Benzylpenicillin can only be given parenterally and is still the drug of choice for some serious infections. However, due to increasing antimicrobial resistance, it should not be used as monotherapy in serious infections without laboratory confirmation that the organism is penicillin-sensitive. Uses include serious streptococcal infections (including infective endocarditis), necrotizing fasciitis and gas gangrene (usually combined with other antibiotics), actinomycosis, anthrax and spirochaetal infections (syphilis, yaws).

Phenoxymethylpenicillin (penicillin V) is an oral preparation that is used chiefly to treat streptococcal pharyngitis and as prophylaxis against rheumatic fever.

Flucloxacillin is used in infections caused by β-lactamase (penicillinase)-producing staphylococci and remains the drug of choice for serious infections caused by meticillin-sensitive *Staph. aureus* (MSSA).

Ampicillin is susceptible to β-lactamase but its antimicrobial activity includes streptococci, pneumococci and enterococci, as well as Gram-negative organisms such as *Salmonella* spp., *Shigella* spp., *E. coli*, *H. influenzae* and *Proteus* spp. Drug resistance has, however, eroded its efficacy against these Gram-negatives. It is widely used in the treatment of respiratory tract infections. Amoxicillin has similar activity to ampicillin but is better absorbed when given by mouth.

The extended-spectrum penicillin, ticarcillin, is active against *Pseudomonas* infections, as is the acylureidopenicillin piperacillin in combination with tazobactam.

Clavulanic acid is a powerful inhibitor of many bacterial β-lactamases and, when given in combination with an otherwise effective agent such as amoxicillin (co-amoxiclav) or ticarcillin, can broaden the spectrum of activity of the drug. Sulbactam acts similarly and is available combined with ampicillin, while tazobactam in combination with piperacillin is effective in appendicitis, peritonitis, pelvic inflammatory disease and complicated skin infections. The penicillin/β-lactamase inhibitor combinations are also active against β-lactamase-producing staphylococci.

Pivmecillinam is used for the treatment of urinary tract infection and has activity against Gram-negative bacteria, including ESBL-producing *E. coli*, *Klebsiella*, *Enterobacter* and *Salmonella*, but not against *Pseudomonas*.

Temocillin is active only against Gram-negative bacteria, including many ESBL producers; it appears to be relatively less likely to trigger *C. difficile* infection and is increasingly used because of resistance. It is not active against *Pseudomonas* or *Acinetobacter* spp.

**Interactions.** Penicillins inactivate aminoglycosides when mixed in the same solution.

**Toxicity.** Generally, the penicillins are safe. Hypersensitivity (skin rash (common), urticaria, anaphylaxis), encephalopathy and tubulointerstitial nephritis can occur. Ampicillin also produces a hypersensitivity rash in approximately 90% of patients with infectious mononucleosis (glandular fever) who receive this drug. Co-amoxiclav causes cholestatic jaundice six times more frequently than amoxicillin, as does flucloxacillin.
**Cephalosporins**

The cephalosporins ([Fig. 11.6](#)) have an advantage over the penicillins in that they are not inactivated by staphylococcal penicillinases (but are still inactive against meticillin-resistant staphylococci except the fifth-generation cephalosporins, ceftaroline and ceftobiprole) and have a broader range of activity that includes both Gram-negative and Gram-positive organisms, but excludes enterococci and anaerobic bacteria. Only certain cephalosporins (e.g. ceftazidime and cefpirome) are active against *Pseudomonas aeruginosa*.

**Indications for use.** These broad-spectrum antibiotics should be reserved for the treatment of specific serious infections, such as meningitis and meningococcal disease and acute epiglottitis. They may be used for severe sepsis secondary to a wide variety of other infections, but in the UK and many other countries they have largely been replaced by other agents because of their link with *C. difficile* infection.

**Interactions.** There are relatively few interactions.

**Toxicity.** The toxicity is similar to that of the penicillins but is less common. Some 10% of patients are allergic to both groups of drugs. The early cephalosporins caused proximal tubule damage, although the newer derivatives have fewer nephrotoxic effects. Second- and third-generation cephalosporins are strongly associated with *C. difficile* infection and alternative antibiotics should be used when possible.

**Monobactams**

Aztreonam is the only member of this class available. It is a synthetic β-lactam and, unlike the penicillins and cephalosporins, has no ring other than the β-lactam; hence its description as a monobactam.

It is not inactivated by most β-lactamases and is less likely to induce β-lactamase production.

**Indications for use.** Aztreonam's spectrum of activity is limited to aerobic Gram-negative bacilli. It is a useful alternative to aminoglycosides in combination therapy, largely for the treatment of intra-abdominal sepsis, has activity against many ESBL producers and is also used in *Pseudomonas* infection (including lung infection in cystic fibrosis).

**Toxicity.** This is as for the β-lactam antibiotics.
Carbapenems

The carbapenems are semisynthetic β-lactams and include imipenem, meropenem, doripenem and ertapenem. They currently have the broadest spectrum of the antibiotics, being active against the majority of Gram-positive (but not MRSA) and Gram-negative, as well as anaerobic, bacterial pathogens. Ertapenem, unlike the others, is not active against *Pseudomonas* or *Acinetobacter* spp. They differ in their dosage and frequency of administration. Imipenem is partially inactivated in the kidney by enzymatic inactivation and is therefore administered in combination with cilastatin.

**Indications for use.** They are used for serious nosocomial infections when multidrug-resistant Gram-negative bacilli or mixed aerobe and anaerobe infections are suspected.

**Toxicity.** This is similar to that of β-lactam antibiotics. Nausea, vomiting and diarrhoea occur in less than 5% of cases. Imipenem may cause seizures and should not be used to treat meningitis; meropenem is safe for this indication.

Aminoglycosides

**Structure.** These antibiotics are polycationic compounds of amino sugars (*Fig. 11.7*).

![FIGURE 11.7](image_url) The structure of an aminoglycoside.

**Mechanism of action.** Aminoglycosides interrupt bacterial protein synthesis by inhibiting ribosomal function (messenger and transfer RNA).

**Indications for use.** Streptomycin is bactericidal and is rarely used except for the treatment of tularemia or plague. Neomycin is used only for the topical treatment of eye, ear and skin infections. Even though it is poorly absorbed, prolonged oral administration can produce ototoxicity.

Gentamicin and tobramycin are given parenterally. They are highly effective against many Gram-negative organisms, including *Pseudomonas* spp. They are synergistic at low doses with penicillins against *Enterococcus* spp. and viridans streptococci, and are therefore often used in endocarditis. Netilmicin and amikacin have a similar spectrum but are more resistant to the aminoglycoside-inactivating enzymes (phosphorylating, adenylating or acetylating) produced by some bacteria. Their use should be restricted to gentamicin-resistant organisms.

**Interactions.** Enhanced nephrotoxicity occurs with other nephrotoxic drugs, ototoxicity with some diuretics and neuromuscular blockade with curariform drugs.
Toxicity. This is dose-related. Aminoglycosides are nephrotoxic and ototoxic (vestibular and auditory), particularly in the elderly. The m.1555A>G mutation has been associated with gentamicin ototoxicity but appears to occur in less than 1% of the general population; rapid pre-treatment testing is not currently feasible. Therapeutic drug monitoring is necessary to ensure therapeutic and non-toxic drug concentrations. Once-daily dosing is used for most indications, with a serum drug level taken at 6–14 hours post dose, followed by application of an appropriate nomogram to determine the subsequent frequency of dosing (e.g. 24- or 48-hourly). When used for endocarditis, low doses are prescribed every 12 hours with different target pre- and post-dose level ranges than for once-daily dosing.

**Tetracyclines and glycyclyclines**

**Structure.** These are bacteriostatic drugs possessing a four-ring hydronaphthacene nucleus (Fig. 11.8). Included among the tetracyclines are tetracycline, oxytetracycline, demeclocycline, lymecycline, doxycycline and minocycline. Tigecycline is an injectable glycyclycline, which is structurally related to the tetracyclines.

**FIGURE 11.8** The structure of a tetracycline. Substitution of CH₃, OH or H at positions A–D produces variants of tetracycline.

**Mechanism of action.** Tetracyclines inhibit bacterial protein synthesis by interrupting ribosomal function (transfer RNA).

**Indications for use.** Tetracyclines are active against Gram-positive and Gram-negative bacteria but their use for the latter is limited due to bacterial resistance. Tetracyclines are active against *V. cholerae*, *Rickettsia* spp., *Mycoplasma* spp., *Coxiella burnetii*, *Chlamydia* spp. and *Brucella* spp., and have good overall activity against community-acquired bacterial respiratory pathogens; they are low-risk for *C. difficile* infection and are therefore increasingly used for respiratory tract infections.

Tigecycline is active against many organisms resistant to tetracycline and other antibiotics. These include vancomycin-resistant enterococci, MRSA and Gram-negative bacilli, including *Acinetobacter* spp., but not *Pseudomonas* or *Proteus* spp.; tigecycline is increasingly used in combination with other antibiotics (e.g. colistimethate sodium) to treat infections due to highly resistant, carbapenemase-producing, Gram-negative bacteria. The licensed indications are complicated skin and soft tissue infections and intra-abdominal sepsis. However, a 2010 US
Food and Drug Administration (FDA) alert raised concern about the efficacy of tigecycline in some serious infections (notably ventilator-associated pneumonia, VAP; see p. 1165) and it should be used only on expert advice.

**Interactions.** The efficacy of tetracyclines is reduced by antacids and oral iron-replacement therapy.

**Toxicity.** Tetracyclines are generally safe drugs, but they may enhance established or incipient renal failure, although doxycycline is safer than others in this group. They cause brown discoloration of growing teeth and thus these drugs are not given to children or pregnant women. Photosensitivity occurs in approximately 1 in 20 patients. Nausea and vomiting are the most frequent adverse effects of tigecycline.

**Macrolides**

**Erythromycin and clarithromycin**

**Structure.** Erythromycin and clarithromycin both consist of a lactone ring with two sugar side-chains, one of which is an aminosugar.

**Mechanism of action.** Macrolides inhibit protein synthesis by interrupting ribosomal function.

**Indications for use.** Erythromycin has a similar (but not identical) antibacterial spectrum to penicillin and may be useful in individuals with penicillin allergy, especially in the management of bacterial respiratory infections. It can be given orally or parenterally, but oral intake is associated with significant gastrointestinal side-effects, while the intravenous formulation is very irritant and causes phlebitis. For these reasons, clarithromycin (which has similar antimicrobial properties but fewer side-effects) is often preferred. These drugs are prefered in the treatment of pneumonias caused by *Legionella* spp. and *Mycoplasma* spp. They are also effective in the treatment of infections due to *Bordetella pertussis* (whooping cough), *Campylobacter* spp. and *Chlamydia* spp. Macrolides are otherwise not usually used for life-threatening or serious infections, such as endocarditis and meningitis.

**Other macrolides**

These include azithromycin and telithromycin. They have a broad spectrum of activity that includes selective Gram-negative organisms, mycobacteria and *Toxoplasma gondii*. Compared with erythromycin, they have superior pharmacokinetic properties with enhanced tissue and intracellular penetration and a longer half-life that allows once-daily dosage. Concern has been raised about the use of azithromycin in bloodstream infections (bacteraemia) because of low serum bioavailability. Azithromycin is also used for trachoma, cholera and for some sexually transmitted infections.

**Interactions.** Erythromycin and other macrolides interact with theophyllines, carbamazepine, digoxin and ciclosporin, occasionally necessitating dose adjustment of these agents.

**Toxicity.** Diarrhoea, vomiting and abdominal pain are the main side-effects of erythromycin
(less with clarithromycin and azithromycin) as a consequence of the intestinal prokinetic properties of the macrolides. QTc prolongation is a recognized cardiac effect of the macrolides and may lead to the potentially life-threatening syndrome of ‘torsades de pointes’ (see p. 975); concomitant use of other drugs that cause QTc prolongation is avoided unless absolutely essential.

**Fidaxomicin**

*Fidaxomicin* is a macrocyclic antibacterial that is poorly absorbed from the intestine and is used for the treatment of *C. difficile* infection. It is thought to have a lower recurrence rate than vancomycin or metronidazole.

**Chloramphenicol**

**Structure.** Chloramphenicol is the only naturally occurring antibiotic containing nitrobenzene *(Fig. 11.9)*. This structure probably accounts for its toxicity in humans and for its activity against bacteria.

![Structure of chloramphenicol](image)

**FIGURE 11.9** The structure of chloramphenicol.

**Mechanism of action.** Chloramphenicol competes with messenger RNA for ribosomal binding. It also inhibits peptidyl transferase.

**Indications for use.** Because of its adverse-effect profile (see below), chloramphenicol had been little used in developed countries for many years. It is increasingly being prescribed again, however, as it remains active against some resistant Gram-negative bacteria. In developing countries, although resistance has emerged as a considerable problem, it has been invaluable in the treatment of meningitis and severe infections caused by *Salmonella typhi* and *S. paratyphi* (enteric fevers), and is also active against *H. influenzae* (meningitis and acute epiglottitis) and *Yersinia pestis* (plague). It is used topically for the treatment of purulent conjunctivitis.

**Interactions.** Chloramphenicol enhances the activity of anticoagulants, phenytoin and some oral hypoglycaemic agents.

**Toxicity.** Severe irreversible bone marrow suppression is rare but nevertheless now
restricts the usage of this drug where other options exist. Therapeutic drug monitoring, where available, is recommended: trough levels <15 mg/L, 2 h after administration 10–25 mg/L. Chloramphenicol should not be given to premature infants or neonates because of their inability to conjugate and excrete this drug; high blood levels lead to circulatory collapse and the often-fatal ‘grey baby syndrome’.

**Sodium fusidate**

**Structure.** Sodium fusidate has a structure resembling that of bile salts.

**Mechanism of action.** It is a potent inhibitor of bacterial protein synthesis. Its entry into cells is facilitated by the detergent properties inherent in its structure.

**Indications for use.** Sodium fusidate is mainly used for penicillinase-producing *Staph. aureus* infections such as osteomyelitis (it is well concentrated in bone) or endocarditis, and for other staphylococcal infections accompanied by sepsicaemia. The drug is well absorbed orally but must be used in combination with another staphylococcal agent to prevent resistance emerging. Resistance may occur rapidly; sodium fusidate is available in topical preparations, but these should be avoided to limit the risk of resistance emerging.

**Toxicity.** Sodium fusidate commonly causes gastrointestinal adverse effects and may occasionally be hepatotoxic; however, it is generally a safe drug and can be given during pregnancy if necessary. Concomitant statin use is avoided.

**Sulphonamides and trimethoprim**

**Structure.** The sulphonamides are all derivatives of the prototype sulfanilamide. Trimethoprim is a 2,4-diaminopyrimidine.

**Mechanism of action.** Sulphonamides block thymidine and purine synthesis by inhibiting microbial folic acid synthesis. Trimethoprim prevents the reduction of dihydrofolate to tetrahydrofolate (see Fig. 16.12).

**Indications for use.** Sulfamethoxazole is mainly used in combination with trimethoprim (as co-trimoxazole). Because of its adverse effect profile, use in developed countries was largely restricted to the treatment and prevention of *Pneumocystis jiroveci* infection and listeriosis, although it is increasingly being prescribed in hospitals again for other infections, such as acute exacerbations of chronic bronchitis and urinary tract infections, as it appears to be of relatively lower risk for triggering *C. difficile* infection and remains useful for some resistant Gram-negative infections. It may also be used for toxoplasmosis and nocardiosis. Trimethoprim alone is often used for urinary tract infections.

Resistance to sulphonamides is often plasmid-mediated and results from the production of sulphonamide-resistant dihydropteroate synthase from altered bacterial cell permeability to these agents.

**Interactions.** Sulphonamides potentiate oral anticoagulants and some hypoglycaemic agents.

**Toxicity.** The adverse effects of co-trimoxazole are most commonly due to the sulphonamide component. Sulphonamides cause a variety of skin eruptions, including toxic epidermal necrolysis, the Stevens–Johnson syndrome, thrombocytopenia, folate deficiency and
megaloblastic anaemia with prolonged usage. They can provoke haemolysis in individuals with glucose-6-phosphate dehydrogenase deficiency and therefore should not be used in such people. Trimethoprim is similar in molecular structure to the potassium-sparing diuretic amiloride; monitoring of renal function is required when using trimethoprim or co-trimoxazole, particularly when the patient is prescribed other potassium-sparing drugs (e.g. angiotensin-converting enzyme (ACE) inhibitors) and during prolonged therapy to avoid hyperkalaemia.

**Quinolones (ciprofloxacin, moxifloxacin, norfloxacin, ofloxacin, levofloxacin and gemifloxacin)**

These are useful oral broad-spectrum antibiotics, related structurally to nalidixic acid. The latter achieves only low serum concentrations after oral administration and its use is limited to the urinary tract, where it is concentrated. Moxifloxacin, levofloxacin and gemifloxacin have greater activity against Gram-positive pathogens.

**Mechanism of action.** The quinolone group of bactericidal drugs inhibits bacterial DNA synthesis by inhibiting topoisomerase IV and DNA gyrase, the enzyme responsible for maintaining the superhelical twists in DNA.

**Indications for use.** The extended-spectrum quinolones such as ciprofloxacin have activity against Gram-negative bacteria, including some *Pseudomonas aeruginosa* and some Gram-positive bacteria (e.g. anthrax; see p. 287). They are useful in Gram-negative bloodstream infections, bone and joint infections, urinary and respiratory tract infections, meningococcal carriage, some sexually transmitted diseases such as gonorrhoea and non-specific urethritis due to *Chlamydia trachomatis*, and severe cases of travellers' diarrhoea (see pp. 277–279). The newer oral quinolones (e.g. moxifloxacin) provide an alternative to β-lactams in the treatment of community-acquired lower respiratory tract infections; cover against *Strep. pneumoniae*, *H. influenzae* and the atypical respiratory bacteria is provided. They are also being used for the treatment of tuberculosis (see pp. 1110–1113).

In many countries, a high proportion of *E. coli* and *Klebsiella* spp. are now resistant. Resistance is also a growing problem among *Salmonella*, *V. cholera*, *Strep. pneumoniae* and *Staph. aureus*; almost all healthcare-associated MRSA strains are resistant. Resistance also occurs in tuberculosis treatment (see pp. 1111–1112).

**Interactions.** Ciprofloxacin can induce toxic concentrations of theophylline.

**Toxicity.** Gastrointestinal disturbances, photosensitive rashes and occasional neurotoxicity can occur. Use should be avoided in pregnancy and, unless the benefit outweighs the risk, in childhood and patients taking corticosteroids. Tendon damage, including rupture, can occur within 48 hours of use and the drug should be stopped immediately; it should not be given in patients with tendonitis. MRSA and *C. difficile* infections in hospitals have been linked to high prescribing rates of quinolones and use is discouraged where an effective alternative is available. As with the macrolides, there is concern about QT_c prolongation; concomitant prescribing with other QT_c-prolonging drugs is avoided whenever possible.

**Oxazolidinones**
**Structure.** Linezolid was the first oxazolidinone antibacterial developed. Tedizolid has recently been approved for use in skin and skin structure infections.

**Mechanism of action.** Linezolid inhibits protein synthesis by binding to the bacterial 23S ribosomal RNA of the 59S subunit, thereby preventing the formation of a functional 70S complex essential to bacterial translation. Tedizolid has a similar mechanism of action.

**Indications for use.** Oxazolidinones are active against a variety of Gram-positive pathogens, including vancomycin-resistant *Enterococcus faecium* (although, unfortunately, resistant organisms have been reported), MRSA and penicillin-resistant *Strep. pneumoniae*. They are also active against group A and group B streptococci. Clinical experience with linezolid has demonstrated efficacy in a variety of hospitalized patients with severe to life-threatening infections, such as bacteraemia, hospital-acquired pneumonia, and skin and soft tissue and bone and joint infections. These drugs can be given both intravenously and by mouth, and are almost 100% bioavailable by the oral route in patients with normal gastrointestinal absorption.

**Interactions.** Oxazolidinones interact reversibly as non-selective inhibitors of monoamine oxidase and have the potential for interacting with serotoninergic and adrenergic agents.

**Toxicity.** Side-effects include gastrointestinal disturbances, headache, rash, hypertension, reversible but potentially severe cytopenias, and occasional reports of optic and peripheral neuropathy in patients receiving linezolid for longer than 28 days. Weekly monitoring of the full blood count for cytopenias, and for other serious adverse effects, is mandatory. Safety has not yet been shown in pregnancy but linezolid has been used successfully for serious infections in children.

**Nitroimidazoles**

**Structure.** These agents are active against anaerobic bacteria and some pathogenic protozoa. The most widely used drug is metronidazole (Fig. 11.10). Others include tinidazole and nimorazole.

![FIGURE 11.10 The structure of metronidazole, a nitroimidazole.](image_url)

**Mechanism of action.** After reduction of their ‘nitro’ group to a nitrosohydroxyl amino group by microbial enzymes, nitroimidazoles cause strand breaks in microbial DNA.

**Indications for use.** Metronidazole plays a major role in the treatment of anaerobic bacterial infections, particularly those due to *Bacteroides* spp. It is also used prophylactically
in colonic surgery. It may be given orally, by suppository (well absorbed and cheap) or intravenously (more expensive). It is also the treatment of choice for mild *C. difficile* infection, amoebiasis, giardiasis and infection with *Trichomonas vaginalis*.

**Interactions.** Nitroimidazoles can produce a disulfiram-like reaction with ethanol and enhance the anticoagulant effect of warfarin; patients should be warned not to drink alcohol whilst taking them.

**Toxicity.** Nitroimidazoles are tumorigenic in animals and mutagenic for bacteria, although carcinogenicity has not been described in humans. They cause a metallic taste and polyneuropathy with prolonged use. High-dose regimens should be avoided in pregnancy and during breast-feeding, unless the benefit is deemed to outweigh the risk.

**Glycopeptides**
The glycopeptides are antibiotics active against Gram-positive bacteria and act by inhibiting cell wall synthesis.

**Vancomycin**
Vancomycin is given intravenously for MRSA and other multi-resistant, Gram-positive organisms. It is also used for treatment and prophylaxis against Gram-positive infections in penicillin-allergic patients. It is given in *Strep. pneumoniae* meningitis, in combination with other effective antibiotics, when disease is caused by penicillin-resistant strains. By mouth, it is not absorbed from the gastrointestinal tract and is the preferred therapy for moderate to severe *C. difficile* infection. Glycopeptide-resistant enterococci (GRE) and *Staphylococcus* spp. (see p. 270) are recognized but, in general, Gram-positive bacteria are more likely to become resistant to β-lactam antibiotics than glycopeptides.

**Toxicity.** Vancomycin can cause ototoxicity and nephrotoxicity, and thus pre-dose (trough) serum levels should be monitored regularly. Serum levels at 1 h post dose (peak) are also monitored to optimize drug efficacy (see p. 236). Care must be taken to avoid extravasation at the injection site, as this causes necrosis and thrombophlebitis. Too rapid infusion can produce symptomatic release of histamine (red man syndrome).

**Teicoplanin**
This glycopeptide antibiotic is less nephrotoxic than vancomycin. It has more favourable pharmacokinetic properties, allowing once-daily or thrice-weekly dosage. It is given intravenously and pre-dose (trough) serum levels are monitored to optimize efficacy.

**Other antibiotics**

**Clindamycin.** This is not widely used because of its strong association with *C. difficile* infection. It is active against Gram-positive cocci, including some penicillin-resistant staphylococci, and is a useful agent for severe streptococcal or staphylococcal cellulitis. It has the added effect of inhibiting staphylococcal toxic shock syndrome toxin 1 (TSST-1) and alpha toxin production and has a role in infections caused by *Staph. aureus* secreting Panton
Valentine leucocidin (PVL). It is also active against anaerobes, especially *Bacteroides*. It is well concentrated in bone and used for osteomyelitis.

**Mupirocin.** Mupirocin prevents bacterial RNA and protein synthesis. It is only used topically, mainly for the nasal eradication of *Staph. aureus*, including MRSA, but can also be used for minor skin infections. Resistance can be a problem.

**Streptogramins.** A combination of quinupristin and dalfopristin is used for Gram-positive bacteria that have failed to respond to other antibacterials. It has found only limited use and is not available in the UK. Virginiamycin and pristinamycin are also available.

**Daptomycin.** This is a lipopeptide with a similar spectrum to vancomycin and is given by the intravenous route. It is used particularly for complicated skin and soft tissue infections, including those caused by MRSA, and is also a useful alternative agent for endocarditis, bone and joint infections, and Gram-positive bloodstream infections.

**Fosfomycin** is a relatively old antibiotic that has been used in some European countries for many years and is effective against many Gram-positive and Gram-negative bacteria, but has limited activity against *Pseudomonas* spp. It has a unique mechanism of action on the cell walls of bacteria, retains activity against many ESBL-producing organisms and is therefore the subject of renewed interest. It is increasingly used in the UK, particularly for resistant urinary tract infections, and is available in oral and intravenous formulations.

**Colistimethate sodium (polymixin E).** This is another old antibiotic that, until recently, was rarely used in clinical practice because of concerns about, usually reversible, neuro- and nephrotoxicity. The emergence of carbapenemase-producing Gram-negative bacteria, however, has resulted in increased use, often in combination with other antibiotics such as tigecycline and high doses of carbapenems. The mechanism of bacterial killing is thought to be due to disruption of the bacterial cell membrane following binding to the lipopolysaccharide component. It is active against most Gram-negative bacilli and is administered intravenously for serious infections. Plasmid-mediated resistance has recently been described.

**Rifaximin.** This is a rifamycin with poor gastrointestinal absorption. It is used in portosystemic encephalopathy (see p. 474) and to prevent traveller's diarrhoea; it may be of short-term benefit in irritable bowel syndrome.

**Anti-tuberculosis drugs**

These are described on pages 1110–1113. Rifampicin is also used in other infections apart from tuberculosis.

**Antifungal drugs**

See *Box 11.16*.

---

**Box 11.16**

**Antifungal agents**
### Polyenes
- Amphotericin, nystatin

### Echinocandins
- Caspofungin
- Anidulafungin
- Micafungin

### Azoles
- Miconazole, ketoconazole, fluconazole, itraconazole, voriconazole, posaconazole, isavuconazole
- Topical clotrimazole, sulconazole, tolnaftate, econazole, tioconazole

### Allylamines
- Terbinafine

### Other antifungals
- Amorolfine (topical only)
- 5-Flucytosine
- Griseofulvin

---

**Polyenes**

Polyenes react with the sterols in fungal membranes, increasing permeability and thus damaging the organism. The most potent is amphotericin, which is used intravenously in severe systemic fungal infections. Nephrotoxicity is a major problem and dosage levels must take background renal function into account. Liposomal amphotericin is less toxic but very expensive. Nystatin is not absorbed through mucous membranes and is therefore useful for the treatment of oral and enteric candidiasis and for vaginal infection. It can only be given orally or as pessaries.

**Azoles**

**Imidazoles.** Imidazoles, such as ketoconazole, miconazole and clotrimazole, are broad-spectrum antifungal drugs. They are predominantly fungistatic and act by inhibiting fungal sterol synthesis, resulting in damage to the cell wall. Ketoconazole is active orally but can produce liver damage. It is effective in candidiasis and deep mycoses, including histoplasmosis and blastomycosis, but not in aspergillosis and cryptococcosis.

Clotrimazole and miconazole are used topically for the treatment of ringworm and cutaneous and genital candidiasis. Econazole is used for the topical treatment of cutaneous and vaginal candidiasis and dermatophyte infections, while tioconazole is indicated for fungal nail infections.
**Triazoles.** These include fluconazole, voriconazole, posaconazole and itraconazole. Fluconazole is noted for its ability to enter CSF and is used for candidiasis and for the treatment of central nervous system (CNS) infection with *Cryptococcus neoformans*. Itraconazole fails to penetrate CSF. It is the agent of choice for non-life-threatening blastomycosis and histoplasmosis. It is also moderately effective in invasive aspergillosis. Toxicity is mild. Voriconazole has broad-spectrum activity that includes *Candida, Cryptococcus* and *Aspergillus* spp. and other filamentous fungi. It is available for oral and intravenous use. Adverse effects include rash, visual disturbance and abnormalities of liver enzymes. It is indicated for invasive aspergillosis and severe *Candida* infections unresponsive to amphotericin and fluconazole, respectively. Isavuconazole has recently been used for invasive mould disease.

**Allylamines**

Terbinafine has broad-spectrum antifungal and also anti-inflammatory activity. It is well absorbed orally and accumulates in keratin. It is useful for the treatment of superficial mycoses, such as dermatophyte infections, onychomycosis and cutaneous candidiasis. A topical formulation is also available to treat fungal skin infections.

**Echinocandins**

These act by inhibiting the cell-wall polysaccharide, glucan. Caspofungin, which is administered intravenously, is active against *Candida* spp. and *Aspergillus* spp., and is indicated for invasive candidiasis and invasive aspergillosis unresponsive to other drugs. Other echinocandins include micafungin and anidulafungin, approved for the treatment of disseminated candidiasis. Severe hepatotoxicity has been reported with micafungin and liver biochemistry must be monitored.

**Flucytosine**

The fluorinated pyridine derivative, flucytosine, is used in combination with amphotericin B for cryptococcal meningitis. Side-effects are uncommon, although it may cause bone marrow suppression. It is active when given orally or parenterally.
Antiviral drugs

Drugs for HIV infection are discussed on pages 341–346, and the treatment of hepatitis C virus infections on pages 460–461.

Anti-herpesvirus drugs

Nucleoside analogues

Aciclovir. Aciclovir (Fig. 11.11A; also known as acycloguanosine) is an acyclic nucleoside analogue that acts as a chain terminator of herpesvirus DNA synthesis. This drug is converted to aciclovir monophosphate by a virus-encoded thymidine kinase produced by the alpha herpesviruses, herpes simplex types 1 and 2, and varicella zoster virus (Box 11.17). Conversion to the triphosphate is then achieved by cellular enzymes. Aciclovir triphosphate acts as a potent inhibitor of viral (but not cellular) DNA polymerase and also competes with deoxyguanine triphosphate for incorporation into the growing chains of herpesvirus DNA, thereby resulting in chain synthesis termination due to its acyclic structure. This highly specific mode of activity, targeted only to virus-infected cells, means that aciclovir has very low toxicity. Crystallization in the renal tubules is a well-recognized adverse effect, and patients should be well hydrated, particularly when high-dose intravenous therapy is being used. Intravenous, oral and topical preparations are available for the treatment of herpes simplex and varicella zoster virus infections. Treatment does not eliminate the virus so relapses do occur.

*For drugs used in HIV, see pp. 340–349; for drugs used in the treatment of hepatitis C virus infection, see pp. 460–461.
CMV, cytomegalovirus; HCV, hepatitis C virus; HSV, herpes simplex virus; i.m., intramuscular; i.v., intravenous; RSV, respiratory syncytial virus; VZV, varicella zoster virus.

**Valaciclovir.** This is an oral pro-drug of aciclovir. Coupling of the amino acid valine to the acyclic side-chain of aciclovir allows better intestinal absorption. The valine is removed by enzymic action and aciclovir is released into the circulation. A similar pro-drug of a related nucleoside analogue (penciclovir) is the antiherpes drug, famciclovir. The mode of action and efficacy of famciclovir are similar to those of aciclovir.

**Ganciclovir.** This guanine analogue is structurally similar to aciclovir, with extension of the acyclic side-chain by a carboxymethyl group. It is active against herpes simplex viruses and varicella zoster virus by the same mechanism as aciclovir. In addition, phosphorylation by a protein kinase encoded by the UL97 gene of cytomegalovirus renders it potently active against this virus. Thus, ganciclovir is currently the first-line treatment for cytomegalovirus disease. Intravenous and oral preparations are available, as is an oral pro-drug, valganciclovir. This is preferred for the initial treatment of CMV retinitis (see pp. 258–259). Unlike aciclovir, ganciclovir has a significant toxicity profile, including neutropenia, thrombocytopenia and, rarely, sterilization by inhibition of spermatogenesis. It is therefore reserved for the treatment or prevention of life- or sight-threatening cytomegalovirus infection in immunocompromised
Nucleotide analogues

*Cidofovir*. This is a phosphonate derivative of an acyclic nucleoside that acts as a viral DNA polymerase inhibitor (*Fig. 11.11B*). It is administered intravenously for the treatment of severe cytomegalovirus infections in patients with advanced HIV infection for whom other drugs are inappropriate. It is given with probenecid and, as it is nephrotoxic, particular attention should be given to hydration and to monitoring of renal function.

*Brincidofovir* (also referred to as CMX001). This consists of cidofovir, which is bound to a lipid moiety, enabling an oral route of administration and avoiding renal toxicity. This drug shows great promise in clinical trials.

Pyrophosphate analogues

*Foscarnet* (*sodium phosphonoformate*). This is a simple pyrophosphate analogue that inhibits viral DNA polymerases. It is active against herpesviruses and its main roles are as a second-line treatment for severe cytomegalovirus disease and in the treatment of aciclovir-resistant herpes simplex infection. It is given intravenously and the potential for severe side-effects, particularly renal damage, limits its use.

Novel anti-herpesvirus agents

New drugs undergoing clinical trials include pritelivir, an inhibitor of the herpes simplex viral helicase-primase enzyme complex; maribavir, an inhibitor of the product of the *UL97* gene of cytomegalovirus, which plays a key role in allowing viral egress from an infected cell; and letermovir, an inhibitor of the cytomegalovirus terminase enzyme complex, which cuts the string of cytomegalovirus genomes synthesized in an infected cell into unit-length genomes for packaging in the capsid.

Anti-influenza drugs

Adamantanes

*Amantadine*. The use of amantadine and derivatives in the treatment and prophylaxis of influenza has largely been superseded by the neuraminidase inhibitors. Amantadine is active prophylactically and therapeutically against influenza A virus (it is inactive against influenza B virus). CNS side-effects, such as insomnia, dizziness and headache, may occur (amantadine is also used as a treatment for Parkinson's disease) and the drug is poorly tolerated, especially in the elderly.

Neuraminidase inhibitors

*Zanamivir* (administered by inhalation) and *oseltamivir* (an oral preparation). These drugs inhibit the action of the neuraminidase of influenza A and B. Both have been shown to be effective in reducing the duration of illness in influenza if given within the first 48 hours.
Oseltamivir is also available for the prophylaxis of influenza among household contacts of an index case. Intravenous peramivir and zanamivir were both reported to be effective in treating patients during the 2010 influenza pandemic, but neither is currently licensed for routine use in this way.

**Anti-hepatitis B drugs**

A number of nucleoside and nucleotide analogues have been shown to inhibit the reverse transcriptase function of hepatitis B virus and thereby suppress viral replication (see p. 458). The first such agents, lamivudine and adefovir, have largely been superseded by the more potent drugs entecavir and tenofovir, both of which also have a considerably higher barrier to resistance.

Telbivudine and emtricitabine are also nucleoside analogue inhibitors of HBV DNA polymerase activity.

**Other drugs**

**Ribavirin.** This synthetic purine nucleoside derivative, which interferes with 5′-capping of messenger RNA, is active against several RNA and DNA viruses, at least in vitro. Its major use is in the treatment of chronic hepatitis C infection in combination with pegylated interferon-alfa (IFN-α), although it has no effect when given alone (see pp. 460–461). It is administered orally. Haemolytic anaemia is the most frequent adverse reaction. It is also administered by a small-particle aerosol generator (SPAG) to infants with acute respiratory syncytial virus (RSV) infection. Another indication is in the treatment of Lassa fever virus infection.

Palivizumab. This monoclonal antibody is specifically indicated to prevent seasonal RSV infection in infants at high risk of this infection. It is administered by intramuscular injection.

**Interferons**

These are naturally occurring proteins with a multiplicity of actions, including antiviral, immunomodulatory and antiproliferative effects. Interferons are produced by virus-infected cells, macrophages and lymphocytes. They induce an antiviral state in uninfected cells, through activation of a complex set of biochemical pathways. They have been synthesized commercially, either by culture of lymphoblastoid cells or by recombinant DNA technology, and are licensed for therapeutic use.

The potency of INF-α has been enhanced by coupling the protein with polyethylene glycol. The resulting PEG interferon given once weekly has been shown to improve the response to, and reduce the side-effects from, treatment for hepatitis B and C (see pp. 457–458 and 460–461).

**Further reading**

---

**Immunization Against Infectious Diseases**

Although effective antimicrobial chemotherapy is available for many diseases, the ultimate aim of any infectious disease control programme is to prevent infection occurring. This is achieved either by:

- eliminating the source or mode of transmission of an infection (see p. 223), or
- reducing host susceptibility to environmental pathogens.

**Immunization, immunoprophylaxis and immunotherapy**

Immunization has changed the course and natural history of many infectious diseases. Passive
immunization by administering preformed antibody, either in the form of immune serum or purified normal immunoglobulin, provides short-term immunity and has been effective in both the prevention (immunoprophylaxis) and treatment (immunotherapy) of a number of bacterial and viral diseases (Box 11.18). The active immunization schedule currently recommended is summarized in Box 11.19. Long-lasting immunity is achieved only by active immunization with a live attenuated or an inactivated organism or a subunit thereof (Box 11.20). Active immunization may also be performed with microbial toxin (either native or modified): that is, a toxoid. Immunization should be kept up to date with booster doses throughout life. Travellers to developing countries, especially if visiting rural areas, should in addition enquire about further specific immunizations.

*Individual vaccines for measles, mumps and rubella are not licensed in the UK. BCG, bacille Calmette–Guérin.*

In 1974, the WHO introduced the Expanded Programme on Immunization (EPI). By 1994, more than 80% of the world's children had been immunized against tuberculosis, diphtheria, tetanus, pertussis, polio and measles. It is hoped that poliomyelitis will be eradicated worldwide in the near future, which will match the past success of global smallpox eradication. Introduction of conjugate vaccines against *Haemophilus influenzae* type b (Hib)
and *Streptococcus pneumoniae* has proved highly effective in controlling invasive *H. influenzae* infection, notably meningitis, and reducing invasive pneumococcal disease (*Fig. 11.12*). A safe and immunogenic vaccine against *Neisseria meningitidis* serogroup B has recently been developed and included in childhood vaccination schedules in some countries. Childhood immunization (e.g. tetanus) should be maintained throughout adulthood; this is often overlooked by patients and healthcare professionals alike.

![FIGURE 11.12 Decline in invasive pneumococcal disease in young children following introduction of a pneumococcal conjugate vaccine (PCV) in the USA. (From the Centers for Disease Control and Prevention (http://www.cdc.gov/pneumococcal/surveillance.html), with permission.]

**Protection for travellers to developing/tropical countries**

There has been a huge increase in the number of people travelling to developing countries, mainly for recreation and leisure. The risk of infection depends on the area to be visited, the type of activity and the underlying health of the traveller. Advice should therefore always be based on an individual assessment.

Protection for travellers against infection can be divided into three categories:

- **personal protection, e.g.**:
  - insect repellents
  - impregnated bed netting
  - avoidance of animals
  - care with food and drink
  - condoms
- **chemoprophylaxis, e.g. antimalarials**
- **immunization, e.g.**:
  - yellow fever
  - hepatitis A and B
  - typhoid.

Because situations and risks can change rapidly, websites (which can be regularly updated)
are often the best source of advice on travel health.

Viral Infections

Introduction
Viruses are much smaller than other infectious agents and contain either DNA or RNA – not both, as do bacteria and other microorganisms. Details of the structure, size and classification of human DNA and RNA viruses are shown in Boxes 11.21 and 11.22, respectively. Since viruses are metabolically inert, they must live intracellularly, using the host cell for synthesis of viral proteins and nucleic acid. Viruses have a central nucleic acid core surrounded by a protein coat (capsid) that is antigenically unique for a particular virus. The capsid imparts a helical or icosahedral structure to the virus. Some viruses also possess an outer envelope consisting of lipid and protein.

MERS, Middle East respiratory syndrome; SARS, severe acute respiratory syndrome.

**Outcomes of virus infection of a cell**

Replication of viruses within a cell may result in sufficient distortion of normal cell function so as to result in cell death – a **cytocidal** or **cytolytic** infection. However, acute cell death is
not an inevitable consequence of virus infection of a cell. In a **chronic**, or **persistent**, infection, virus replication continues throughout the lifespan of the cell but does not interfere with the normal cellular processes necessary for cell survival. Hepatitis B and C viruses may interact with cells in this way. Some viruses, such as those of the herpesvirus family, are able to go **latent** within a cell; in such a state, the virus genome is present within the cell, but there is very little, if any, production of viral proteins and no production of mature virus particles. Finally, some viruses are able to **transform** cells, leading to uncontrolled cell division – for example, Epstein–Barr virus infection of B lymphocytes – resulting in the generation of an immortal lymphoblastoid cell line.

**Virus Infections of the Skin and Mucous Membranes**

A number of different virus infections are associated with skin rashes (exanthems) or eruptions on the mucous membranes (enanthems) (see **Box 11.8**). Rashes may be **vesicular** (i.e. consisting of fluid-filled vesicles) or **maculopapular**.

**Vesicular viral rashes**

**Herpes simplex virus infection**

Members of the *Herpesviridae* family are causes of a wide range of human diseases (**Box 11.23**). The hallmark of all herpesvirus infections is the ability of the viruses to establish latent infections that then persist for the life of the individual.

**Box 11.23**

**Major diseases caused by human herpesviruses**
Two types of herpes simplex virus (HSV; **Fig. 11.13**) have been identified: HSV-1 is the major cause of herpetic stomatitis, herpes labialis (‘cold sore’), keratoconjunctivitis and encephalitis, whereas HSV-2 causes genital herpes and may also be responsible for systemic infection in the immunocompromised host. These divisions are not rigid, however, for HSV-1 can give rise to genital herpes and HSV-2 can cause infections in the mouth. The site of latency for both HSV-1 and 2 is the nerve cell body.
HSV-1
The portal of entry of HSV-1 infection is usually via the mouth or, occasionally, the skin. The primary infection may go unnoticed, or may produce a severe inflammatory reaction with vesicle formation leading to painful ulcers (gingivostomatitis; Fig. 11.14). Virus may be reactivated from the trigeminal ganglion by stress, trauma, febrile illnesses and ultraviolet radiation, producing the recurrent form of the disease known as herpes labialis (‘cold sore’). Approximately 70% of the population is infected with HSV-1 and recurrent infections occur in one-third of individuals. Reactivation often produces localized paraesthesiae in the lip before the appearance of a cold sore.

Complications of HSV-1 infection include transfer to the eye (dendritic ulceration, keratitis), acute encephalitis (see p. 865), nail-bed infections (herpetic whitlow) and erythema multiforme (p. 1363).

HSV-2
The clinical features, diagnosis and management of genital herpes are described on pages 327–328. The virus remains latent in the sacral ganglia and, during recurrence, can produce a radiculomyelopathy, with pain in the groin, buttocks and upper thighs. Primary anorectal herpes infection is common in men having sex with men (see p. 327).

Neonates may develop primary HSV infection following vaginal delivery in the presence of active genital HSV infection in the mother, particularly if the maternal disease is a primary, rather than a recurrent, infection. The disease in the baby varies from localized skin lesions (about 10–15%) to widespread visceral disease most often affecting the lungs, liver and brain, with a poor prognosis. Caesarean section should therefore be performed if active genital HSV infection is present during labour.

Immunocompromised patients, such as those receiving intensive cancer chemotherapy or
those with AIDS, may develop disseminated HSV infection involving many of the viscera. In severe cases, death may result from hepatitis and encephalitis. Eczema herpeticum is a serious complication in individuals with eczema, where the non-intact skin allows spread of lesions across large areas and bloodstream access, which may lead to herpetic involvement of internal organs.

### Diagnosis and management

Confirmation of clinical diagnosis is most commonly obtained by detection of HSV DNA in vesicle fluid by PCR. Treatment of HSV-associated disease is with aciclovir and derivatives.

### Varicella (chickenpox) and herpes zoster (shingles)

Infection with varicella zoster virus (VZV), another herpesvirus, produces two distinct diseases: varicella (chickenpox) and herpes zoster (shingles). The **primary infection** is chickenpox. It usually occurs in childhood, the virus entering through the mucosa of the upper respiratory tract. In some countries (e.g. the Indian subcontinent), a different epidemiological pattern exists, with most infections occurring in adulthood. Chickenpox rarely occurs twice in the same individual. Infectious virus is spread from the throat and from fresh skin lesions by air-borne transmission or direct contact. The period of infectivity in chickenpox extends from 2 days before the appearance of the rash until the skin lesions are all at the crusting stage. Following recovery from chickenpox, the virus remains latent in dorsal root and cranial nerve ganglia. **Reactivation** of infection then results in shingles.

### Clinical features of chickenpox

Some 14–21 days after exposure to VZV, a brief prodromal illness of fever, headache and malaise heralds the eruption of chickenpox, characterized by the rapid progression of macules to papules to vesicles to pustules in a matter of hours *(Fig. 11.15)*. In young children, the prodromal illness may be very mild or absent. The illness tends to be more severe in older children and can be debilitating in adults. The lesions occur on the face, scalp, trunk and, to a lesser extent, on the extremities. It is characteristic to see skin lesions at all stages of development on the same area of skin. Fever subsides as soon as new lesions cease to appear. Eventually, the pustules crust and heal without scarring.
Complications of chickenpox include pneumonia, which generally begins 1–6 days after the skin eruption, and bacterial superinfection of skin lesions. Pneumonia is more common in adults than in children, and cigarette smokers are at particular risk. Pulmonary symptoms are usually more striking than the physical findings, although a chest X-ray usually shows diffuse changes throughout both lung fields. CNS involvement occurs in about 1 per 1000 cases and most commonly presents as an acute truncal cerebellar ataxia. The immunocompromised are susceptible to disseminated infection, with multiorgan involvement. Women in pregnancy are prone to severe chickenpox and, in addition, there is a risk of intrauterine infection with structural damage to the fetus (if maternal infection is within the first 20 weeks of pregnancy, the risk of varicella embryopathy is 1–2%).

Clinical features of shingles

Shingles (see p. 1344) arises from the reactivation of VZV latent within the dorsal root or cranial nerve ganglia. It may occur at any age but is most common in the elderly, producing skin lesions similar to those of chickenpox, although classically they are unilateral and restricted to a sensory nerve (i.e. dermatomal) distribution (Fig. 11.16). The onset of the rash of shingles is usually preceded by severe dermatomal pain, indicating the involvement of sensory nerves in its pathogenesis. Virus is disseminated from freshly formed vesicles and may cause chickenpox in susceptible contacts.
The most common complication of shingles is post-herpetic neuralgia (PHN; see p. 866).

**Diagnosis**

The diseases are usually recognized clinically but can be confirmed by detection of VZV DNA within vesicular fluid using PCR, electron microscopy, immunofluorescence or culture of vesicular fluid, and by serology.

**Prevention and management**

*Chickenpox* usually requires no treatment in healthy children and infection results in life-long immunity. Aciclovir and derivatives are, however, licensed for this indication in the USA, where the argument for treatment is that the sooner the child recovers, the sooner the carer can return to work. However, the disease may be fatal in the immunocompromised, who should therefore be offered protection, after exposure to the virus, with zoster-immune globulin (ZIG) and high-dose aciclovir at the first sign of development of the disease.

Anyone with chickenpox who is over the age of 16 years should be given antiviral therapy with aciclovir or a similar drug, if they present within 72 hours of onset. Prophylactic ZIG is recommended for susceptible pregnant women exposed to VZV and, if chickenpox develops, aciclovir treatment should be given. (N.B. Aciclovir has not been licensed for use in pregnant women.) If a woman has chickenpox at term, her baby should be protected by ZIG if delivery occurs within 7 days of the onset of the mother's rash. An effective live attenuated varicella vaccine is licensed as a routine vaccination of childhood in the USA; it is available on a named patient basis in the UK and also for susceptible healthcare workers.

*Shingles* involving motor nerves – for example, the VIIth cranial nerve, leading to facial palsy – is also treated with aciclovir (or derivatives thereof), as the duration of lesion formation and time to healing can be reduced by early treatment. Aciclovir, valaciclovir and famciclovir have all been shown to reduce the burden of PHN when treatment is given in the
acute phase. Shingles involving the ophthalmic division of the trigeminal nerve has an associated 50% incidence of acute and chronic ophthalmic complications. Early treatment with aciclovir reduces this to 20% or less. As for chickenpox, all immunocompromised individuals should be given aciclovir at the onset of shingles, no matter how mild the attack appears when it first presents.

Vaccination of all adults over the age of 60 (USA) or 70 (UK), with a live vaccine at a dose higher than that used for chickenpox prophylaxis in childhood, reduces shingles-related morbidity and PHN, and is recommended.

**Picornavirus infections**

The picornaviruses (pico = small) are a large family of small RNA viruses, which includes the enteroviruses and rhinoviruses, and also hepatitis A virus (see p. 452). The term enterovirus refers to the enteric means of spread of these viruses: that is, via the faeco-oral route. The enteroviruses include poliovirus types 1–3, Coxsackie A and B viruses, echoviruses and enteroviruses (EV) 68–71. There are several newly described EVs yet to be officially classified.

**Herpangina**

This disease is mainly caused by Coxsackie A viruses and presents with a vesicular eruption on the fauces, palate and uvula. The lesions evolve into ulcers. The illness is usually associated with fever and headache but is short-lived, recovery occurring within a few days.

**Hand, foot and mouth disease**

This disease is mainly caused by Coxsackievirus A16 or A10. It is also the main feature of infection with EV71. Oral lesions are similar to those seen in herpangina but may be more extensive in the oropharynx. Vesicles and a maculopapular eruption also appear, typically on the palms of the hands and the soles of the feet, but also on other parts of the body. This infection commonly affects children. Recovery occurs within a week.

**Poxvirus infections**

**Smallpox (variola)**

This disease was eradicated in 1977 following an aggressive vaccination policy. Its possible use in bioterrorism has resulted in the re-introduction of smallpox vaccination in some countries (see p. 233).

**Monkeypox**

This is a rare zoonosis that occurs in small villages in tropical rainforests in several countries of West and Central Africa. Its clinical effects, including a generalized vesicular rash, are indistinguishable from those of smallpox, but person-to-person transmission is unusual. Most
infections occur in children who have not been vaccinated against smallpox. Disease can be severe, with mortality rates of 10–15% in unvaccinated individuals. Serological surveys indicate that several species of squirrel are the likely animal reservoir. The virus was introduced into the USA in 2003 via West African small mammals illegally imported as pets. Widespread infection of prairie dogs resulted and there were 37 laboratory confirmed cases in humans.

**Cowpox**

Cowpox produces large vesicles that are classically found on the hands of individuals in contact with infected cows. The lesions are associated with regional lymphadenitis and fever. Cowpox virus has been found in a range of species, including domestic and wild cats, and the reservoir is thought to exist in a range of rodents.

**Vaccinia virus**

This is a laboratory virus and does not occur in nature in either humans or animals. Its origins are uncertain but it has been invaluable in its use as the vaccine to prevent smallpox.

**Orf**

This poxvirus causes contagious pustular dermatitis in sheep and hand lesions in humans (see p. 1345).

**Molluscum contagiosum**

This is discussed on pages 1344–1345.

**Human papillomavirus infections**

These cause warts (see p. 1344). They also cause cervical cancer (p. 265).

**Maculopapular viral rashes**

**Measles (rubeola)**

Measles virus is a paramyxovirus (see Box 11.22). Measles is a highly communicable disease that occurs worldwide. With the introduction of aggressive immunization policies, the incidence of measles has fallen dramatically in the West but in 2012 there were 122 000 measles deaths globally, mostly in Africa and South-east Asia, with mortality being highest in children younger than 12 months of age. It is spread by droplet infection and the period of infectivity is from 4 days before until 2 days after the onset of the rash.

**Clinical features**

The incubation period is 8–14 days. Two distinct phases of the disease can be recognized.
Typical measles

• **Pre-eruptive and catarrhal stage.** This is the stage of viraemia and viral dissemination. Malaise, fever, rhinorrhea, cough, conjunctival suffusion and the pathognomonic Koplik's spots are present during this stage. Koplik's spots are small, greyish, irregular lesions surrounded by an erythematous base and are found in greatest numbers on the buccal mucous membrane opposite the second molar tooth. They occur a day or two before the onset of the rash.

• **Eruptive or exanthematous stage.** This is characterized by the presence of a maculopapular rash that initially occurs on the face, chiefly the forehead, and then spreads rapidly to involve the rest of the body (*Fig. 11.17*). At first, the rash is discrete but later it may become confluent and patchy, especially on the face and neck. It fades in about 1 week and leaves behind a brownish discoloration.

*FIGURE 11.17 Measles* (Courtesy of Dr MW McKendrick, Royal Hallamshire Hospital, Sheffield.)

The most feared complication in an immunocompetent child is acute measles encephalitis, which has an incidence of 1/1000–1/5000 cases of measles. This is post-infectious – that is, virus is not present in the brain – and the encephalitis presumably arises through an aberrant cross-reaction of the host immune response to infection. Prognosis is poor, with a high mortality (30%), and severe residual damage in survivors.

Measles carries a high mortality in the malnourished and in those who have other diseases. Complications are common in such individuals and include bacterial pneumonia, bronchitis, otitis media and severe diarrhoea. Less commonly, myocarditis, hepatitis and encephalomyelitis occur. In those who are malnourished or those with defective cell-mediated immunity, the classical maculopapular rash may not develop and widespread desquamation may occur. The virus also causes the rare condition called subacute sclerosing panencephalitis, which may follow measles infection occurring early in life (<18 months of age). Persistence of the virus with reactivation before puberty results in accumulation of virus in the brain, progressive mental deterioration and a fatal outcome (see p. 867).
Maternal measles, unlike rubella, does not cause fetal abnormalities. It is, however, associated with spontaneous abortions and premature delivery.

**Diagnosis and management**

Most cases of measles are diagnosed clinically but detection of measles-specific IgM in blood or oral fluid, or genome or antigen detection from nasopharyngeal aspirates or throat swabs, should be used to confirm the diagnosis.

Management is supportive. Antibiotics are indicated only if secondary bacterial infection occurs.

**Prevention**

A previous attack of measles confers a high degree of immunity and second attacks are uncommon. Normal human immunoglobulin given within 5 days of exposure effectively aborts an attack of measles. It is indicated for previously unimmunized children below 3 years of age, during pregnancy and in those with debilitating disease.

**Active immunization**

Children in the UK are immunized with the combined mumps/measles/rubella (MMR) vaccine (see Box 11.19). In developing countries, the first measles vaccination is given at 9 months. Measles vaccination resulted in a 78% drop in measles deaths between 2000 and 2012 worldwide.

**Rubella**

Rubella (‘German measles’) is caused by a spherical, enveloped RNA virus belonging to the rubivirus genus of the family Togaviridae, which is easily killed by heat and ultraviolet light. While the disease can occur sporadically, epidemics are not uncommon. It has a worldwide distribution. Spread of the virus is via droplets; maximum infectivity occurs before and during the time the rash is present.

**Clinical features**

The incubation period is 14–21 days, averaging 18 days. The clinical features are largely determined by age, symptoms being mild or absent in children under 5 years.

During the prodrome, the patient may develop malaise, fever, mild conjunctivitis and lymphadenopathy involving particularly the suboccipital, post-auricular and posterior cervical groups of lymph nodes. Small petechial lesions on the soft palate (Forchheimer spots) are suggestive but not diagnostic. Splenomegaly may be present.

The eruptive or exanthematous phase usually occurs within 7 days of the initial symptoms. The rash first appears on the forehead and then spreads to involve the trunk and limbs. It is
pinkish red, macular and discrete, although some of these lesions may coalesce (Fig. 11.18). It usually fades by the second day and rarely persists beyond 3 days after its appearance.

**Complications**

Complications are rare. They include superadded pulmonary bacterial infection, arthralgia (more common in females), haemorrhagic manifestations due to thrombocytopenia, and encephalitis. Maternal infection in pregnancy may result in the congenital rubella syndrome. Rubella affects the fetuses of up to 80% of all women who contract the infection during the first trimester of pregnancy. The incidence of congenital abnormalities diminishes in the second trimester and no ill-effects result from infection in the third trimester.

Congenital rubella syndrome is characterized by the presence of fetal cardiac malformations, especially patent ductus arteriosus and ventricular septal defect, eye lesions (especially cataracts), microcephaly, mental retardation and deafness. Hepatosplenomegaly, myocarditis, interstitial pneumonia and metaphyseal bone lesions also occur.

**Diagnosis and management**

Laboratory diagnosis is essential (especially in pregnancy) to distinguish the illness from other virus infections (e.g. erythrovirus B19, echovirus) and drug rashes. This is achieved by the detection of rubella-specific IgM by enzyme-linked immunosorbent assay (ELISA) in an acute serum sample, preferably confirmed by the demonstration of IgG seroconversion (or a rising titre of IgG) in a subsequent sample taken 14 days later. Viral genome can be detected in throat swabs (or oral fluid samples), urine and, in the case of intrauterine infection, the products of conception.

Management is supportive.
Prevention

Several live attenuated rubella vaccines have been used with great success in preventing this illness and these have been successfully combined with measles and mumps vaccines in the MMR vaccine. Use of the vaccine is contraindicated during pregnancy or if there is a likelihood of pregnancy within 3 months of immunization. Inadvertent use of the vaccine during pregnancy has not, however, revealed a risk of teratogenicity.

Erythrovirus infections

Human erythrovirus (also known as parvovirus) B19 causes erythema infectiosum (fifth disease), a common infection in schoolchildren. The rash is typically on the face (the ‘slapped cheek’ appearance). The patient is well and the rash can recur over weeks or months. Asymptomatic infection occurs in 20% of children. Non-specific respiratory tract illness is another common manifestation of infection. In adults, the rash may be clinically indistinguishable from rubella. Moderately severe self-limiting polyarthropathy (see p. 691) is common if infection occurs in adulthood, especially in women (also true of rubella). The virus infects bone marrow cells, and aplastic crisis may occur in patients with chronic haemolysis (e.g. sickle cell disease). Chronic infection with anaemia occurs in immunocompromised subjects. Hydrops fetalis (3% risk) and spontaneous abortion (9% risk) may result from maternal infection in the first and second trimesters of pregnancy.

Diagnosis of acute infection is by detection of parvovirus-specific IgM and/or DNA.

Human herpesvirus types 6 and 7 infection

These human herpesvirus occur worldwide and exist as latent infections in over 85% of the adult population. They are spread by contact with oral secretion. Human herpesvirus type 6 (HHV-6) causes roseola infantum (exanthem subitum), which presents as a high fever followed by a generalized macular rash in infants. HHV-6 is a common cause of febrile convulsions, and aseptic meningitis or encephalitis occurs as a rare complication. Reactivation in the immunocompromised may lead to severe pneumonia.

The full spectrum of disease due to HHV-7 has not yet been fully characterized but, like HHV-6, it may cause roseola infantum in infants.

Management

Supportive management only is recommended for the common infantile disease. Ganciclovir can be used in the immunocompromised.

Further reading

Virus Infections of the Respiratory Tract

There are many viruses that can cause upper respiratory tract infection (URTI): for example, in the nose (rhinitis), throat (tonsillitis, pharyngitis), sinuses (sinusitis), ear (otitis media), eye (conjunctivitis) or larynx (laryngitis) (Box 11.24). Infections below the larynx are referred to as lower respiratory tract infections (LRTIs). URTIs are common but relatively trivial; LRTIs are less common but may result in hospitalization and even death.

MERS, Middle East respiratory syndrome.

**Upper respiratory tract infections**

**The common cold – coryza, rhinitis**

Rhinovirus infection is the most common cause of the common cold (see pp. 1075–1076). Peak incidence rates occur in the colder months, especially spring and autumn. There are multiple rhinovirus serotypes (>100), which explains why infection occurs throughout life and makes vaccine control impracticable. In contrast to enteroviruses, which replicate at 37°C, rhinoviruses grow best at 33°C (the temperature of the upper respiratory tract), which explains
the localized disease characteristic of common colds.

Human coronaviruses were first isolated in the mid-1960s and the majority of isolates (related to the reference strains 229E and OC43) have been associated with common colds. In 2004 and 2005, two new coronavirus infections of humans were described: NL63 and HKU1. These are also associated with coryzal symptomatology. Coronaviruses have recently become of interest owing to the discovery of two new viruses causing life-threatening LRTI (see below).

### Parainfluenza

Parainfluenza is caused by the parainfluenza viruses types I–IV; these have a worldwide distribution and cause acute respiratory disease. Type IV appears to be less virulent than the other types and has been linked only to mild upper respiratory diseases in children and adults.

Parainfluenza is essentially a disease of children and presents with features similar to those of the common cold. When severe, a brassy cough with inspiratory stridor and features of laryngotracheitis (croup) are present. Fever usually lasts for 2–3 days and may be more prolonged if pneumonia develops. The development of croup is due to sub-mucosal oedema and consequent airway obstruction in the subglottic region. This may lead to cyanosis, subcostal and intercostal recession and progressive airway obstruction. Infection in the immunocompromised is usually prolonged and may be severe. Management is supportive with oxygen, humidification and sedation when required. The role of steroids and the antiviral agent ribavirin is controversial.

### Adenovirus infection

Over 50 adenovirus serotypes have been identified as human pathogens, infecting a number of different cell types and therefore resulting in different clinical syndromes. Adenovirus infection commonly presents as an acute pharyngitis, and extension of infection to the larynx and trachea in infants may lead to croup. By school age, the majority of children show serological evidence of previous infection. Certain subtypes produce an acute conjunctivitis associated with pharyngitis. In adults, adenovirus causes acute follicular conjunctivitis and, rarely, pneumonia that is clinically similar to that produced by *Mycoplasma pneumoniae* (see p. 1104). Certain adenoviruses cause gastroenteritis (see pp. 273–279) without respiratory disease, and adenovirus infection may be responsible for acute mesenteric lymphadenitis in children and young adults. Mesenteric adenitis due to adenoviruses may lead to intussusception in infants. Infection in an immunocompromised host, such as a bone marrow transplant recipient, may result in multisystem failure and fatal disease.

### Other viral causes of URTI

Human erythrovirus B19 infection may present as a URTI. Bocavirus is a recently identified erythrovirus, which accounts for around 3–5% of respiratory tract infections in young children.
Coxsackie and echoviruses, which both belong to the enterovirus family, are occasionally found in respiratory tract secretions of young babies. WU and KI polyomaviruses have been recently identified. These may be associated with respiratory tract infections in young children.

**Lower respiratory tract infections**

Viral infections resulting in life-threatening LRTIs are influenza, respiratory syncytial virus and the Middle East respiratory syndrome coronavirus. However, other causes of viral pneumonia occasionally arise, and these are listed in *Box 11.24*.

**Influenza**

Influenza viruses belong to the family orthomyxoviridae, having a segmented negative strand RNA genome. The influenza virus is a spherical or filamentous enveloped virus. Haemagglutinin (H), a surface glycoprotein, aids attachment of the virus to the surface of susceptible host cells at specific sialic acid receptor sites. Release of replicated viruses from the cell surface, effected by budding through the cell membrane, is facilitated by the action of the enzyme neuraminidase (N), which is also present on the viral envelope. Three types of influenza virus are recognized – A, B and C – distinguishable by the nature of their internal proteins. In addition, sixteen H subtypes (H1–H16) and nine N subtypes (N1–N9) have been identified for influenza A viruses but only H1, H2, H3, N1 and N2 have established stable lineages in the human population since 1918.

- **Influenza A** is generally responsible for pandemics and epidemics.
- **Influenza B** often causes smaller or localized and milder outbreaks, such as in camps or schools. There are no subtypes of influenza B.
- **Influenza C** rarely produces disease in humans.

**Antigenic shift** generates new influenza A subtypes, which emerge at irregular intervals and give rise to influenza pandemics. Possible mechanisms include:

- Genetic reassortment of the RNA of the virus (which is arranged in eight segments) with that of an avian influenza virus. This requires co-infection of a host with both human and avian viruses. The pig is one animal in which this may occur. Alternatively, humans may act as the mixing vessel.
- Trans-species transmission of an avian influenza virus to humans. Viruses transmitted in this way are usually not well adapted to growth in their new host but adaptation may occur as a result of spontaneous mutations, leading to the emergence of a pandemic strain.

**Antigenic drift** (minor changes in influenza A and B viruses) results from point mutations leading to amino acid changes in the two surface glycoproteins, haemagglutinin and neuraminidase, which induce humoral immunity. This enables the virus to evade previously induced immune responses and is the process whereby annual influenza epidemics arise.

Thus, changes due to antigenic shift or drift render the individual's immune response less able to combat the new variant.
The incidence of infection increases during the winter months. Spread is mainly by droplet infection but fomites and direct contact have also been implicated. Influenza pandemics of the 20th century are listed in Box 11.25.

**Box 11.25**

**Influenza pandemics of the 20th century**

*Not thought to be a natural occurrence.*

In 1997, avian influenza A/H5N1 viruses were first isolated from humans, raising the spectre of another pandemic. As of January 2014, over 650 sporadic human A/H5N1 infections have been reported from 15 countries, mostly in Asia (Indonesia, China and Vietnam) and almost always arising from direct contact with infected chickens, with a mortality of >50%. While this virus is highly pathogenic to humans, due to the induction of a cytokine storm within the lungs, it still has not evolved to replicate well in human cells and human-to-human spread is unusual. However, anxieties remain that either genetic re-assortment will occur in a human co-infected with human A/H1N1 or A/H3N2 viruses, or adaptive mutations will occur within infected human hosts, such that a truly pandemic strain will emerge.

In April 2009, a novel influenza A virus, now referred to as A(H1N1)pdm09, was identified in patients with severe respiratory illness in Mexico and North America. The virus quickly spread across the world, with the WHO declaring an official pandemic on 11 June 2009. The virus was the end-product of several re-assortments between pre-existing swine, avian and human virus lineages, with the swine H1 protein showing around 20% amino acid sequence divergence from previously circulating human seasonal H1N1 influenza viruses. Although unquestionably highly transmissible (with estimates of millions of infections worldwide within 1 year), this pandemic virus was (perhaps fortunately) not especially virulent. Most infections occurred in children; adults over 50 years of age had evidence of pre-existing protective immunity. A minority of infections resulted in serious disease, with an estimated 200 000 deaths worldwide. Risk factors for serious disease included pre-existing underlying medical conditions, age <5 years, obesity and pregnancy. The pandemic was declared officially over by the WHO in August 2010, the virus now behaving as a normal seasonal influenza virus, and replacing the previously circulating A H1N1 virus.

Novel influenza viruses may continue to infect humans sporadically, raising the possibility
of a new pandemic. In 2013, over 100 cases of infection with an H7N9 virus were reported from China, a third of whom died. Most cases gave a history of exposure to live animals, including chickens.

Purified haemagglutinin and neuraminidase from recently circulating strains of influenza A and B viruses are incorporated in current vaccines.

The clinical features, diagnosis, treatment and prophylaxis of influenza are discussed on page 1078.

**Respiratory syncytial virus infection**

Respiratory syncytial virus (RSV) is a paramyxovirus that causes many respiratory infections in epidemics each winter. It is a common cause of bronchiolitis in infants, complicated by pneumonia in approximately 10% of cases. The infection normally starts with upper respiratory symptoms. After an interval of 1–3 days, a cough and low-grade fever may develop. The onset of bronchiolitis is characterized by dyspnoea and hyperexpansion of the chest with subcostal and intercostal recession. The disease may be severe and potentially fatal in babies with underlying cardiac, respiratory (including prematurity) or immunodeficiency disease. The virus undergoes antigenic drift and, consequently, re-infection occurs throughout life. RSV is occasionally the cause of outbreaks of influenza-like illness or pneumonia in the elderly (in residential homes) and in the immunocompromised.

Transfer of infection between children in hospital (hospital-acquired infection) commonly occurs unless infected patients are isolated or cohorted. Meticulous attention to hand-washing and other infection control measures reduces the risk of transmission by staff members (see p. 224).

**Diagnosis and management**

Genome detection or immunofluorescence on nasopharyngeal aspirates, virus culture and serology are the usual ways of confirming the diagnosis.

Management is generally supportive, but aerosolized ribavirin can be given to severe cases, particularly those with underlying cardiac or respiratory disease.

**Prevention**

No vaccine is currently available for RSV but high-risk children (including those with bronchopulmonary dysplasia and congenital heart disease) can be protected against severe disease by monthly administration of either a hyperimmune globulin against RSV, or a humanized monoclonal antibody (palivizumab) during the winter months.

**Metapneumovirus**

Human metapneumovirus (hMPV) belongs to the same virus family as RSV, and causes approximately 10% of LRTIs in infants and young children. Infection is clinically
indistinguishable from that caused by RSV.

Coronavirus infection – severe acute respiratory and Middle East respiratory syndromes

In November 2002, an apparently new LRTI occurred in China and spread rapidly in other parts of the Far East and across the world.

This disease, known as ‘severe acute respiratory syndrome’ (SARS), of which bronchopneumonia is a major feature, was caused by a previously unknown coronavirus (SARS-CoV). Similarity of this virus to coronaviruses isolated from civet cats, raccoons and ferret badgers indicates the likelihood that SARS is a zoonotic disease. Bats are the likely host species for this virus. The epidemic was finally brought under control in the summer of 2003, by which time there had been >8000 cases with approximately 800 deaths. Naturally acquired infection has not been reported since.

In 2012, a new coronavirus, Middle East respiratory syndrome coronavirus (MERS-CoV), was identified in a patient who died of acute respiratory failure in Saudi Arabia. There have been over 750 cases since, with a mortality of around 40%, almost all acquired in the Middle East, the most likely source being a virus from camels. Person-to-person spread has been described but has not been sufficient to cause large-scale outbreaks.

Systemic Viral Infections

Dengue

This is the most common arthropod-borne viral infection in humans; over 100 million cases occur every year in the tropics, with over 10 000 deaths from dengue haemorrhagic fever (Fig. 11.19). Dengue is caused by a flavivirus. The disease is endemic in all tropical regions, including northern Australia, most South-east Asian countries, tropical Africa and the Middle East, and Caribbean countries. Cases of dengue are also imported into the continental USA and Europe (e.g. Italy) via tourists returning from endemic countries.
Four different antigenic varieties of dengue virus are recognized and all are transmitted by the daytime-biting *Aedes aegypti*, which breeds in standing water in refuse dumps in inner cities. *A. albopictus* is a less common transmitter. Humans are infective during the first 3 days of the illness (the viraemic stage; Fig. 11.20). Mosquitoes become infective about 2 weeks after feeding on an infected individual and remain so for life. The disease is usually endemic. Heterotypic immunity between serotypes after the illness is partial and lasts only a few months, although homotype immunity is life-long.
Clinical features

The incubation period is 5–6 days following the mosquito bite. Asymptomatic or mild infections are common. Two clinical forms are recognized (Fig. 11.20).

Classic dengue fever

Classic dengue fever is characterized by the abrupt onset of fever, malaise, headache, facial flushing, retrobulbar pain that worsens on eye movements, conjunctival suffusion and severe backache, which is a prominent symptom. Lymphadenopathy, petechiae on the soft palate and transient, morbilliform skin rashes may also appear on the limbs with subsequent spread to involve the trunk. Desquamation occurs subsequently. Cough is uncommon. The fever subsides after 3–4 days, the temperature returns to normal for a couple of days and then the fever returns, together with the features already mentioned, but milder. This biphasic or ‘saddleback’ pattern is considered characteristic. Severe fatigue, a feeling of being unwell and depression are common for several weeks after the fever has subsided.

Dengue haemorrhagic fever

Dengue haemorrhagic fever (DHF) is a severe form of dengue fever and is believed to be the result of two or more sequential infections with different dengue serotypes. It is characterized by the capillary leak syndrome, thrombocytopenia, haemorrhage, hypotension and shock. It is characteristically a disease of children, occurring most commonly in South-east Asia. The disease has a mild start, often with symptoms of an URTI. This is then followed by the abrupt onset of shock and haemorrhage into the skin and ear, epistaxis, haematemesis and melaena, known as the dengue shock syndrome. This has a mortality of up to 44%. Serum complement levels are depressed and there is laboratory evidence of disseminated intravascular coagulation (DIC; see pp. 573–574).

Diagnosis and management

• Isolation of dengue virus by tissue culture, or detection of viral RNA by PCR in sera obtained during the first few days of illness, is diagnostic.
• Detection of virus-specific IgM antibodies, or of rising IgG titres in sequential serum samples, haemagglutination inhibition, ELISA or complement-fixation assays confirm the diagnosis.
• Blood tests show leucopenia and thrombocytopenia.

Management is supportive with analgesics and adequate fluid replacement. Corticosteroids are of no benefit and convalescence can be slow. In DHF, blood transfusion may be necessary, as well as intensive care support.

Prevention
Travellers should be advised to sleep under impregnated nets but this is not very effective, as the mosquito bites in daytime. Topical insect repellents should be used. Adult mosquitoes should be destroyed by sprays and breeding sites, such as small pools of stagnant water, should be eradicated. There is no effective vaccine yet, although some are being trialled.

### Zika virus infection

Zika virus, a flavivirus closely related to dengue viruses, has come to prominence in 2016 following an explosive pandemic throughout South and Central America, and the Caribbean. Like dengue, Zika is an arbovirus, transmitted to humans by Aedes mosquitoes. Illness, when it arises, is usually unremarkable, with fever, myalgia, eye pain, prostration and maculopapular rash, with spontaneous resolution. However, the epidemiological association of the emergence of Zika virus outbreaks with subsequent dramatic increases in the number of cases of microcephaly in infants (e.g. Brazil reported a 20-fold increase in incidence from 2014–2015) has led the WHO to declare Zika a public health emergency of international concern. The link between Zika infection in pregnancy and subsequent microcephaly is not yet proven beyond doubt, but the circumstantial evidence is suggestive, and there are recent reports of findings of Zika virus RNA in the brain tissue of an affected neonate. There are also data suggesting an increase in Guillain–Barré syndrome following Zika virus epidemics. Accurate diagnosis of infection is complicated by serological cross-reactivity with dengue viruses. Further research on the consequences of infection with Zika virus is urgently needed.

### Chikungunya

Chikungunya virus is an alphavirus, a genus within the Togavirus family. Viruses spread by insects are collectively referred to as arthropod-borne viruses, or arboviruses (Boxes 11.26 and 11.27). There are eight alphaviruses that result in human disease. These are transmitted by mosquitoes, are globally distributed and tend to acquire their names from the location where they were first isolated (such as Ross River, Eastern, Venezuelan and Western equine encephalitis viruses) or from the local expression for a major symptom caused by the virus (such as chikungunya, meaning ‘doubled up’). Infection is characterized by fever, headache, maculopapular skin rash, arthralgia, myalgia and sometimes encephalitis. After 1 year, at least 20% of patients still suffer recurrent joint pains. Mortality is around 0.1%, mostly in the elderly or very young.

---

**Box 11.26**

**Arbovirus (arthropod-borne) infection**

**Defining features of arboviruses**

- Arboviruses are zoonotic viruses, transmitted through the bites of insects, especially
mosquitoes and ticks
• >385 viruses are classified as arboviruses
• Most are members of the Togavirus, Flavivirus and Bunyavirus families (see Box 11.27)
• *Culex, Aedes* and *Anopheles* mosquitoes account for transmission of the majority of these viruses

**Clinical features of arbovirus infection**

• Most arbovirus diseases are generally mild; epidemics are frequent and when these occur, the mortality is high

• In general, the incubation period is short (<10 days). Common features include a biphasic illness, pyrexia, conjunctival suffusion, a rash, retro-orbital pain, myalgia and arthralgia. Lymphadenopathy is seen in dengue

• **Haemorrhage** (from increased vascular permeability, capillary fragility, consumptive coagulopathy) is a feature of some arbovirus infections (see Box 11.33)

• **Encephalitis** resulting from cerebral invasion may be prominent in some arbovirus fevers.

E, encephalitis or aseptic meningitis; F, tropical fever, often with headache, myalgia, rash, arthralgia; H, haemorrhagic fever.

Major epidemics of chikungunya, spread via *A. aegypti* or *A. albopictus*, have been reported in India, Sri Lanka and islands in the Indian Ocean (including Reunion, Mauritius and the
Seychelles) in 2005 and 2006, with at least 1 million cases and several hundred deaths. The severity of these epidemics is possibly due to a viral strain with mutations resulting in a higher neurovirulence. Several European countries reported cases of chikungunya in returning travellers, including 133 cases in the UK in 2006. The virus may now populate the local Aedes mosquito via increased numbers of travellers, who may import virus into countries where it has not previously been described; for example, an outbreak in Italy in 2007 involved over 150 cases with one death, and two locally acquired confirmed cases were reported from the French mainland in 2010. In 2013, an outbreak in the Caribbean islands spread to contiguous Central and South American countries, and over 200 cases were reported in 2014 in the USA.

A chikungunya virus-like particle vaccine is in clinical trial.

Infectious mononucleosis: Epstein–Barr virus infection

Globally, most individuals are infected with Epstein–Barr virus (EBV) at an early age (0–5 years), at which time clinical symptoms are unusual. Infection at an older age is associated with an acute febrile illness known as infectious mononucleosis (glandular fever), which occurs worldwide in adolescents and young adults. EBV is probably transmitted in saliva and by aerosol.

Clinical features

The predominant symptoms of infectious mononucleosis are fever, headache, malaise and sore throat. Palatal petechiae and a transient macular rash are common, the latter occurring in 90% of patients who have received ampicillin (inappropriately) for the sore throat. Cervical lymphadenopathy, particularly of the posterior cervical nodes, and splenomegaly are characteristic. Mild hepatitis is common, but other complications such as myocarditis, meningitis, encephalitis, cerebellar ataxia, mesenteric adenitis and splenic rupture are rare. Splenic rupture may occur in the first 3 weeks of illness and contact sport should be avoided during this period.

Although some young adults remain debilitated and depressed for some months after infection, the evidence for reactivation of latent virus in healthy individuals is controversial, although this is thought to occur in immunocompromised patients. The site of EBV latency is in resting memory B lymphocytes. Severe, often fatal, infectious mononucleosis may result from a rare X-linked lymphoproliferative syndrome affecting young boys. Those who survive have an increased risk of hypogammaglobulinaemia and/or lymphoma. EBV is the cause of oral hairy leucoplakia in AIDS patients and is intimately linked to the generation of a number of malignancies (see below). EBV is a cause of haemophagocytic lymphohistiocytosis (HLH), a rare condition presenting with fever, rash, jaundice, hepatosplenomegaly and enlarged lymph nodes. Blood tests show cytopenia and a high ferritin, and the bone marrow shows haemophagocytosis. HLH can be primary (inherited) or secondary (e.g. to EBV), and has a high mortality.
**Diagnosis**

EBV infection should be strongly suspected if atypical mononuclear cells (activated CD8-positive T lymphocytes) are found in the peripheral blood in large numbers. It can be confirmed during the second week of infection by a positive Paul–Bunnell reaction, which detects heterophile antibodies (IgM) that agglutinate sheep erythrocytes, in around 90% of cases. False-positives can occur in other conditions, such as viral hepatitis, Hodgkin's lymphoma and acute leukaemia. The Monospot test is a sensitive and easily performed screening test for heterophile antibodies. Specific EBV IgM antibodies indicate recent infection by the virus. Clinically similar illnesses are produced by cytomegalovirus, toxoplasmosis and acute HIV infection (the so-called seroconversion illness) but these can be distinguished serologically.

**Management**

The majority of cases require no specific treatment and recovery is rapid. Corticosteroid therapy is advised when there is neurological involvement (e.g. encephalitis, meningitis, Guillain–Barré syndrome), when there is marked thrombocytopenia or haemolysis, or when the tonsillar enlargement is so marked as to cause respiratory obstruction.

**Cytomegalovirus infection**

Clinically significant cytomegalovirus (CMV) infection arises particularly in two patient groups: fetuses who acquire the infection transplacentally and are born congenitally infected, and patients who are immunosuppressed, such as transplant recipients or people with HIV infection. As with all herpesviruses, the virus persists for life, usually as a latent infection but one that may become reactivated, especially in immunocompromised patients. Over 50% of the adult population has serological evidence of latent CMV infection.

**Clinical features**

In healthy children and adults, CMV infection is usually asymptomatic but may cause an illness similar to infectious mononucleosis, with fever, occasionally lymphocytosis with atypical lymphocytes, and hepatitis with or without jaundice. The Paul–Bunnell test for heterophile antibody is negative. Infection may be spread in saliva (accounting for extensive person-to-person spread in childcare units), sexual intercourse or blood transfusion, and transplacentally to the fetus. Disseminated fatal infection with widespread visceral involvement occurs in the immunocompromised (see p. 352) and may cause encephalitis, retinitis, pneumonitis and diffuse involvement of the gastrointestinal tract.

Intrauterine infection may arise from either primary or reactivated maternal infection. CMV is, by far, the most common congenital infection; in developed countries, such as the UK, 0.3–1% of all babies are born congenitally infected with CMV. Around 5–10% of such babies have
severe disease evident at birth, with a poor prognosis. CNS involvement may cause microcephaly and motor disorders. Jaundice and hepatosplenomegaly are common and thrombocytopenia and haemolytic anaemia also occur. Periventricular calcification is seen on skull X-ray. A further 5–10% of infected babies are normal at birth but developmental abnormalities become apparent later: for example, sensorineural nerve deafness. The remaining 80–85% of infected babies are normal at birth and develop normally.

### Diagnosis

Serological tests can identify latent (IgG) or primary (IgM) infection. However, most infections are now diagnosed by detection and quantification of CMV DNA or RNA using molecular amplification techniques, in blood or other body fluid samples. The virus can also be identified in tissues by the presence of characteristic intranuclear ‘owl’s eye’ inclusions (*Fig. 11.21*) on histological staining and by direct immunofluorescence.

![FIGURE 11.21 Typical ‘owl’s eye’ inclusion-bearing cell infected with cytomegalovirus.](image)

### Management

In the immunocompetent, infection is usually self-limiting and no specific treatment is required. In the immunosuppressed, ganciclovir (5 mg/kg twice daily for 14–21 days) reduces retinitis and gastrointestinal damage, and can eliminate CMV from blood, urine and respiratory secretions. It is less effective against pneumonitis. In patients who are continually immunocompromised, maintenance therapy may be necessary. Drug resistance may arise during long-term therapy, such as in transplant recipients. Bone marrow toxicity is common. Valganciclovir, foscarnet and cidofovir are also available, and there are promising new drugs undergoing clinical trial including brincidofovir, maribavir and letermovir (see p. 244). Treatment of CMV in neonates is difficult, but therapy of infected babies with evident CNS
involvement has been shown to improve long-term hearing outcome, and 6 months of valganciclovir therapy is now recommended.

**Mumps**

Mumps is the result of infection with a paramyxovirus. It is spread by droplet infection, by direct contact or through fomites. Humans are the only known natural hosts. The peak period of infectivity is 2–3 days before the onset of the parotitis and for 3 days afterwards.

**Clinical features**

The incubation period averages 18 days. Although no age is exempt, it is primarily a disease of school-aged children and young adults; it is uncommon before the age of 2 years. The prodromal symptoms are non-specific and include fever, malaise, headache and anorexia. This is usually followed by severe pain over the parotid glands, with either unilateral or bilateral parotid swelling (**Fig. 11.22**). These enlarged glands obscure the angle of the mandible and may elevate the ear lobe, which does not occur in cervical lymph node enlargement. Trismus due to pain is common at this stage. Submandibular gland involvement occurs less frequently.

**Complications**

CNS involvement is the most common extrasalivary gland manifestation of mumps. Clinical
meningitis occurs in 5% of all infected patients, and 30% of patients with CNS involvement have no evidence of parotid gland involvement.

Epididymo-orchitis develops in about one-third of patients who develop mumps after puberty. Bilateral testicular involvement results in sterility in only a small percentage of these patients. Pancreatitis, oophoritis, myocarditis, mastitis, hepatitis and polyarthritis may also occur.

## Diagnosis and management

The diagnosis of mumps is on the basis of the clinical features. Viral RNA can be demonstrated by genome detection assays in saliva, throat swabs, urine and CSF. Serological demonstration of a mumps-specific IgM response in an acute blood or oral fluid sample is also diagnostic.

Treatment is supportive. Attention should be given to adequate nutrition and mouth care. Analgesics should be used to relieve pain.

## Prevention

Children in the UK are immunized with the live attenuated MMR vaccine (see Box 11.19) and the mumps vaccine is given in most developing countries. Vaccination is contraindicated in immunosuppressed individuals, during pregnancy, or in those with severe febrile illnesses.

## HIV infections

The human immunodeficiency viruses (HIV) belong to the Retrovirus family (Box 11.28), and are characterized by their ability to replicate through a DNA intermediate using the enzyme reverse transcriptase.

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus; HTLV, human T-cell lymphotropic virus.

HIV-1 and the related virus, HIV-2, are further classified as lentiviruses (‘slow’ viruses)
because of their slowly progressive clinical effects.

HIV-1 and HIV-2 give rise to the acquired immunodeficiency syndrome (AIDS) and are discussed on page 333.

Human T-cell lymphotropic virus type 1 (HTLV-1) causes adult T-cell leukaemia/lymphoma and tropical spastic paraparesis.

### Myocarditis and skeletal muscle infection

Enterovirus infection is a cause of acute myocarditis and pericarditis, from which, in general, there is complete recovery. However, these viruses can also cause chronic congestive cardiomyopathy and, rarely, constrictive pericarditis. Skeletal muscle involvement, particularly of the intercostal muscles, is a feature of Bornholm disease, a febrile illness usually due to Coxsackievirus B. The pain may be of such an intensity as to mimic pleurisy or an acute abdomen. The infection affects both children and adults and may be complicated by meningitis or cardiac involvement. Myocarditis and pericarditis are also discussed on pages 1036-1037 and 1043.

### Postviral/chronic fatigue syndrome

Many viral infections have been implicated aetiologically, including EBV, Coxsackie B viruses, echoviruses, CMV and hepatitis A virus. Non-viral causes, such as allergy to *Candida* spp., have also been proposed. Only a minority of patients have an identifiable precipitating infectious illness (see also p. 900).

### Virus Infections of the Nervous System
Poliovirus infection (poliomyelitis)

Poliomyelitis occurs when a susceptible individual is infected with poliovirus type 1, 2 or 3. These viruses have a propensity for the nervous system, especially the anterior horn cells of the spinal cord and cranial motor neurones. Spread is usually via the faeco-oral route, as the virus is excreted in the faeces.

Clinical features

The incubation period is 7–14 days. Although polio is essentially a disease of childhood, no age is exempt. The clinical manifestations vary considerably. The most common outcome (95% of individuals) is asymptomatic seroconversion.

- **Abortive poliomyelitis** occurs in approximately 4–5% of cases, characterized by the presence of fever, sore throat and myalgia. The illness is self-limiting and of short duration.

- **Non-paralytic poliomyelitis** (poliovirus meningitis) has features of abortive poliomyelitis, as well as signs of meningeal irritation, but recovery is complete.

- **Paralytic poliomyelitis** occurs in approximately 0.1% of infected children (1.3% of adults). Factors predisposing to the development of paralysis include male sex, exercise early in the illness, trauma, surgery or intramuscular injection, which localize the paralysis, and recent tonsillectomy (bulbar poliomyelitis).

  The paralytic form of the disease follows about 4–5 days after an initial illness simulating abortive poliomyelitis. Meningeal irritation and muscle pain recur and are followed by the onset of asymmetric flaccid paralysis without sensory involvement.

  Aspiration pneumonia, myocarditis, paralytic ileus and urinary calculi are late complications of poliomyelitis.

Diagnosis

The diagnosis is a clinical one. Distinction from Guillain–Barré syndrome is easily made by the absence of sensory involvement and the asymmetrical nature of the paralysis in poliomyelitis. Laboratory confirmation and distinction between the wild virus and vaccine strains is achieved by genome detection techniques, virus culture, neutralization and temperature marker tests.

Management

Management is supportive. Bed rest is essential during the early course of the illness. Respiratory support with intermittent positive-pressure respiration is required if the muscles of respiration are involved.

Prevention and control
In 1988, the World Health Assembly adopted the goal of eliminating poliomyelitis worldwide. Since then, the estimated 350 000 annual cases arising in 125 countries have been reduced by over 99%, with only Pakistan, Nigeria and Afghanistan never having terminated indigenous transmission. The eradication campaign has relied on improvements in sanitation, hygiene and the widespread use of polio vaccines. However, spread of infection via travel from endemic countries has led to the disease reappearing in a number of states, including China, Cameroon, Syria and Somalia, and in 2014, the WHO declared the spread of poliomyelitis to be a global public health emergency. The creation of a poliomyelitis-free world remains the goal, with a revised strategic plan to achieve this by 2018. Vaccination remains the bedrock of the campaign. New preparations of inactivated IM poliovirus vaccine (IPV) have greater potency than the original Salk IPV. The greater reliability of IPV in hot climates and the scientific and ethical problems of continuing to use oral polio vaccine (OPV) in countries free from poliomyelitis mean that IPV has replaced OPV in the routine immunization schedules in many countries.

### Coxsackievirus, echovirus and other enterovirus infections

These viruses are also spread by the faeco-oral route. They each have a number of different types and are responsible for a broad spectrum of disease involving the skin and mucous membranes, muscles, nerves, heart (Box 11.29) and, rarely, other organs, such as the liver and pancreas. They are frequently associated with pyrexial illnesses and are the most common cause of aseptic meningitis.

Clinical features

• **Neurological disease.** Other enteroviruses in addition to poliovirus can cause a broad range of neurological disease, including meningitis, encephalitis and a paralytic disease similar to poliomyelitis. EV71, more usually associated with hand, foot and mouth disease, has a particular predilection for neuroinvasion. Epidemics of EV71 are not infrequent; an estimated 6 million cases have occurred globally in the past 10 years, with over 2000 deaths from a variety of serious neuromotor syndromes. An inactivated EV71 vaccine has shown promising results in recent trials in China.

• **Meningitis and encephalitis.** Many virus infections may result in either meningitis or an encephalitic illness (Box 11.30). The latter may arise by direct virus invasion of nervous tissue, or by induction of an aberrant cross-reactive immune response (post-infectious encephalitis). Encephalitis due to herpes simplex virus is described on page 865.

**Encephalitis, post-infectious**

May arise from a number of different virus infections including measles (1 in 1000–5000 cases of measles), influenza, varicella zoster

---

**Japanese encephalitis**

Japanese encephalitis is a mosquito-borne encephalitis caused by a flavivirus. It has been reported most frequently from the rice-growing countries of South-east Asia and the Far East. *Culex tritaeniorhynchus* is the usual vector and this feeds mainly on pigs, as well as birds such as herons and sparrows. Humans are accidental hosts.

The incubation period is 5–15 days. Most infections are asymptomatic. When disease arises, the onset is heralded by severe rigors. Fever, headache and malaise last 1–6 days. Weight loss
is prominent. In the acute encephalitic stage, the fever is high (38–41°C), neck rigidity occurs and neurological signs, such as altered consciousness, hemiparesis and convulsions, develop. Mental deterioration occurs over a period of 3–4 days and culminates in coma. Mortality varies from 7% to 40% and is higher in children. Residual neurological defects, such as deafness, emotional lability and hemiparesis, occur in about 70% of patients who have had CNS involvement. Convalescence is prolonged. Antibody detection in serum and CSF by IgM capture ELISA is a useful rapid diagnostic test. Vaccines containing formalin-inactivated viruses derived from mouse brain are effective and available. Management is supportive.

West Nile encephalitis

In 1999, West Nile virus was first recognized in the Western hemisphere (New York, USA) having been previously reported in Africa, Asia and parts of Europe. By the end of 2009, the US outbreak had resulted in over 25,000 human cases and over 1100 deaths. The vast majority of infections are asymptomatic. In a minority of cases, infection presents as a febrile illness with a maculopapular rash, 1% resulting in severe encephalitis. Disease severity and mortality are age-related, being greatest in the elderly. The primary hosts of infection are birds. It is spread by mosquitoes and may also infect humans and horses. It can also be transmitted by blood transfusions, breast-feeding and organ donation from an infected individual. Diagnosis is by genome detection in appropriate samples, or specialized serology for the detection of IgM virus-specific antibodies.

Tick-borne encephalitis

This arises from infection with a flavivirus (actually a series of closely related viruses) transmitted by Ixodes spp. ticks. It occurs in an area extending from Western Europe to Japan. The tick is the main reservoir for the virus, which is transmitted when it feeds on mice and other rodents.

The disease starts 4–28 days after a bite from an infected tick and is biphasic in 80% of patients. Fever, malaise, headache and fatigue are followed, after a symptom-free period of about 7 days, by encephalitis. There may be associated limb paralysis, which is due to anterior horn cell involvement mainly of the cervical region. Cranial nerve involvement also occurs. Tick-borne encephalitis virus (TBEV) IgM and IgG antibodies are present and the virus can be detected in blood by reverse transcription polymerase chain reaction (RT-PCR). Overall mortality is about 1% (but can be considerably higher for certain strains); 30% have impairment in neurological function with persistent paralysis in 6%. A preventative vaccine is available.

Lymphocytic choriomeningitis

This infection is a zoonosis, the natural reservoir of lymphocytic choriomeningitis (LCM) virus (an arenavirus; see Box 11.22) being the house mouse. Infection is by inhalation from urine-
contaminated rubbish and is characterized by:
- non-nervous-system illness, with fever, malaise, myalgia, headache, arthralgia and vomiting
- meningitis in addition to the above symptoms.

Occasionally, a more severe form occurs, with encephalitis leading to disturbance of consciousness.
This illness is generally self-limiting and requires no specific treatment.

### Hendra and Nipah virus infection

Hendra virus and Nipah virus are zoonotic viruses that have caused disease in humans who have been in contact with infected animals (horses and pigs, respectively). The viruses are named after the locations where they were first isolated – Hendra in Australia and Nipah in Malaysia – and both are classified as paramyxoviruses. Hendra virus has caused severe respiratory distress in horses and humans, and Nipah virus caused a major outbreak of viral encephalitis (265 cases and 105 deaths) in Malaysia between September 1998 and April 1999. Management of these conditions is largely supportive, although there is some evidence that early treatment with ribavirin may reduce their severity.

### Rabies

Rabies is a major problem in some countries, with an estimated 55,000 deaths per year worldwide. Established infection is almost invariably fatal; there are only a handful of recorded cases of survival from clinical rabies. It is caused by the rabies virus, a single-stranded RNA virus of the Lyssavirus genus. The virus is bullet-shaped and has spike-like structures arising from its surface containing glycoproteins that cause the host to produce neutralizing, haemagglutination-inhibiting antibodies. The virus has a marked affinity for nervous tissue and the salivary glands. It exists in two major epidemiological settings:
- **Urban rabies** is most frequently transmitted to humans through rabid dogs and, less frequently, cats.
- **Sylvan (wild) rabies** is maintained in the wild by a host of animal reservoirs such as foxes, skunks, jackals, mongooses and bats.

With the exception of Australia, New Zealand and the Antarctic, human rabies has been reported from all continents. Transmission is usually through the bite of an infected animal. However, the percentage of rabid bites leading to clinical disease ranges from 10% (on the legs) to 80% (on the head). Other forms of transmission, if they occur, are rare.

Virus replicates in the muscle cells near the entry wound. It penetrates the nerve endings and travels in the axoplasm to the spinal cord and brain. In the CNS, the virus again proliferates before spreading to the salivary glands, lungs, kidneys and other organs via the autonomic nerves.
Clinical features

The incubation period is variable, ranging from a few weeks to several years; on average, it is 1–3 months. In general, bites on the head, face and neck have a shorter incubation period than those elsewhere. In humans, two distinct clinical varieties of rabies are recognized:

• **Furious rabies** – the classic variety. The only characteristic feature in the prodromal period is the presence of pain and tingling at the site of the initial wound. Fever, malaise and headache are also present. About 10 days later, marked anxiety and agitation or depressive features develop. Hallucinations, bizarre behaviour and paralysis may also occur. Hyperexcitability, the hallmark of this form of rabies, is precipitated by auditory or visual stimuli. Hydrophobia (fear of water) is present in 50% of patients and is due to severe pharyngeal spasms on attempting to eat or drink. Aerophobia (fear of air) is considered pathognomonic of rabies. Examination reveals hyper-reflexia, spasticity and evidence of sympathetic overactivity indicated by pupillary dilatation and diaphoresis. The patient goes on to develop convulsions, respiratory paralysis and cardiac arrhythmias. Death usually occurs in 10–14 days.

• **Dumb rabies** – the paralytic variety. Dumb rabies, or paralytic rabies, presents with a symmetrical ascending paralysis resembling the Guillain–Barré syndrome. This variety of rabies commonly occurs after bites from rabid bats.

Diagnosis

The diagnosis of rabies is generally made clinically. Skin-punch biopsies are used to detect antigen with an immunofluorescent antibody test on frozen section. Viral RNA can be isolated using RT-PCR. Isolation of viruses from saliva or the presence of antibodies in blood or CSF may establish the diagnosis. The corneal smear test is not recommended, as it is unreliable. The classic Negri bodies are detected at postmortem in 90% of all patients with rabies; these are eosinophilic, cytoplasmic, ovoid bodies, 2–10 nm in diameter, seen in greatest numbers in the neurones of the hippocampus and the cerebellum. The diagnosis should be made pathologically on the biting animal using RT-PCR, immunofluorescence assay (IFA) or tissue culture of the brain.

Management

Once the CNS disease is established, therapy is symptomatic, as death is virtually inevitable. The patient should be nursed in a quiet, darkened room. Nutritional, respiratory and cardiovascular support may be necessary.

Drugs such as morphine, diazepam and chlorpromazine should be used liberally in patients who are excitable.

Prevention and control
Pre-exposure prophylaxis
This is given to individuals with a high risk of contracting rabies, such as laboratory workers, animal handlers and veterinarians. Three doses of human diploid (HDCV) or chick embryo cell vaccine, given by deep subcutaneous or intramuscular injection on days 0, 7 and 28, provide effective immunity. A reinforcing dose is given after 12 months and additional reinforcing doses are given every 3–5 years, depending on the risk of exposure. Vaccines of nervous tissue origin are still used in some parts of the world. These, however, are associated with significant side-effects and should not be used if HDCV is available.

Post-exposure prophylaxis
The wound should be cleaned carefully and thoroughly with soap and water, and left open. Human rabies immunoglobulin should be given immediately (20 IU/kg); half should be injected around the area of the wound and the other half should be given intramuscularly. Five 1.0-mL doses of HDCV should be given intramuscularly: the first dose is given on day 0 and is followed by injections on days 3, 7, 14 and 28. Reaction to the vaccine is uncommon.

Control
Domestic animals should be vaccinated if there is any risk of rabies in the country. In the UK, control has been by quarantine of imported animals for 6 months and no indigenous case of rabies has been reported for many years. The Pet Travel Scheme (PETS) enables certain pet animals to enter or re-enter Great Britain without quarantine if they come from qualifying countries via designated routes, are carried by authorized transport companies and meet the conditions of the scheme. Wild animals in ‘at-risk’ countries must be handled with great care.

Progressive multifocal leucoencephalopathy
JC virus, a polyomavirus, is the cause of progressive multifocal leucoencephalopathy (PML), which presents as dementia in the immunocompromised and is due to progressive cerebral destruction resulting from accumulation of the virus in brain tissue. The virus is acquired usually in childhood, and may reactivate if the host immune system becomes compromised in later life. Reactivation of JC virus and development of PML have recently been described in multiple sclerosis patients treated with the monoclonal antibody, natalizumab, directed against the cell adhesion molecule, α4 integrin.

Virus Infections of the Gastrointestinal Tract

Virus infections that commonly result in acute gastroenteritis (diarrhoea and vomiting) are listed in Box 11.31.

---

**Box 11.31**

**Viruses associated with gastroenteritis**

- Rotaviruses (groups A, B and C)
- Enteric adenoviruses (types 40 and 41)
- Caliciviruses (includes noroviruses and sapoviruses)
- Astroviruses

---

**Rotavirus infection**

Rotaviruses are a major cause of infantile gastroenteritis worldwide. The virus (Latin *rota* = wheel) is so named because of its electron microscopic appearance with a characteristic circular outline and radiating spokes (*Fig. 11.23*). It belongs to the reovirus family, which have double-stranded RNA segmented genomes. More than 500,000 infected children under the age of 5 years are estimated to die annually in resource-deprived countries, compared with 75–150 in the USA. The prevalence is higher during the winter months in non-tropical areas. Asymptomatic infections are common and bottle-fed babies are more likely to be symptomatic than those that are breast-fed.

---

**FIGURE 11.23**  Electron micrograph of human rotavirus.

Adults may become infected with rotavirus but symptoms are usually mild or absent. The
virus may, however, cause diarrhoea in immunosuppressed adults, or outbreaks in patients on care of the elderly wards.

Clinical features

The illness is characterized by vomiting, fever, diarrhoea and the metabolic consequences of water and electrolyte loss.

Diagnosis and differential diagnosis

The diagnosis can be established by PCR for genome detection, or ELISA for the detection of rotavirus antigen in faeces and by electron microscopy of faeces. Histology of the jejunal mucosa in children shows shortening of the villi, with crypt hyperplasia and mononuclear cell infiltration of the lamina propria.

Management and prevention

Management is directed at overcoming the effects of water and electrolyte imbalance with adequate oral rehydration therapy and, when indicated, intravenous fluids (Box 11.32). Antibiotics should not be prescribed. A controlled trial in Egypt in children with rotavirus diarrhoea demonstrated faster recovery (31 h versus 75 h) in those given nitazoxanide, a broad-spectrum anti-infective agent, for 3 days compared with placebo.

Box 11.32

Oral rehydration solutions (ORS) and intravenous solutions used in moderate and severe diarrhoea
### Rotavirus vaccines

Despite a major setback when the first licensed rotavirus vaccine was rapidly withdrawn from the market in 1999 following reports of increased rates of intussusception, two new vaccines have been developed and are now used in many countries. Both are live vaccines. One (Rotarix) contains an attenuated human strain, the relevant antigens being P[8] and G1; the other (Rotateq) is based on a bovine parent strain and comprises five single-gene reassortants, each containing a human-strain outer capsid gene encoding the most common human antigenic types (P[8] and G1–4). Routine rotavirus vaccination was introduced in the UK in 2012, following which the first full year’s data demonstrated a 71% drop in laboratory-confirmed cases.

### Calicivirus infection

The caliciviruses are an extensive virus family, named after the cup-shaped (Latin *calyx* = cup) indentations on their viral surface seen by electron microscopy. The family contains four genera, two of which, the noroviruses and sapoviruses, infect humans and cause gastroenteritis.  

*Norovirus* is the major cause of acute non-bacterial gastroenteritis, causing outbreaks in nursing homes, hospitals, schools, leisure centres, restaurants and cruise ships. In countries that have adopted routine rotavirus vaccination of infants, norovirus has become the leading cause of clinically significant acute gastroenteritis in children. Transmission is mostly faeco-oral with outbreaks suggesting a common source, such as food and water, and fomites. Aerosol transmission also occurs and noroviruses can be detected in vomit. Illness is usually self-limiting (12–48 h) and mild, consisting of nausea, headache and abdominal cramps, followed by diarrhoea and vomiting, which may be the only feature (winter vomiting). Diagnosis is by
demonstration of viral nucleic acid or antigen in diarrhoeal faeces. Treatment is with oral rehydration solutions. Prevention can be difficult but hand-washing and good hygienic food preparation are required.

*Sapovirus* causes gastroenteritis, mainly in children.

**Further reading**

**Viral Hepatitis**

A number of distinct virus infections may result in inflammation of the liver (hepatitis). The viruses belong to different virus families, are spread by different routes, and may have differing clinical consequences (see *Box 14.5*). Viral hepatitis is discussed further on pages 452-461.

**Viruses and Malignant Disease**

Around 15–20% of all human malignant disease arises from infection. Recognition of the infectious cause of a particular cancer raises the possibility of developing an anti-cancer vaccine, as has now happened for both hepatitis B virus and human papillomavirus.

**Hepatitis viruses and primary hepatocellular carcinoma**

Globally, hepatocellular carcinoma is amongst the most common causes of death due to malignant disease. A high percentage arises in patients infected with either hepatitis B or C viruses. These are discussed in more detail on page 485.

**Human papillomaviruses and cancer of the uterine cervix**

Papillomaviruses tend to produce chronic infections (see also p. 318). Human papillomaviruses (HPVs), of which there are at least 100 types, are responsible for the common skin and genital warts, and certain types (mainly 16 and 18) are the cause of carcinoma of the cervix and some oral cancers (type 16). Vaccines against HPV types 16 and 18 are available. The current recommendations in many countries are for vaccination of all girls at age 9–14 years. It may also be sensible to vaccinate boys but this strategy is much less cost-effective. (For *genital warts*, see p. 326.)
Epstein–Barr virus and malignant disease
EBV infection has been associated with a number of malignant diseases, including Burkitt's lymphoma, undifferentiated nasopharyngeal carcinoma, post-transplant lymphoma, the immunoblastic lymphoma of AIDS patients, some forms of Hodgkin's lymphoma and gastric cancer. Different levels of expression of EBV latency genes occur in these proliferative conditions caused by the virus, and various co-factors are also involved in their pathogenesis; for example, in Burkitt's lymphoma, the most common tumour of childhood in sub-Saharan Africa, epidemiological evidence points to an interplay between EBV infection and the presence of hyperendemic (i.e. present all year round) malaria.

Kaposi's sarcoma and human herpesvirus type 8
HHV-8 is strongly associated with the aetiology of all forms of Kaposi’s sarcoma. Antibody prevalence is high in those with tumours but relatively low in the general population of most industrialized countries. High rates of infection (>50% population) have been described in Central and Southern Africa, and this matches the geographical distribution of classical Kaposi's sarcoma before the era of AIDS. HHV-8 is transmitted sexually and through exposure to blood from needle sharing. It is thought that salivary transmission may be the predominant route in Africa. HHV-8 RNA transcripts have been detected in Kaposi's sarcoma cells and in circulating mononuclear cells from patients with the tumour. This virus also has an aetiological role in two rare lymphoproliferative diseases: multicentric Castleman’s disease (a disorder of the plasma cell type) and primary effusion lymphoma (body-cavity-based lymphoma), which is characterized by pleural, pericardial or peritoneal lymphomatous effusions in the absence of a solid tumour mass.

Other rare malignancies due to virus infection
HTLV-1, a lentivirus belonging to the same virus family as HIV, is the aetiological agent of adult T-cell leukaemia/lymphoma. Merkel cell polyomavirus has been identified in the malignant tissue of the rare Merkel cell carcinoma of the skin.

Viral Haemorrhagic Fevers
These comprise infection with a range of different viruses (Box 11.33), which have in common the clinical feature of haemorrhagic manifestations.
### Viral infections associated with haemorrhagic manifestations

#### Flavivirus
- Yellow fever (urban and sylvan)
- Dengue haemorrhagic fever
- Kyasanur Forest disease
- Omsk haemorrhagic fever

#### Bunyavirus
- Rift Valley fever
- Congo–Crimean haemorrhagic fever
- Hantavirus infections

#### Arenavirus
- Argentinian haemorrhagic fever
- Bolivian haemorrhagic fever
- Lassa fever
- Epidemic haemorrhagic fever

#### Filovirus
- Marburg
- Ebola

---

*Most of these are arboviruses. Some (e.g. Hantavirus, Lassa fever) have a rodent vector. The source and transmission route of filoviruses are not known.*

---

### Yellow fever

Yellow fever, caused by a flavivirus, is an illness of widely varying severity. It is confined to Africa (90% of cases) and South America between latitudes 15°N and 15°S. For poorly understood reasons, yellow fever has not been reported from Asia, despite the fact that climatic conditions are suitable and the vector, *Aedes aegypti*, is common. The infection is transmitted in the wild by *A. africanus* in Africa and the *Haemagogus* species in South and Central America. Extension of infection to humans (via the mosquito from monkeys) leads to the occurrence of ‘jungle’ yellow fever. *A. aegypti*, a domestic mosquito that lives in close relationship to humans, is responsible for human-to-human transmission in urban areas (urban yellow fever). Once infected, a mosquito remains so for life.
Clinical features

The incubation period is 3–6 days. Mild infection is indistinguishable from other viral fevers such as influenza or dengue.

Three phases in the severe (classical) illness are recognized. Initially, the patient presents with a high fever of acute onset, usually 39–40°C, which then returns to normal in 4–5 days. During this time, headache is prominent. Retrobulbar pain, myalgia, arthralgia, a flushed face and suffused conjunctivae are common. Epigastric discomfort and vomiting are present when the illness is severe. Relative bradycardia (Faget's sign) is present from the second day of illness. The patient then makes an apparent recovery and feels well for several days. Following this ‘phase of calm’, the patient again develops increasing fever, deepening jaundice and hepatomegaly. Ecchymosis, bleeding from the gums, haematemesis and melaena may occur. Coma, which is usually a result of uraemia or haemorrhagic shock, occurs for a few hours preceding death. The mortality rate is up to 40% in severe cases. The pathology of the liver shows mid-zone necrosis and eosinophilic degeneration of hepatocytes (Councilman bodies; see pp. 451–452).

Diagnosis and management

The diagnosis is established by a history of travel and vaccination status and by isolation of the virus (when possible) from blood during the first 3 days of illness. Serodiagnosis is possible, but in endemic areas cross-reactivity with other flaviviruses is a problem.

Management is supportive. Bed rest (under mosquito nets), analgesics and maintenance of fluid and electrolyte balance are required.

Prevention and control

Yellow fever is an internationally notifiable disease. It is easily prevented by using the attenuated 17D chick embryo vaccine but concerns over safety have arisen because of infection with the 17D virus. Vaccination is not recommended for children under 9 months or immunosuppressed patients, unless there are compelling reasons. For the purposes of international certification, immunization is valid for 10 years, but protection lasts much longer than this and probably for life. The WHO Expanded Programme of Immunization includes yellow fever vaccination in endemic areas.

Congo–Crimean haemorrhagic fever

Congo–Crimean haemorrhagic fever (CCHF) virus belongs to the Nairovirus genus of the family Bunyaviridae. This family contains more than 200 viruses, grouped into a number of genera, most of which are arthropod-borne.

The disease CCHF is found mainly in Asia and Africa. The primary hosts are cattle and hares, and the vectors are the Hyalomma ticks. Following an incubation period of 3–6 days,
there is an influenza-like illness with fever and haemorrhagic manifestations. The mortality is 10–50%.

**Hantavirus infection**

Hantaviruses belong to the Hantavirus genus of Bunyaviridae and are enzootic viruses of wild rodents, which are spread by aerosolized excreta and not by insect vectors. The most severe form of this infection is Korean haemorrhagic fever (also known as haemorrhagic fever with renal syndrome, HFRS). This condition has a mortality of 5–10% and is characterized by fever, shock and haemorrhage followed by an oliguric phase. Milder forms of the disease are associated with related viruses (e.g. Puumala virus) and may present as nephropathia epidemica, an acute fever with renal involvement, seen in Scandinavia and in other European countries in people who have been in contact with bank voles. In the USA, a hantavirus (transmitted by the deer mouse) termed Sin Nombre was identified as the cause of outbreaks of acute respiratory disease (hantavirus pulmonary syndrome, HPS) in adults. Other hantavirus types and rodent vector systems have been associated with this syndrome.

Diagnosis of hantavirus infection is made by an ELISA technique for specific antibodies.

**Rift Valley fever**

Rift Valley fever, caused by a virus from the Phlebovirus genus of the Bunyaviridae, is primarily an acute febrile illness of livestock: sheep, goats and camels. It is found in southern and eastern Africa. The vector in East Africa is *Culex pipiens* and in southern Africa, *Aedes caballus*, but disease can be transmitted by the bite of an infected animal. Following an incubation period of 3–6 days, the patient has an acute febrile illness that is difficult to distinguish clinically from other viral fevers. The temperature pattern is usually biphasic. The initial febrile illness lasts 2–4 days and is followed by a remission and a second febrile episode. Complications are indicative of severe infection and include retinopathy, meningoencephalitis, haemorrhagic manifestations and hepatic necrosis. Mortality approaches 50% in severe forms of the illness. Management is supportive. Animals can be vaccinated.

**Lassa fever**

Lassa fever virus belongs to the Arenavirus family. Arenaviruses are pleomorphic, round or oval viruses with diameters ranging from 50 to 300 nm. The virion surface has club-shaped projections and the virus itself contains a variable number of characteristic electron-dense granules that represent residual, non-functional host ribosomes. The illness called Lassa fever was first documented in the town of Lassa, Nigeria, in 1969 and is confined to sub-Saharan West Africa (Nigeria, Liberia and Sierra Leone). The multimammate rat, *Mastomys natalensis*, is known to be the reservoir. Humans are infected by ingesting foods contaminated by rat urine or saliva containing the virus. Person-to-person spread by body fluids also occurs. Only 10–30% of infections are symptomatic. Related arenaviruses are the causative agents of
Argentinian and Bolivian haemorrhagic fevers.

Clinical features

The incubation period is 7–18 days. The disease is insidious in onset and is characterized by fever, myalgia, severe backache, malaise and headache. A transient maculopapular rash may be present. A sore throat, pharyngitis and lymphadenopathy occur in over 50% of patients. In severe cases, epistaxis and gastrointestinal bleeding may occur, hence the classification of Lassa fever as a viral haemorrhagic fever. The fever usually lasts 1–3 weeks, and recovery within 1 month of the onset of illness is usual. However, death occurs in 15–20% of hospitalized patients, usually from irreversible hypovolaemic shock.

Diagnosis

The diagnosis is established by serial serological tests (including the Lassa virus-specific IgM titre) or by genome detection by means of RT-PCR in throat swab, serum or urine.

Management

Management is supportive. In addition, clinical benefit and reduction in mortality can be achieved with ribavirin therapy, if given in the first week.

In non-endemic countries, strict isolation procedures should be used, the patient ideally being nursed in a flexible-film isolator. Specialized units for the management of Lassa fever and other haemorrhagic fevers have been established in the UK. As Lassa fever virus and other causes of haemorrhagic fever (Marburg/Ebola and Congo–Crimean haemorrhagic fever viruses; Box 11.33) have been transmitted from patients to staff in healthcare situations, great care should be taken in handling specimens and clinical material from these patients.

Marburg virus disease and Ebola virus disease

These severe haemorrhagic, febrile illnesses are discussed together because their clinical manifestations are similar, and the causative negative-strand RNA viruses belong to the same virus family, the Filoviridae, so called because the viruses have a filamentous appearance on electron microscopy. The diseases are named after Marburg in Germany and the Ebola river region in the Sudan and Zaire, where these viruses first appeared. The natural reservoir for these viruses has not been identified and the precise mode of spread from one individual to another has not been elucidated. Five distinct species of Ebola virus have been identified, which vary in terms of case fatality rates: less than 40% for Bundibugyo, 50% for Sudan, and 70–90% for Zaire Ebola viruses. There has only been one (non-fatal) case of Tai Forest Ebola virus infection. Reston Ebola virus, the only Asian species, has not been associated with human mortality.

Epidemics have occurred periodically in recent years, mainly in sub-Saharan Africa. Ebola
viruses are zoonotic pathogens, with fruit bats thought to be the natural host. The illness is characterized by the acute onset of severe headache, myalgia, vomiting and high fever, followed by prostration. On about the fifth day of illness, a non-pruritic maculopapular rash develops on the face and then spreads to the rest of the body. Diarrhoea is profuse and is associated with abdominal cramps and vomiting. Haematemesis, melaena or haemoptysis may occur between the seventh and sixteenth days. Hepatosplenomegaly and facial oedema are usually present. In Ebola virus disease, chest pain and a dry cough are prominent symptoms.

In August 2014, the WHO declared the ongoing outbreak of Zaire Ebola virus infection in West Africa a public health emergency of international concern, with an estimated several thousand deaths. Guinea, Sierra Leone and Liberia were the worst affected countries. Treatment is symptomatic, although a number of experimental therapies, mostly focused on monoclonal antibodies, are being tried. Experimental vaccines are also being developed. In the absence of effective therapy, accurate diagnosis and infection control precautions are the only intervention strategies. Lack of infrastructure to support rapid molecular diagnostic techniques, and to allow institution of the meticulous patient isolation necessary to interrupt human-to-human transmission of infection, has contributed to generating the largest outbreak yet recorded. Asymptomatic people may be infected but have a low viral count, making transmission unlikely.
Transmissible Spongiform Encephalopathies (Prion Diseases)

Transmissible spongiform encephalopathies (TSEs) are caused by the accumulation in the nervous system of a protein, termed a ‘prion’, which is an abnormal isoform (PrPSc) of a normal host protein (PrPc).

Although familial forms of prion disease are known to exist, these conditions can be transmissible, particularly if brain tissue enters another host. There is no convincing evidence for the presence of nucleic acid in association with prions; thus these agents cannot be considered orthodox viruses and it is the abnormal prion protein itself that is infectious and can trigger a conversion of the normal protein into the atypical isoform. After infection, a long incubation period is followed by CNS degeneration associated with dementia or ataxia, which invariably leads to death. Histology of the brain reveals spongiform change with an accumulation of the abnormal prion protein in the form of amyloid plaques.

The human prion diseases are Creutzfeldt–Jakob disease, including the sporadic, familial, iatrogenic and variant forms of the disease, Gerstmann–Straussler–Scheinker syndrome, fatal familial insomnia and kuru.

• **Creutzfeldt–Jakob disease (CJD).** CJD usually occurs sporadically worldwide with an annual incidence of 1 per million of the population. Although, in most cases, the epidemiology remains obscure, iatrogenic transmission to others has occurred as a result of administration of human cadaveric growth hormone or gonadotrophin, from dura mater and corneal grafting and in neurosurgery from reuse of contaminated instruments and electrodes (iatrogenic CJD).

• **Variant CJD (vCJD).** In the UK, knowledge that large numbers of cattle with the prion disease, bovine spongiform encephalopathy (BSE), had gone into the human food chain, led to enhanced surveillance for emergence of the disease in humans. Based on transmission studies in mice and on glycosylation patterns of prion proteins, the evidence is convincing that this has occurred and, to date, there have been approximately 170 confirmed and suspected cases of vCJD (human BSE) in the UK and 40 in the rest of the world. In contrast to sporadic CJD, which presents with dementia at a mean age of onset of 60 years, vCJD presents with ataxia, dementia, myoclonus and chorea at a mean age of onset of 29 years. The epidemic curves of BSE and vCJD in the UK and Europe are shown in Figure 11.24, with very few UK cases identified in the last 5 years.
**Gerstmann–Straussler–Scheinker syndrome** and **fatal familial insomnia**. These are rare prion diseases, usually occurring in families with a positive history. The pattern of inheritance is autosomal dominant with some degree of variable penetrance. The gene encoding PrP<sup>C</sup> in these families often contains mutations.

**Kuru.** This disease was described and characterized in the Fore highlanders in north-east New Guinea. Transmission was associated with ritualistic cannibalism of deceased relatives. With the cessation of cannibalism by 1960, the disease has gradually diminished and recent cases had all been exposed to the agent before 1960.

The infectious agents of prion disease have remarkable characteristics. In the infected host there is no evidence of inflammatory, cytokine or immune reactions. The agent is highly resistant to decontamination, and infectivity is not reliably destroyed by autoclaving or by treatment with formaldehyde and most other gas or liquid disinfectants. It is very resistant to γ-irradiation. Autoclaving at a high temperature (134–137°C for 18 min) is used for decontamination of instruments and hypochlorite (20 000 p.p.m. available chlorine) or 1 molar sodium hydroxide is used for liquid disinfection. Uncertainty about the reliability of any methods for safe decontamination of surgical instruments has necessitated the introduction of guidelines for patient management.

**Bacterial Infections**
**Classification of bacteria**

Bacteria are unicellular organisms (prokaryotes), of which only a small fraction are of medical relevance. They have traditionally been classified according to the Gram stain, which distinguishes Gram-positive from Gram-negative organisms. Using light microscopy, these can then largely be divided into cocci (spheres) and bacilli (rods). Some have a spiral appearance (spirochaetes) while others, such as *Clostridium* spp., may produce spores *(Box 11.34)*.

- **Gram-positive organisms.** The cell-wall arrangement of Gram-positive cocci contains a phospholipid bilayer surrounded by peptidoglycan made up of repeating units of \(N\)-acetylglucosamine and \(N\)-acetylmuramic acid.

- **Gram-negative organisms.** Gram-negative bacilli possess a second outer lipid bilayer containing protein and lipopolysaccharide (endotoxin).

### Box 11.34

**Classification of bacteria affecting humans**
### Genetic classification

Genetic classification is redefining bacteria in terms of DNA sequence information and has led to the reclassification of several bacterial species.

### Culturing bacteria

Bacteria can often be cultured in broth or on solid agar. Those growing in the absence of oxygen are strict anaerobes (e.g. *Bacteroides* spp.), while oxygen-dependent bacteria are known as aerobes (e.g. *Pseudomonas* spp.). Many pathogens can tolerate reduced concentrations of oxygen (e.g. *E. coli*). Some organisms are more demanding in their growth requirements and require special laboratory media (e.g. *Mycoplasma* spp. and *Mycobacterium* spp.); others require more prolonged incubation (e.g. *Brucella* spp.).

The history and examination usually localize the infection to a specific organ or body site. A systemic response may accompany such localized disease or, in the case of bloodstream infections, be the primary mode of presentation. The microbiological diagnosis is difficult to establish in most community-managed infections; even in hospital, where there is ready access to diagnostic laboratories, only a minority of infections are identified. In practice, most bacterial infections are initially diagnosed and managed empirically, with a precise microbiological diagnosis made later, if at all.

**Bacterial Infections of the Skin and Soft Tissues**

**Superficial infections**

Infections of the skin and the soft tissues beneath are common. These are usually bacterial or fungal (see pp. 1345–1347). Most skin and soft tissue infections are caused by the Gram-positive cocci *Staphylococcus aureus* and *Streptococcus pyogenes*, although many other species have been implicated (*Box 11.35*).

---

The classification of soft tissue infections is complex, because imprecise and overlapping terms are in use. (The commonly encountered infections are described in more detail on pp. 285–288.)

The majority of skin and superficial soft tissue infections are due to bacteria on the skin surface penetrating the dermis or the subcutaneous tissues. Infection can take place via hair follicles, insect bites, cuts and abrasions or skin damaged by superficial fungal infection. Sometimes infection is introduced by an animal bite or a penetrating foreign body; in these cases, more unusual organisms may be found. A number of factors predispose to cellulitis and
other soft tissue infections (Box 11.36).

### Box 11.36

**Predisposing factors for skin and soft tissue infection**

- Diabetes mellitus
- Chronic lymphoedema
- Peripheral vascular disease
- Venous ulcers
- Steroid treatment
- Malnutrition
- Some immunodeficiency states (e.g. Job syndrome)
- Nasal carriage of *Staphylococcus aureus*

### *Staphylococcus aureus* infection

*Staphylococci* are part of the normal microflora of the human skin and nasopharynx; up to 25% of people are carriers of *Staph. aureus*, the species responsible for the majority of staphylococcal infections. Other species of staphylococci are only rarely pathogenic. Although soft tissue infections are the most common manifestation of *Staph. aureus* disease, numerous other sites can be affected (see Box 11.6).

### Invasive staphylococcal infection

Invasive staphylococcal infection is often associated with breaches in the skin: for example, due to injecting drug use, iatrogenic cannulation, surgery or trauma. In clinical situations, scrupulous attention to disinfection and hygiene when performing invasive procedures can minimize the risk of infection (see the Matching Michigan programme, ‘Further reading’). Although *Staph. aureus* is the most common species of staphylococci implicated in catheter-related infections, other normally non-pathogenic species, such as *Staph. epidermidis* (which is often intrinsically resistant to flucloxacillin), may be found. Flucloxacillin remains the first-choice antibiotic in staphylococcal infection when the organism is known to be sensitive, but with the increasing prevalence of meticillin-resistant *Staph. aureus* (MRSA), other agents are often needed. Other options in uncomplicated cellulitis include clindamycin and clarithromycin, while, for more serious infections (or when MRSA is suspected), agents include glycopeptides, linezolid and daptomycin.

### Staphylococcal virulence factors

*Staph. aureus* can produce a variety of toxins and virulence factors that affect the type and severity of infection. These include staphylococcal enterotoxin A, superantigenic
Staphylococcal exotoxins, toxic shock toxin 1 and Panton Valentine leucocidin (PVL). The last of these has been found mainly in community-associated strains of Staph. aureus (both MRSA and meticillin-sensitive MSSA), rather than in hospital-acquired or epidemic strains. Community-associated PVL-producing MRSA and MSSA are becoming an increasingly common cause of invasive soft tissue and lung infections in some countries (notably the USA), although it is unclear whether PVL itself is directly responsible for the increased virulence.

**Meticillin-resistant Staphylococcus aureus**

*Staph. aureus* is commonly resistant to penicillin, and isolated resistance to other β-lactam antibiotics, such as meticillin (now rarely used) and flucloxacillin, has been recognized since the development of the first semi-synthetic penicillins in the early 1960s. However, in the last 40 years, strains of meticillin-resistant *Staphylococcus aureus* (MRSA) with resistance to a much wider range of antibiotics have emerged. In some cases, only the glycopeptide antibiotics, vancomycin and teicoplanin, are effective (along with the new agents discussed below) and a few organisms have been isolated with decreased sensitivity even to these.

Vancomycin-insensitive *Staph. aureus* (VISA) develops because the organism produces a thick cell wall by changing the synthesis of cell-wall material. Vancomycin-resistant *Staph. aureus* (VRSA) acquires resistance by receiving the *van A* gene from vancomycin-resistant enterococci (see Fig. 11.4).

Apart from the glycopeptides, such as vancomycin, four other *classes of antibiotic* are effective against β-lactam resistant Gram-positive bacteria, including MRSA: these are the oxazolidinones (e.g. linezolid), tigecycline, daptomycin, and the lesser used streptogramins (e.g. quinupristin with dalfopristin).

MRSA is usually found as a skin commensal, especially in hospitalized patients or nursing home residents. However, it can cause a variety of infections in soft tissues and elsewhere, and can lead to death. It is particularly associated with surgical wound infections. Eradication of the organism is difficult and people who are known to be colonized should be isolated from those at risk of significant infection. Topical decolonization is often used but is of limited efficacy. Hand-washing is more effective at controlling spread (see p. 224).

Although MRSA is generally regarded as a hospital-associated organism, it is commonly seen in people away from the hospital setting, both as a colonizer and as a cause of disease. Often the organisms are the typical ‘hospital’ strains of MRSA and have been acquired directly or indirectly from a healthcare setting (e.g. in workers in care homes). However, there is an increasing prevalence in some countries of true community-associated MRSA (CA-MRSA), with no discernible links to hospital or residential care. These CA-MRSA have different resistance profiles to typical hospital strains (often retaining sensitivity to tetracyclines, clindamycin and co-trimoxazole) and are more likely to produce PVL.

**Detection**

Culture takes 24 hours. A rapid (2-h) real-time PCR assay is also available.
Pasteurellosis

*Pasteurella multocida* is found in the oropharynx of up to 90% of cats and 70% of dogs. It can cause soft tissue infections following animal bites. Although the infection initially resembles other forms of cellulitis, there is a greater tendency to spread to deeper tissues, resulting in osteomyelitis, tenosynovitis or septic arthritis. The organism is sensitive to penicillin, but as infections following animal bites are often polymicrobial, co-amoxiclav is a better choice.

Cat-scratch disease

Cat-scratch disease is a zoonosis caused by *Bartonella henselae*. Asymptomatic bacteraemia is relatively common in domestic and, especially, feral cats, and human infection is probably due to direct inoculation from the claws or via cat flea bites. Regional lymphadenopathy appears 1–2 weeks after infection; the nodes become tender and may suppurate. Histology of the nodes shows granuloma formation and the illness may be mistaken for mycobacterial infection or lymphoma. There are usually few systemic symptoms in immunocompetent patients, although more severe disease may be seen in the immunocompromised. In these patients, tender cutaneous or subcutaneous nodules are seen (*bacillary angiomatosis*), which may ulcerate. The lymphadenopathy resolves spontaneously over weeks or months, although surgical drainage of very large suppurring nodes may be necessary. *B. henselae* is sensitive to azithromycin, doxycycline and ciprofloxacin, but drug selection and clinical benefit of treatment are variable according to the primary site of the infection.

Toxin-mediated skin disease

A number of skin conditions, although caused by bacteria, are mediated by exotoxins rather than direct local tissue damage.

Staphylococcal scalded skin syndrome

The scalded skin syndrome is caused by a toxin-secreting strain of *Staph. aureus*. It principally affects children under the age of 5. The toxin, exfoliatin, causes intra-epidermal cleavage at the level of the stratum corneum, leading to the formation of large, flaccid blisters that shear readily. It is a relatively benign condition and responds to treatment with flucloxacillin.

Toxic shock syndrome

Toxic shock syndrome (TSS) is usually due to toxin-secreting staphylococci but toxin-secreting streptococci have also been implicated. Although historically associated with vaginal colonization and tampon use in women, this is not always the case. The exotoxin (normally toxic shock syndrome toxin 1, TSST-1) causes cytokine release with abrupt onset of fever and shock, with a diffuse macular rash and desquamation of the palms and soles. Many patients are severely ill and mortality is about 5%. Management is mainly supportive, although the
organism should be eradicated.

**Scarlet fever**

See pages 271–272.

**Deep soft tissue infections**

Infections of the deeper soft tissues are much less common than superficial infections and tend to be more serious. Usually, they are related to penetrating injuries (including injecting drug use) or to surgery, and the causative organisms relate to the nature of the wound.

**Necrotizing fasciitis**

Necrotizing fasciitis is a fulminant, rapidly spreading infection associated with widespread tissue destruction (through all tissue planes) and a high mortality. Historically, two forms are described. Type 1, caused by a mixture of aerobic and anaerobic bacteria, is usually seen following abdominal surgery or in diabetics. Type 2, caused by group A streptococci (GAS), arises spontaneously in previously healthy people. Other organisms are now also recognized as causing necrotizing fasciitis, most notably *Vibrio* species (*V. vulnificans*), associated with sea water in the tropics. All types are characterized by severe pain at the site of initial infection, rapidly followed by tissue necrosis. Infection tracks rapidly along the tissue planes, causing spreading erythema, pain and sometimes crepitus. In patients with fever, toxicity and pain that is out of proportion to the skin findings, necrotizing fasciitis should be suspected and must be treated aggressively and promptly with antibiotics and urgent surgical exploration, with extensive debridement or amputation if necessary (*Fig. 11.25*). Laboratory investigations show a high CRP and a very raised white count (often $>25 \times 10^9/L$). Imaging with ultrasound/CT may be helpful but should not delay urgent surgical exploration. Multiorgan failure is common and mortality is high.
Confirmed GAS necrotizing fasciitis is treated with high doses of benzylpenicillin and clindamycin; mixed- or unknown-organism infection is treated with a broad-spectrum combination, which should include metronidazole.

**Gas gangrene**

Gas gangrene is caused by deep tissue infection with *Clostridium* spp., especially *C. perfringens*, and follows contaminated penetrating injuries. It is historically associated with battlefield wounds but is also seen in intravenous drug users and following abdominal surgery. The initial infection develops in an area of necrotic tissue caused by the original injury; toxins secreted by the bacteria kill surrounding tissue and enable the anaerobic organism to spread rapidly. Toxins are also responsible for the severe systemic features of gas gangrene. Treatment consists of urgent surgical removal of necrotic tissue and treatment with benzylpenicillin and clindamycin.

**Further reading**

Bacterial Infections of the Respiratory Tract

Infections of the respiratory tract are divided into those affecting the upper and respiratory tract and those affecting the lower respiratory tract, which are separated by the larynx. In health, the lower respiratory tract is normally sterile owing to a highly efficient defence system (see pp. 1064–1065). Infections of the upper respiratory tract are particularly common in childhood, when they are usually the result of virus infection. The paranasal sinuses and middle ear are contiguous structures and can be involved secondary to viral infections of the nasopharynx. The lower respiratory tract is frequently compromised by smoking, air pollution, aspiration of upper respiratory tract secretions and chronic lung disease, notably chronic obstructive pulmonary disease. Infections of the respiratory tract are defined clinically, sometimes radiologically (as in the case of pneumonia), and by appropriate microbiological sampling.

Upper respiratory tract infections

• The common cold (acute coryza) (viral; see pp. 1075–1076).
• Sinusitis (see p. 1319).
• Rhinitis (see pp. 1076–1077).
• Pharyngitis (see pp. 1077–1078).

Scarlet fever

Scarlet fever occurs when the infectious organism (usually a group A streptococcus but occasionally C and G) produces erythrogenic toxin in an individual who does not possess neutralizing antitoxin antibodies. Infections may be sporadic or epidemic, occurring in residential institutions such as schools, prisons and military establishments.

Clinical features

The onset of this relatively mild disease, which mainly affects children, is 2–4 days following a streptococcal infection (usually in the pharynx). Regional lymphadenopathy, fever, rigors, headache and vomiting are present. The rash, which blanches on pressure, usually appears on the second day of illness. It is generalized, but typically absent from the face, palms and soles. The rash usually lasts about 5 days and is followed by extensive desquamation of the skin (Fig. 11.26). The face is flushed, with characteristic circumoral pallor. Early in the disease, the tongue has a white coating, through which prominent bright red papillae can be seen (‘strawberry tongue’). Later, the white coating disappears, leaving a raw-looking, bright red colour (‘raspberry tongue’). The patient is infective for 10–21 days after the onset of the rash, unless treated with penicillin.
Scarlet fever may be complicated by peritonsillar or retropharyngeal abscesses and otitis media.

**Diagnosis**
The diagnosis is established by the typical clinical features and culture of a throat swab.

**Management**
Treatment of the underlying infection is with phenoxymethylpenicillin 500 mg 6-hourly for 10 days, or parenteral benzylpenicillin if necessary.

**Diphtheria**
Diphtheria (caused by *Corynebacterium diphtheriae*) occurs worldwide. Its incidence in the West has fallen dramatically following widespread active immunization, but has re-emerged in Eastern Europe. Transmission is mainly through air-borne droplet infection. *C. diphtheriae* is a Gram-positive bacillus; only strains that carry the tox+ gene are capable of toxin production.

**Clinical features**
Diphtheria was formerly a disease of childhood but may affect adults in countries where childhood immunization has been interrupted or uptake is poor. The incubation period is 2–7 days. The manifestations are local (due to the membrane) or systemic (due to exotoxin). The presence of a membrane, however, is not essential to the diagnosis. The illness is insidious in onset but co-infection with other bacteria, such as *Strep. pyogenes*, occurs.

* Nasal diphtheria is characterized by the presence of a unilateral, serosanguineous nasal discharge that crusts around the external nares.

* Pharyngeal diphtheria is associated with the greatest toxicity and is characterized by
marked tonsillar and pharyngeal inflammation and the presence of a membrane. The tough, greyish yellow membrane is formed by fibrin, bacteria, epithelial cells, mononuclear cells and polymorphs, and is firmly adherent to the underlying tissue. Regional lymphadenopathy, often tender, is prominent and produces the so-called ‘bull-neck’.

**Laryngeal diphtheria** is usually a result of extension of the membrane from the pharynx. A husky voice, a brassy cough and, later, dyspnoea and cyanosis due to respiratory obstruction are common features.

Clinically evident myocarditis occurs, often weeks later, in patients with pharyngeal or laryngeal diphtheria. Acute circulatory failure due to myocarditis may occur in convalescent individuals around the tenth day of illness and is usually fatal. Neurological manifestations occur either early in the disease (palatal and pharyngeal wall paralysis) or several weeks after its onset (cranial nerve palsies, paraesthesiae, polyneuropathy or, rarely, encephalitis).

**Cutaneous diphtheria** is uncommon but seen in association with burns and in individuals with poor personal hygiene. Typically, the ulcer is punched-out with undermined edges and is covered with a greyish white to brownish adherent membrane. Constitutional symptoms are uncommon.

### Diagnosis

This must be made on clinical grounds since therapy is usually urgent; the mortality rate is about 10%. It is confirmed by bacterial culture and toxin studies.

### Management

Antitoxin therapy is the only specific treatment. It must be given promptly to prevent further fixation of toxin to tissue receptors, since fixed toxin is not neutralized by antitoxin. Depending on the severity, 20,000–100,000 units of horse-serum antitoxin should be administered intramuscularly, after an initial test dose to exclude any allergic reaction. Intravenous therapy may be required in a very severe case. There is a risk of acute anaphylaxis after antitoxin administration and of serum sickness 2–3 weeks later (*Box 11.37*). However, the risk of death outweighs the problems of anaphylaxis. Antibiotics should be administered concurrently to eliminate the organisms and thereby remove the source of toxin production. Benzylpenicillin 1.2 g four times daily is given for 1 week, or amoxicillin 500 mg three times daily.

---

**Box 11.37**

Antitoxin administration

- Many antitoxins are heterologous and therefore dangerous
- Hypersensitivity reactions are common

Prior to treatment
• Question the patient about:
  – allergic conditions (e.g. asthma, hay fever)
  – previous antitoxin administration
• Read the instructions on the antitoxin package carefully
• Always give a subcutaneous test dose
• Have adrenaline (epinephrine) available

The cardiac and neurological complications need intensive therapy. Recovery and rehabilitation can take many weeks.

**Prevention**

Patients with suspected diphtheria must be isolated, and the local public health authorities should be informed. Staff caring for the patient should have documented immunization status. All contacts of the patient should have throat swabs sent for culture; those with a positive result should be treated with penicillin or a macrolide, and be given active immunization or a booster dose of diphtheria toxoid. Diphtheria is prevented by active immunization in childhood (see p. 245). Booster doses should be given to those travelling to endemic areas if more than 10 years have elapsed following their primary course of immunization.

**Pertussis (whooping cough)**

Pertussis occurs worldwide. Humans are both the natural hosts and reservoirs of infection. The disease is caused by *Bordetella pertussis*, a Gram-negative coccobacillus. *B. parapertussis* and *B. bronchiseptica* produce milder infections. Pertussis is highly contagious and is spread by droplet infection. In its early stages, it is indistinguishable from other types of upper respiratory tract infection. Epidemic disease occurred in the UK when the safety of the whooping cough vaccine was questioned; currently, uptake exceeds 95% and the disease is uncommon.

**Clinical features**

The incubation period is 7–10 days. Whooping cough is mainly a disease of childhood, with 90% of cases occurring below 5 years of age. However, no age is exempt, as the antibody levels fall over the years, although in adults mild infection may not be recognised.

During the *catarrhal stage*, the patient is highly infectious and cultures from respiratory secretions are positive in over 90% of patients. Malaise, anorexia, mucoid rhinorrhea and conjunctivitis are present. The *paroxysmal stage*, so called because of the characteristic paroxysms of coughing, begins about 1 week later. Paroxysms with the classic inspiratory whoop are seen only in younger individuals in whom the lumen of the respiratory tract is compromised by mucus secretion and mucosal oedema. These paroxysms usually terminate in
vomiting. Conjunctival suffusion and petechiae, and ulceration of the frenulum of the tongue, are common. Lymphocytosis due to the elaboration of a lymphocyte-promoting factor by *B. pertussis* is characteristic. This stage lasts approximately 2 weeks and may be associated with several complications, including pneumonia, atelectasis, rectal prolapse and inguinal hernia. Cerebral anoxia may occur, especially in younger children, resulting in convulsions. Bronchiectasis is a rare sequel.

## Diagnosis

The diagnosis is suggested clinically by the characteristic whoop and a history of contact with an infected individual. PCR tests are rapid and highly sensitive, but culture of a nasopharyngeal swab remains necessary for definitive diagnosis.

## Management

If the disease is recognized in the catarrhal stage, macrolides will abort or decrease the severity of the infection (although resistance to these agents has been reported in the USA). Azithromycin for 5 days is frequently used. In the paroxysmal stage, antibiotics have little role to play in altering the course of the illness.

## Prevention and control

Affected individuals should be isolated. Pertussis is an easily preventable disease and effective active immunization is available (see *Box 11.19*). Convulsions and encephalopathy have been reported as rare complications of vaccination but they are probably less frequent than after whooping cough itself. Any exposed susceptible infant should receive prophylactic clarithromycin.

### Acute epiglottitis

Acute epiglottitis (see p. 1078) has been virtually eliminated among children in those countries that have introduced *Haemophilus influenzae* vaccine, as in the UK. Occasionally, infections are seen in adults. The clinical features are described on page 1078.

### Acute laryngotracheobronchitis (croup)

See page 1078.

### Influenza

Influenza is a viral infection; see page 1078.

**Lower respiratory tract infections**
Pneumonia

For community-acquired pneumonia, see pages 1100–1104; hospital-acquired pneumonia, pages 1105-1106; and pneumonia in immunocompromised persons, page 1106.

Ornithosis (psittacosis)

Although originally thought to be limited to the psittacine birds (parrots, parakeets and macaws), it is known that the disease is widely spread among many species of birds, including pigeons, turkeys, ducks and chickens (hence the broader term ‘ornithosis’). Human infection is related to exposure to infected birds and is therefore a true zoonosis. The causative organism, *Chlamydia psittaci*, is excreted in avian secretions; it can be isolated for prolonged periods from birds that have apparently recovered from infection. The organism gains entry to the human host by inhalation. (For clinical features and treatment, see p. 1105.)

Acinetobacter infection

This Gram-negative coccobacillus is becoming increasingly prominent in hospital-acquired infections, particularly as a cause of ventilator-associated pneumonia (see p. 1165) and vascular catheter infections. It is a cause of community-acquired infections in tropical countries and is associated with wars and natural disasters. The organism is resistant to many antibiotics, including carbapenems. Polymyxin and tigecycline are being used but resistance is still a problem.

Other respiratory infections

*Chlamydophila pneumoniae* causes a relatively mild pneumonia in young adults, clinically resembling infection caused by *Mycoplasma pneumoniae*. Diagnosis can be confirmed by specific IgM serology. Treatment is with clarithromycin 500 mg 12-hourly, tetracycline 500 mg every 6–8 h or a fluoroquinolone (see also p. 1103).

Other *Chlamydophila* infections include trachoma (see p. 288), lymphogranuloma venereum (p. 330) and other genital infections.

*Legionnaires’ disease* is caused by *Legionella pneumophila* and other *Legionella* spp. It is described on page 1103.

*Lung abscess* is described on pages 1104–1105.

*Tuberculosis* is described on page 1106–1113.

Bacterial Infections of the Gastrointestinal Tract

Gastroenteritis

The most common form of acute gastrointestinal infection is gastroenteritis, causing diarrhoea with or without vomiting. Children in the developing world can expect, on average, 3–6 bouts of severe diarrhoea every year. Although oral rehydration programmes have cut the death toll significantly, up to 2 million people die every year as a direct result of diarrhoeal disease. In the Western world, diarrhoea is both less common and less likely to cause death. However, it remains a major cause of morbidity, especially in the elderly. Other groups who are at increased risk of infectious diarrhoea include travellers to developing countries, men having sex with men, and infants in day-care facilities.

Aetiology

Viral gastroenteritis (see pp. 263–265) is a common cause of diarrhoea and vomiting in young children but is less commonly seen in adults, other than in the context of common source outbreaks (usually due to norovirus). It is a major cause of morbidity and mortality among infants in low-income countries. Protozoal and helminthic gut infections (see pp. 305–307) are rare in the West but relatively common in developing countries. However, the most common cause of significant adult gastroenteritis worldwide is bacterial infection.

Mechanisms

Bacteria can cause diarrhoea in three different ways (Box 11.38). Some species may employ more than one of these methods. In addition to these direct mechanisms, a proportion of people develop post-infectious irritable bowel syndrome, a functional bowel disorder triggered by infection but persisting after resolution of the inflammation (see p. 431).

### Mucosal adherence

Most bacteria causing diarrhoea must first adhere to specific receptors on the gut mucosa. A number of different molecular adhesion mechanisms have been elaborated: for example, adhesions at the tip of the pili or fimbriae that protrude from the bacterial surface aid adhesion. For some pathogens, this is merely the prelude to invasion or toxin production but others, such as enteropathogenic *Escherichia coli* (EPEC), cause attachment–effacement mucosal lesions on electron microscopy and produce a secretory diarrhoea directly as a result of adherence. Enteroaggregative *E. coli* (EAggEC) adhere in an aggregative pattern, with the bacteria clumping on the cell surface, and its toxin causes persistent diarrhoea. Diffusely adhering *E. coli* (DAEC) adheres in a uniform manner and may also cause diarrhoea. Both are mainly seen in low-income countries with poor hygiene and inadequate clean water supply.

*E. coli* O104:H4, which was responsible for a huge outbreak of gastroenteritis in Germany in 2011, has two different diarrhoea-causing *E. coli* pathotypes: typical enteroaggregative *E. coli* and Shiga-toxin-producing *E. coli*.

### Mucosal invasion

Invasive pathogens, such as *Shigella* spp., enteroinvasive *E. coli* (EIEC) and *Campylobacter* spp., penetrate into the intestinal mucosa. Initial entry into the mucosal cells is facilitated by the production of ‘invasins’, which disrupt the host-cell cytoskeleton. Subsequent destruction of the epithelial cells allows further bacterial entry, which also causes the typical symptoms of dysentery: low-volume bloody diarrhoea, with abdominal pain.

### Toxin production

Gastroenteritis can be caused by different types of bacterial toxins (see [Fig. 11.2](#)): 
• **Enterotoxins**, produced by the bacteria adhering to the intestinal epithelium, induce excessive fluid secretion into the bowel lumen, leading to watery diarrhoea, without physically damaging the mucosa (e.g. cholera, enterotoxigenic *E. coli* (ETEC)). Some enterotoxins pre-formed in the food primarily cause vomiting (e.g. *Staph. aureus* and *Bacillus cereus*). A typical example of this is ‘fried rice poisoning’, in which *B. cereus* toxin is present in cooked rice left standing overnight at room temperature.

• **Cytotoxins** damage the intestinal mucosa and, in some cases, vascular endothelium as well (e.g. *E. coli* O157).

### Clinical syndromes

Bacterial gastroenteritis can be divided on clinical grounds into two broad syndromes: **watery diarrhoea** (usually due to enterotoxins or adherence) and **dysentery** (usually due to mucosal invasion and damage) ([Box 11.39](#)). With some pathogens, such as *Campylobacter jejuni*, there may be overlap between the two syndromes.

#### Box 11.39

**Bacterial causes of watery diarrhoea and dysentery**

**Watery diarrhoea**
- *Bacillus cereus*
- *Staphylococcus aureus*
- *Vibrio cholerae*
- Enterotoxigenic *Escherichia coli* (ETEC)
- Enteropathogenic *Escherichia coli* (EPEC)
- Campylobacter jejuni
- *Clostridium perfringens*
- *Clostridium difficile*

> plus profuse vomiting

**Dysentery**
- *Shigella* spp.
- *Salmonella* spp.
- *Campylobacter* spp.
- Enteroinvasive *Escherichia coli* (EIEC)
- Enterohaemorrhagic *Escherichia coli* (EHEC)
- *Yersinia enterocolitica*
- *Vibrio parahaemolyticus*
- *Clostridium difficile*

### Management

Bacterial gastroenteritis is usually self-limiting and does not require antibacterials unless the infection is severe or the patient is immunocompromised. Details are given on page 275.

### Salmonella

Gastroenteritis can be caused by many of the numerous serotypes of *Salmonella* (all of which are members of a single species, *S. choleraesuis*), but the most commonly implicated are *S.
enteritidis and S. typhimurium. These organisms, which are found all over the world, are commensals in the bowels of livestock (especially poultry) and in the oviducts of chicken (where the eggs can become infected). They are usually transmitted to humans in contaminated foodstuffs and water.

Salmonellae can affect both the large and small bowel, and induce diarrhoea both by production of enterotoxins and by invasion. The typical symptoms commence abruptly 12–48 h after infection and consist of nausea, cramping abdominal pain, diarrhoea and, sometimes, fever. The diarrhoea can vary from profuse and watery to a bloody dysentery syndrome. Spontaneous resolution usually occurs in 3–6 days, although the organism may persist in the faeces for several weeks. Bacteraemia occurs in 1–4% of cases and is more common in the elderly and the immunosuppressed. Occasionally, bacteraemia is complicated by metastatic infection, especially of atheroma on vascular endothelium, with potentially devastating consequences. In healthy adults, Salmonella gastroenteritis is usually a relatively minor illness, but young children and the elderly are at risk of significant dehydration.

Specific diagnosis is made by culturing the organism from blood or faeces, but management is usually empirical and includes oral rehydration (see Box 11.32).

Campylobacter jejuni

C. jejuni is also a zoonotic infection, existing as a bowel commensal in many species of livestock, such as poultry and cattle. It is found worldwide and is a common cause of childhood gastroenteritis in developing countries. Adults in these countries may be tolerant of the organism, excreting it asymptptomatically. In the West, it is a common cause of sporadic food-borne outbreaks of diarrhoea (with about 450 000 cases per year in the UK). The most common sources are undercooked meat (especially beefburgers and chicken) and contaminated milk products and water.

Like Salmonella, Campylobacter can affect the large and small bowel and can cause a wide variety of symptoms. The incubation period is usually 2–4 days, after which there is an abrupt onset of nausea, diarrhoea and severe abdominal cramps. The diarrhoea is usually profuse and watery, but an invasive haemorrhagic colitis is sometimes seen. Bacteraemia is very rare and infection is usually self-limiting in 3–5 days. Diagnosis is made from stool cultures. Quinolone resistance is now widespread (30% in the UK) and, if symptoms are severe, azithromycin 500 mg once daily is the drug of choice (Box 11.40).

| **Dysentery**  
*Suspected or confirmed shigellosis* | Most patients | Ciprofloxacin 500 mg twice daily | Ampicillin 500 mg four times daily  
Azithromycin 500 mg once daily  
Co-trimoxazole 960 mg twice daily | Relieve symptoms  
Shorten illness  
Reduce mortality in children  
Decrease transmission |
| **Cholera** | All patients | Ciprofloxacin 500 mg twice daily | Tetracycline 250 mg four times daily  
Azithromycin 1 g single dose  
Doxycycline 300 mg single dose | Relieve symptoms  
Shorten illness  
Decrease transmission |
| **Empirical therapy of watery diarrhoea*†** | Severe symptoms  
Prolonged illness  
Elderly patients  
Immunosuppressed | Ciprofloxacin 500 mg twice daily | Azithromycin 500 mg once daily  
Co-trimoxazole 960 mg twice daily | Relieve symptoms  
Shorten illness  
May decrease complications |
| **Travellers’ diarrhoea*†** | Rarely used | Ciprofloxacin 500 mg twice daily | Co-trimoxazole 960 mg twice daily | Relieve symptoms  
Shorten illness |
| **Treatment of confirmed Salmonella*†** | Symptoms not improving (rarely needed) | Ciprofloxacin 500 mg twice daily | Azithromycin 500 mg once daily | May shorten illness |
| **Treatment of confirmed Campylobacter*†** | Symptoms not improving (rarely needed) | Azithromycin 500 mg once daily | Co-trimoxazole 960 mg twice daily | May shorten illness |
| **Clostridium difficile** | Most cases (unless symptoms resolved) | Metronidazole 400 mg three times daily | Vancomycin 125–250 mg four times daily  
Fidaxomicin 200 mg twice daily | Relieve symptoms  
Shorten illness  
May reduce relapse rate |

*Antibiotics are not needed for the majority of adult cases in developed countries.*

---

**Shigella**

Shigellae are enteroinvasive bacteria, which cause classical bacillary dysentery. The principal species causing gastroenteritis are *S. dysenteriae*, *S. flexneri* and *S. sonnei*, which are found with varying prevalence in different parts of the world. All cause a similar syndrome, as a result of damage to the intestinal mucosa. Some strains of *S. dysenteriae* also secrete a cytotoxin affecting vascular endothelium. Although shigellae are found worldwide, transmission is strongly associated with poor hygiene. The organism is spread from person to person and only small numbers need to be ingested to cause illness (<200, compared with $10^4$ for *Campylobacter* and $>10^5$ for *Salmonella*). Bacillary dysentery is far more prevalent in the developing world, where the main burden falls on children.

Symptoms start 24–48 h after ingestion and typically consist of frequent, small-volume stools containing blood and mucus. Dehydration is not as significant as in the secretory diarrhoeas, but systemic symptoms and intestinal complications are worse. The illness is usually self-limiting in 7–10 days, but in children in developing countries the mortality may be as high as 20%.

Antibiotic treatment decreases the severity and duration of diarrhoea, reduces mortality in children and possibly lowers the risk of further transmission. Resistance to antibiotics is
widespread and, wherever possible, treatment should be based on known local sensitivity patterns. In some areas, amoxicillin or co-trimoxazole may still be effective but in many places ciprofloxacin is needed, although resistance to this agent is increasing.

**Enteroinvasive Escherichia coli**

Enteroinvasive *Escherichia coli* (EIEC) causes an illness indistinguishable from shigellosis. Definitive diagnosis is made by stool culture but most cases are probably treated empirically as shigellosis.

**Enterohaemorrhagic Escherichia coli**

Enterohaemorrhagic *Escherichia coli* (EHEC; usually serotype O157:H7 and also known as verotoxin-producing *E. coli*, or VTEC) is a well-recognized cause of gastroenteritis in humans. It is a zoonosis that is usually associated with cattle and there have been a number of major outbreaks (notably in Scotland and Japan) associated with contaminated food. A variety of modes of transmission have been reported and EHEC is a paradigm for all enteric livestock-associated zoonoses (*Fig. 11.27*). EHEC secretes a toxin (Shiga-like toxin 1), which affects vascular endothelial cells in the gut and in the kidney. After an incubation period of 12–48 h, it causes diarrhoea (frequently bloody), associated with abdominal pain and nausea. Some days after the onset of symptoms, the patient may develop thrombotic thrombocytopenic purpura (see pp. 570–571) or haemolytic uraemic syndrome (HUS; see pp. 749–750). This is more common in children and may lead to permanent renal damage or death. Non-O157 serotypes are of increasing concern.

*FIGURE 11.27* Routes of human infection with *E. coli* O157.
Between May and June 2011, the largest ever recorded outbreak of Shiga toxin-producing *E. coli* (STEC) causing HUS was recorded in Germany. The outbreak was caused by the O104 serotype and over 2000 people were affected. High rates of HUS were observed in adults not in the typical ‘at-risk’ age range. The increased virulence of this strain is possibly due to it having two different pathotypes (see p. 274).

Treatment is mainly supportive; there is evidence that antibiotic therapy might precipitate HUS by causing increased toxin release, although this remains controversial.

### Enterotoxigenic *Escherichia coli*

Enterotoxigenic *Escherichia coli* (ETEC) produce both heat-labile and heat-stable enterotoxins, which stimulate secretion of fluid into the intestinal lumen. The result is watery diarrhoea of varying intensity, which usually resolves within a few days. Transmission is normally from person to person via contaminated food and water. The organism is common in developing countries and is a major cause of travellers' diarrhoea (see below).

### Vibrio

*Vibrio* cholera, due to *Vibrio cholerae*, is the prototypic pure enterotoxigenic diarrhoea; it is described on pages 288–289.

*V. parahaemolyticus* causes acute watery diarrhoea after raw fish or shellfish is eaten that has been kept for several hours without refrigeration. Explosive diarrhoea, abdominal cramps and vomiting occur, with a fever in 50%. It is self-limiting, lasting up to 10 days.

### Yersiniosis

*Yersinia enterocolitica* infection is a zoonosis of a variety of domestic and wild mammals. Human disease can arise either via contaminated food products, such as pork, or from direct animal contact. *Y. enterocolitica* can cause a range of gastroenteric symptoms, including watery diarrhoea, dysentery and mesenteric adenitis. The illness is usually self-limiting but ciprofloxacin may shorten the duration. *Y. pseudotuberculosis* is a much less common human pathogen; it causes mesenteric adenitis and terminal ileitis.

### Staphylococcus aureus

Some strains of *Staph. aureus* can produce a heat-stable toxin (enterotoxin B), which causes massive secretion of fluid into the intestinal lumen. It is a common cause of food-borne gastroenteritis in Europe and the USA, outbreaks usually occurring as a result of poor food hygiene. Because the toxin is pre-formed in the contaminated food, onset of symptoms is rapid, often within 2–4 hours of consumption. There is violent vomiting, followed within hours by profuse watery diarrhoea. Symptoms have usually subsided within 24 hours.
**Bacillus cereus**

*B. cereus* produces two toxins. The first one causes vomiting 2–4 hours after ingesting pre-formed heat stable exotoxins. The second causes watery diarrhoea up to 12 hours after uncooked food is ingested that contains spores or viable bacteria that multiply and produce a toxin within the bowel. The cause is germination of spores, often in semi-cooked rice stored in warm temperatures prior to ingestion. Rarely liver failure occurs (see p. 486).

**Clostridial infections**

**Clostridium difficile**

*Clostridium difficile* causes watery diarrhoea, colitis and pseudomembranous colitis. It is a Gram-positive, anaerobic, spore-forming bacillus and is found as part of the normal bowel flora in 3–5% of the population and even more commonly (up to 20%) in hospitalized people.

**Pathogenesis.** *C. difficile* produces two toxins: toxin A is an enterotoxin while toxin B is cytotoxic and causes bloody diarrhoea. It causes illness either in patients who have been given antibiotic therapy that has eliminated other bowel commensals, or in those who are debilitated for other reasons. Almost all antibiotics have been implicated but an increase in cases has been attributed in part to the overuse of quinolones (e.g. ciprofloxacin). Hospital-acquired infections remain common, partly due to increased spread from person to person and via fomites. Strains of *C. difficile* with greater capacity for toxin production have been reported (e.g. the ribotype NAP1/BI/027) in a number of hospital outbreaks with a high mortality.

**Clinical features.** *C. difficile*-associated diarrhoea (CDAD) can begin anything from 2 days to some months after taking antibiotics. Elderly hospitalized patients are most frequently affected. It is unclear why some carriers remain asymptomatic. Symptoms can range from mild diarrhoea to profuse, watery, haemorrhagic colitis, along with lower abdominal pain. The colonic mucosa is inflamed and ulcerated, and can be covered by an adherent membrane-like material (pseudomembranous colitis). The disease is usually more severe in the elderly and can cause intractable diarrhoea, leading to toxic megacolon and death. Markers of severity include:

- temperature >38.5°C
- white cell count >15 × 10⁹
- serum creatinine >50% above baseline
- raised serum lactate
- severe abdominal pain.

**Diagnosis.** Diagnosis is made by detecting A or B toxins in the stools using ELISA or PCR for *C. difficile* nucleic acid.

**Management.** Treatment is with metronidazole 400 mg three times daily (mild or moderate disease) or oral vancomycin 125–500 mg four times daily (in more severe or relapsing cases).
Fidaxomicin is also effective. Causative antibiotics should be discontinued if possible. In refractory or relapsing cases, instilling faeces from the bowel of a healthy donor (faecal transplant) can restore normal bowel flora and eradicate the *C. difficile* infection. This therapy may become the standard for *C. difficile* infections.

**Prevention.** Infection control relies on:

- Responsible use of antibiotics (see pp. 234–235).
- Hygiene, which should involve all health workers, as well as patients and relatives. Washing hands thoroughly using soap and water is essential, as alcohol disinfectants do not kill spores (see pp. 224–247).
- Hospital cleaning of surfaces should be performed regularly to try to reduce transmission from fomites.
- Isolation of patients with *C. difficile*.

**Clostridium perfringens**

*C. perfringens* infection is due to inadequately cooked food, usually meat or poultry allowed to cool for a long time, during which period the spores germinate. The ingested organism produces an enterotoxin that causes watery diarrhoea with severe abdominal pain, usually without vomiting.

**Travellers' diarrhoea**

Travellers' diarrhoea is defined as the passage of three or more unformed stools per day in a resident of an industrialized country travelling in a developing nation. Infection is usually food- or water-borne, and younger travellers are most often affected (probably reflecting behaviour patterns). Reported attack rates vary from country to country but approach 50% for a 2-week stay in many tropical countries. The disease is usually benign and self-limiting; treatment with quinolone antibiotics may hasten recovery but is not normally necessary. Prophylactic antibiotic therapy may also be effective for short stays but should not be used routinely. The common causative organisms are listed in *Box 11.41*.

---

**Box 11.41**

**Commonly identified causes of travellers' diarrhoea**

---
### Organism | Frequency (varies from country to country)
--- | ---
Enterotoxigenic *Escherichia coli* | 30–70%
*Shigella* spp. | 0–15%
*Salmonella* spp. | 0–10%
*Campylobacter* spp. | 0–15%
Viral pathogens | 0–10%
*Giardia intestinalis* | 0–3%

*In most cases, no microbiological diagnosis is made.*

---

#### Management of acute gastroenteritis (**Fig. 11.28**)

In children in low-income countries, untreated diarrhoea has a high mortality due to dehydration, often on a background of malnutrition and other chronic infection. Death and serious morbidity are less common in adults but still occur, particularly in developing countries and in the elderly.

![Management of acute gastroenteritis](image)

**FIGURE 11.28** Gastroenteritis: management plan. ORS, oral rehydration solution.

The mainstay of treatment for all types of gastroenteritis is oral rehydration solutions (ORS) (see **Box 11.32**). The use and formulation of ORS are discussed on [pages 264 and 288–289](#). It is also important to remember that other diseases, notably urinary tract infections and chest infections in the elderly, and malaria at any age, can present with acute diarrhoea. Most cases of acute gastroenteritis (especially in developed countries) resolve within 10 days; if symptoms persist, other causes, such as colitis, are more likely.
Food poisoning

Food poisoning is a legally notifiable condition in England and Wales. There is some overlap between food poisoning (defined as ‘any disease of an infective or toxic nature caused by or thought to be caused by the consumption of food and water’) and gastroenteritis. However, not all cases of gastroenteritis are due to food poisoning, as the pathogens are not always food- or water-borne. Conversely, some types of food poisoning (e.g. botulism) do not primarily cause gastroenteritis. Common bacterial causes of food poisoning are listed in Box 11.42. Food poisoning may also be caused by a number of non-infectious organic and inorganic toxins (Box 11.43). (Listeriosis is described on see pp. 283–284.)

Organic toxins causing food poisoning

---
The increase in reported food poisoning in developed countries is due, at least in part, to changes in the production and distribution of food. Livestock raised and slaughtered under modern intensive farming conditions is frequently contaminated with *Salmonella* or *Campylobacter*. However, the main problem is not at this stage. Only 0.02–0.1% of the eggs from a flock of chickens infected with *S. enteritidis* will be affected and then only at a level of less than 20 cells per egg – harmless to most healthy individuals. It is flaws in the processing, storage and distribution of food products that allow massive amplification of the infection, resulting in extensive contamination. The internationalization of the food supply encourages widespread and distant transmission of the resulting infections.

**Enteric fever**

See page 289.

**Other gastrointestinal infections**

Gastric infection with *Helicobacter pylori* is discussed on pages 378–381, *Whipple's disease* on page 400 and *bacterial peritonitis* on pages 434–435.

**Further reading**

Bacterial Infections of the Cardiovascular System

*Infective endocarditis* is discussed on pages 1017–1021.

Bacterial Infections of the Nervous System

The central and peripheral nervous systems can be affected by a variety of microorganisms, including bacteria, viruses (see p. 862) and protozoa (p. 267), which cause disease by direct invasion or via toxins. The nervous system is also vulnerable to prion disease (see pp. 267–268 and 434–435).

### Bacterial meningitis

The most common bacterial disease affecting the CNS is acute meningitis (see pp. 862–865), which causes about 175,000 deaths per year, predominantly in the developing world. Epidemic meningitis due to *Neisseria meningitidis* (usually group A) is common in a broad belt across sub-Saharan Africa and is also seen in parts of Asia. In Europe and North America, bacterial meningitis is usually sporadic, with serogroup B predominating. A conjugate vaccine for serogroup C meningococcus has resulted in a fall in the number of cases of group C meningitis in those countries where it is now part of the childhood immunization schedule. Vaccines against group B meningococcus have been approved in many countries.

*Streptococcus pneumoniae* is the other major cause of meningitis throughout the world, while tuberculous meningitis (see pp. 864–865) is common in sub-Saharan Africa and parts of Asia.

*Haemophilus influenzae* type b (Hib) was once a common cause of meningitis in children, but since an effective vaccine has been available, serious *H. influenzae* infections have become rare in countries that have also instituted immunization programmes; however, invasive *H. influenzae* infection remains common in some parts of the world.

Other less common causes of meningitis in adults include group B streptococci, *Listeria monocytogenes* (see pp. 283–284), *Staph. aureus* and Gram-negative bacilli. These organisms are usually associated with an underlying illness or immunocompromising condition, or with a CSF leak.
**Toxin-mediated infections**

### Botulism

*Clostridium botulinum* is a common environmental organism that produces spores that can survive heating to 100°C. It causes illness by contaminating canned or bottled foodstuffs, in which the anaerobic organism can multiply and elaborate a neurotoxin. After ingestion, the toxin causes profound neuromuscular blockade, leading to autonomic and motor paralysis. The first symptoms, occurring 18–24 hours after ingestion, are nausea and diarrhoea. These are followed by cranial nerve palsies and then progressive symmetrical paralysis, leading to respiratory failure.

The diagnosis is usually clinical and is confirmed by detection of toxin in faeces or in the contaminated food. Management is mainly supportive, with mechanical ventilation if necessary. Antitoxin is available in some countries (including the UK); the risk of anaphylaxis is relatively high and antitoxin should only be used in severe cases. A subcutaneous test dose should be given before intravenous or intramuscular injection. Antibiotics have no proven role. The overall mortality from botulism is high, but patients who survive the acute paralysis can make a full recovery.

Botulism may also follow the contamination of wounds and injection of street heroin contaminated with *C. botulinum*; in infants, botulism may be related to bowel colonization by the organism.

### Tetanus

Tetanus is also due to a toxin-secreting clostridium: *C. tetani*. The organism is found in soil, and illness usually results from a contaminated wound. The injury itself may be trivial and disregarded by the individual. Tetanus can also complicate injecting drug use. In developing countries, neonatal tetanus follows contamination of the umbilical stump, often after the area is dressed with dung. The overall incidence of tetanus across the world has fallen significantly in the past 20 years, due mainly to active immunization.

The organism is not invasive and clinical manifestations of the disease are due to the potent neurotoxin, tetanospasmin. Tetanospasmin acts on both the α and δ motor systems at synapses, resulting in disinhibition. It also produces neuromuscular blockade and skeletal muscle spasm, and acts on the sympathetic nervous system. The end result is marked flexor muscle spasm and autonomic dysfunction.
The incubation period varies from a few days to several weeks. The most common form of the disease is generalized tetanus. General malaise is rapidly followed by trismus (lockjaw) due to masseter muscle spasm. Spasm of the facial muscles produces the characteristic grinning expression known as risus sardonicus. If the disease is severe, painful reflex spasms develop, usually within 24–72 hours of the initial symptoms. The interval between the first symptom and the first spasm is referred to as the ‘onset time’. The spasms may occur spontaneously but are easily precipitated by noise, handling of the patient, or light. Respiration may be impaired because of laryngeal spasm; oesophageal and urethral spasm lead to dysphagia and urinary retention, respectively, and there is arching of the neck and back muscles (opisthotonus). Autonomic dysfunction produces tachycardia, a labile blood pressure, sweating and cardiac arrhythmias. Patients with tetanus are mentally alert.

Death results from aspiration, hypoxia, respiratory failure, cardiac arrest or exhaustion. Mild cases with rigidity usually recover. Poor prognostic indicators include a short incubation period, short onset time and extremes of age.

Localized tetanus is a milder form of the disease. Pain and stiffness are confined to the site of the wound, with increased tone in the surrounding muscles. Recovery is usual.

Cephalic tetanus is uncommon but invariably fatal. It usually occurs when the portal of entry of C. tetani is the middle ear. Cranial nerve abnormalities, particularly of the VIIth nerve, are usual. Generalized tetanus may or may not develop.

Neonatal tetanus is characterized by failure to thrive, poor sucking, grimacing and irritability, followed by the rapid development of intense rigidity and spasms. Mortality approaches 100%. One aim of the WHO Expanded Programme on Immunization (EPI) is to eliminate this condition by immunizing all women of child-bearing age, providing clean delivery facilities and strengthening surveillance in high-risk areas.

### Diagnosis

Few diseases resemble tetanus in its fully developed form and the diagnosis is therefore usually clinical. Rarely, C. tetani is isolated from wounds. Phenothiazine overdosage, strychnine poisoning, meningitis and tetany can occasionally mimic tetanus.

### Management

**Suspected tetanus**

Any wound must be cleaned and debrided to remove the source of toxin. Human tetanus immunoglobulin 250 units should be given, along with an intramuscular injection of tetanus toxoid. If the patient is already protected, a single booster dose of the toxoid is given; otherwise, the full three-dose course of adsorbed vaccine is given (see below).

**Established tetanus**

Management is supportive medical and nursing care. Improvement in this area has contributed,
more than any other single measure, to the decrease in the mortality rate from 60% to nearer 20%. Patients are nursed in a quiet, isolated, well-ventilated, darkened room. Benzodiazepines are used to control spasms and sedate the patient; if the airway is compromised, intubation and mechanical ventilation may be necessary. Magnesium sulphate infusion may decrease the need for antispasmodics.

Antibiotics and antitoxin should be administered, even in the absence of an obvious wound. Intravenous metronidazole for 7–10 days is the drug of choice, although penicillin is also effective. Human tetanus immunoglobulin (HTIG) should be given as soon as possible, by either intravenous infusion or intramuscular injection to neutralize any circulating toxin. If HTIG is not available, human normal immunoglobulin (HNIG) can be used. If the patient recovers, active immunization should be instituted, as immunity following tetanus is incomplete.

**Prevention**

An effective, safe and relatively cheap vaccine means that tetanus is an eminently preventable disease. After initial active immunization, boosters are recommended at 10-year intervals for all adults. Infant immunization schedules in all countries include tetanus (see **Box 11.19**). Protection by passive immunization with HTIG or HNIG is short-lived, lasting only about 2 weeks.

Systemic/Multisystem Bacterial Infections

Many infections are confined to a particular body organ or system, owing to the metabolic requirements of the organism, the route of infection or the response of host defences. Other infections can potentially affect several systems or the entire body. Under unusual circumstances, such as altered host immunity, infections that are normally circumscribed may become systemic. This section describes those infections that commonly cause multisystem disease in an immunocompetent host.

Bacteraemia and sepsis syndrome

(See also pp. 1150–1161.)

**Bacteraemia**, the transient presence of organisms in the blood, can occur in healthy people without causing symptoms. It can follow surgery, dental treatment and even tooth-brushing. Bacteraemia can also occur from the bowel or bladder, especially in the presence of local inflammation. Unless a site of metastatic infection is established (such as the heart valves), most organisms are rapidly cleared from the blood.

**Sepsis** is the term used to describe the signs and symptoms of a systemic inflammatory response syndrome (SIRS; see p. 221) to a localized primary site of infection. Viral, bacterial, fungal and parasitic disease can all trigger the sepsis syndrome.

SIRS is not unique to infection and may complicate a variety of events and conditions such as trauma, chronic inflammatory diseases and malignancy (e.g. lymphoma).

Severe sepsis and septic shock are described on pages 1154–1155.

Meningococcal sepsis

*Neisseria meningitidis* is found worldwide, in five major sero-groups. In sub-Saharan Africa and parts of Asia, where group A meningococcus is prevalent, it usually causes epidemic disease. Groups Y and W can also cause epidemic infection, while groups B and C (the predominant strains in Europe and North America) tend to be sporadic.

Humans are the only known reservoir for the organism, which is carried asymptptomatically in the nasopharynx of 5–20% of the general population. Meningococcal disease occurs when the bacteria invade the nasal mucosa and enter the bloodstream; this only happens in a small percentage of those colonized. Invasion depends on both host and bacterial factors. It is more likely to take place soon after colonization has occurred and following viral upper respiratory infections.

Clinical features

Invasive meningococcal infection may cause meningitis, the meningococcal sepsis syndrome or both. Meningitic disease (see p. 863) usually presents with the classical triad of headache, fever and neck stiffness. Vomiting, diminished consciousness and focal neurological signs
occur, although some patients, especially in the early stages, only have mild symptoms. Meningococcal septicaemia causes the typical features of septic shock, such as fever, myalgia and hypotension (see pp. 1154–1155), and may be accompanied by a petechial or haemorrhagic rash (Fig. 11.29). In some cases, the patient can deteriorate rapidly, with shock, disseminated intravascular coagulation and multiorgan failure.

![Meningococcal infection, showing a purpuric rash.](image)

**Diagnosis**

The presence of meningitis and sepsis syndrome with a typical rash is strongly suggestive of meningococcal disease. Gram-negative diplococci may be seen on Gram stain of CSF or of aspirate from petechiae; meningococci can also be cultured from CSF or blood, or detected by PCR.

**Management**

*N. meningitidis* is sensitive to benzylpenicillin (in most cases), third-generation cephalosporins and chloramphenicol; cefotaxime or ceftriaxone is the recommended treatment in the UK (see Box 21.57). Meningococcal sepsis should be managed in the same way as any other form of bacterial sepsis. The mortality from meningococcal sepsis in developed countries is currently approximately 10%, while that from meningococcal meningitis alone is less than 5% (see below). Mild neurological sequelae (especially vestibular nerve damage) are common but serious brain damage is relatively unusual.

The meningococcal C conjugate vaccine has contributed to an overall reduction of invasive meningococcal disease in the UK: 800 cases were reported in England and Wales in 2013, compared with 2784 in 1999 (when the group C meningococcal immunization programme began). Group B vaccines were licensed and approved for use in the UK in 2014, and from the
start of 2016 are being introduced into the routine childhood/young adult immunization programme. A combined A/C/W135/Y vaccine is available for control of outbreaks caused by these strains and for travellers to endemic areas.

Close contacts of a case of meningococcal disease should be given prophylaxis with oral rifampicin or ciprofloxacin to eradicate the bacteria from the nasopharynx and reduce the risk of onward spread. In the case of group C disease, contacts should be offered immunization.

**Rheumatic fever**

Rheumatic fever is an inflammatory disease that occurs in children and young adults (the first attack usually takes place between 5 and 15 years of age) as a result of infection with group A streptococci (GAS). It affects the heart, skin, joints and CNS. It is relatively common in the Middle and Far East, Eastern Europe and South America, but is now rare in Western Europe and North America. This decline in the incidence of rheumatic fever in the developed world (from 10% of children in the 1920s to 0.01% today) parallels the reduction in all streptococcal infections and is largely due to improved hygiene and the use of antibiotics.

Pharyngeal infection with GAS is followed, in a small proportion of cases, by the clinical syndrome of rheumatic fever. This is thought to develop because of an autoimmune reaction triggered by molecular mimicry between the cell-wall M proteins of the infecting *Streptococcus pyogenes* and cardiac myosin and laminin. The condition is not due to direct infection of the heart or to the production of a toxin.

**Clinical features**

The disease presents suddenly, with fever, joint pains and malaise. Diagnosis relies on the presence of two or more major clinical manifestations, or one major manifestation plus two or more minor features, in addition to evidence of current or recent streptococcal infection. These are known as the modified Jones criteria *(Box 11.44)*.

---

**Box 11.44**

**Modified Jones criteria for the diagnosis of rheumatic fever**

**Evidence of antecedent streptococcal infection**

- Positive throat culture for group A streptococcus
- Good clinical history (e.g. of scarlet fever)
- Elevated antistreptolysin O titre (or other serological assay for streptococci)

**Major criteria**

- Carditis
- Polyarthritis
• Chorea
• Erythema marginatum
• Subcutaneous nodules

**Minor criteria**

• Fever
• Arthralgia (unless arthritis counted as major criterion)
• Previous rheumatic fever
• Raised ESR/C-reactive protein
• Leucocytosis
• Prolonged PR interval on ECG (unless carditis counted as major criterion)

ESR, erythrocyte sedimentation rate.

**Carditis** manifests as:
– new or changed heart murmurs
– development of cardiac enlargement or cardiac failure
– appearance of a pericardial effusion and electrocardiographic (ECG) changes of pericarditis, myocarditis, AV block or other cardiac arrhythmias.

**Non-cardiac features** include the following:

• Fever.

• The arthritis associated with rheumatic fever (see pp. 703–704) is classically a fleeting migratory polyarthritis affecting large joints such as the knees, elbows, ankles and wrists. Once the acute inflammation disappears, the rheumatic process leaves the joints normal

• Sydenham's chorea (or St Vitus' dance; see p. 856) is involvement of the CNS that develops late after a streptococcal infection. Sufferers are noticeably ‘fidgety’ and display spasmodic, unintentional, choreiform movements. Speech is often affected

• Skin manifestations include erythema marginatum, a transient pink rash with slightly raised edges, which occurs in 20% of cases. The erythematous areas found mostly on the trunk and limbs coalesce into crescentic ring-shaped patches. Subcutaneous nodules, which are painless, pea-sized, hard nodules beneath the skin, may also occur.

**Investigations**

• *Throat swabs* for GAS.
• *Antistreptolysin O titre* and *anti-DNAse B*.
• *Cardiac investigations*, e.g. ECG, echocardiogram.
Absolute bed rest is usually recommended, although the evidence for this dates from the pre-antibiotic era. It is probably reasonable to start mobilizing the patient when acute symptoms start to improve.

Residual streptococcal infections should be eradicated with oral phenoxyethylpenicillin 500 mg four times daily for 1 week. This therapy should be administered even if nasal or pharyngeal swabs do not culture the streptococci.

The arthritis of rheumatic fever usually responds to non-steroidal anti-inflammatory drugs (NSAIDs), although these have no impact on long-term cardiac sequelae. There is no good evidence that steroids are of benefit, although some experts give high-dose prednisolone if there is severe carditis. Recurrences are most common when persistent cardiac damage is present and are prevented by the continued administration of oral phenoxyethylpenicillin 250 mg twice daily or i.m. benzathine penicillin G 1.2 million units monthly until the age of 20 years or for 5 years after the latest attack (see p. 293). Erythromycin or clarithromycin is used if the patient is allergic to penicillin. Any streptococcal infection that does develop should be treated promptly.

**Prognosis**

More than 50% of those who suffer acute rheumatic fever with carditis will later (after 10–20 years) develop chronic rheumatic valvular disease, predominantly affecting the mitral and aortic valves.

**Leptospirosis**

Leptospirosis is a zoonosis caused by the spirochaete *Leptospira interrogans*. There are over 200 serotypes. The main types affecting humans are:

- *L. i. icterohaemorrhagiae* (normal host: rodents)
- *L. i. canicola* (dogs and pigs)
- *L. i. hardjo* (cattle)
- *L. i. pomona* (pigs and cattle).

Leptospires are excreted in the animal's urine and enter the host through a skin abrasion or through intact mucous membranes. Leptospirosis can also be caught by ingestion of contaminated water. The organism can survive for many days in warm fresh water and for up to 24 h in sea water.

In England and Wales, only about 50 cases of leptospirosis are reported every year (although many mild infections probably go undiagnosed) and it remains largely an occupational disease of farmers, vets and others who work with animals. In some parts of the world (e.g. Hawaii, where the annual incidence is high), it is associated with a variety of recreational activities that bring people into closer contact with rodents. Outbreaks of leptospirosis have also been associated with flooding.
Clinical features

In 1896, Weil described a severe illness consisting of jaundice, haemorrhage and renal impairment caused by *L. i. icterohaemorrhagiae*, but fortunately 90–95% of infections are subclinical or cause only a mild fever. The incubation period of leptospirosis is usually 7–14 days and the illness typically has two phases. A leptospiraemic phase, which lasts for up to a week, is followed after a couple of days' interval by an immunological phase. The first phase is characterized by severe headache, malaise, fever, anorexia and myalgia. Most patients have conjunctival suffusion. Hepatosplenomegaly, lymphadenopathy and various skin rashes are sometimes seen. The second phase is usually mild. Half of patients have meningism, about a third of whom have a CSF lymphocytosis. The majority of patients recover uneventfully at this stage.

In severe disease, there may not be a clear distinction between phases. Following the initial symptoms, patients progressively develop hepatic and kidney injury, haemolytic anaemia and circulatory collapse. Cardiac failure and pulmonary haemorrhage may also occur. Even with full supportive care, the mortality is around 10%, rising to 15–20% in the elderly.

Diagnosis

The diagnosis is usually a clinical one. Leptospires can be cultured from blood or CSF during the first week of illness, but culture requires special media and may take several weeks. Leptospiral DNA can be detected by PCR in the blood and urine. A minority of patients may also excrete the organism in their urine from the second week onwards. Confirmation is usually serological. Specific IgM antibodies start to appear from the end of the first week and the diagnosis is often made retrospectively with a microscopic agglutination test (MAT) showing a fourfold rise. There is typically a leucocytosis and, in severe infection, thrombocytopenia and an elevated creatine phosphokinase.

Management

Early antibiotic therapy may limit the progress of the disease; if antibiotics are used, they should be started as quickly as possible. The efficacy of antibiotics in mild disease is debated; if they are used, oral doxycycline is the best choice. Intravenous penicillin or ceftriaxone should be given in more severe cases. Intensive supportive care is needed for those patients who develop hepatorenal failure.

Brucellosis

Brucellosis (Malta fever, undulant fever) is a zoonosis and has a worldwide distribution, although it has been virtually eliminated from cattle in the UK, where there have been few infections – mainly imported – in recent years. The highest incidence is in the Mediterranean countries, the Middle East and the tropics; there are about 500 000 new cases diagnosed per
The organisms usually gain entry into the human body via the mouth; less frequently, they may enter via the respiratory tract, genital tract or abraded skin. The bacilli travel in the lymphatics and infect lymph nodes. This is followed by haematogenous spread with ultimate localization in the reticulo-endothelial system. Acquisition is usually by the ingestion of raw milk from infected cattle or goats, although occupational exposure is also common. Person-to-person transmission is rare.

**Clinical features**

The incubation period of acute brucellosis is 1–3 weeks. The onset is insidious, with malaise, headache, weakness, generalized myalgia and night sweats. The fever pattern is classically undulant, although continuous and intermittent patterns are also seen. Lymphadenopathy and hepatosplenomegaly are common; sacroiliitis, arthritis, osteomyelitis, epididymo-orchitis, meningoencephalitis and endocarditis have all been described.

Untreated brucellosis can give rise to chronic infection, lasting a year or more. This is characterized by easy fatigability, myalgia and occasional bouts of fever and depression. Splenomegaly is usually present. Occasionally, infection can lead to localized brucellosis, which may not be associated with systemic symptoms. Bones and joints, spleen, endocardium, lungs, urinary tract and nervous system may be involved.

**Diagnosis**

Blood (or bone marrow) cultures are positive during the acute phase of illness in 50% of patients (higher in *B. melitensis*), but prolonged culture is needed. In chronic disease, serological tests are of greater value. The *Brucella* agglutination test, which demonstrates a fourfold or greater rise in titre (>1 in 160) over a 4-week period, is highly suggestive of brucellosis. An elevated serum IgG level is evidence of current or recent infection; a negative test excludes chronic brucellosis. In localized brucellosis, antibody titres are low and the diagnosis is usually established by culturing the organisms from the involved site. Species-specific PCR tests are also available.

**Management and prevention**

Brucellosis should be treated with a combination of doxycycline, rifampicin and an aminoglycoside (usually gentamicin). Prevention and control involve careful attention to hygiene when handling infected animals, eradication of infection in animals through vaccination, and the pasteurization of milk. No vaccine is available for use in humans.

**Listeriosis**

*Listeria monocytogenes* is an environmental organism that is widely disseminated in soil and
decayed matter. It affects both animals and humans; the most common route of human infection is in contaminated foodstuffs. The organism can grow at temperatures as low as 4°C and the most commonly implicated foods are unpasteurized soft cheeses, raw vegetables and chicken pâtés. Listeriosis is a rare but serious infection affecting mainly neonates, pregnant women, the elderly and the immunocompromised. \textit{L. monocytogenes} has also been recognized as a cause of self-limiting, food-borne gastroenteritis in healthy adults, but the incidence of this is unknown.

In pregnant women, \textit{Listeria} causes an influenza-like illness, but infection of the fetus can lead to septic abortion, premature labour and stillbirth. Early treatment of \textit{Listeria} in pregnancy may prevent this but the overall fetal loss rate is about 50%. In the elderly and the immunocompromised, \textit{Listeria} can cause meningoencephalitis. Bacteraemia and a variety of focal infections have also been described.

The diagnosis is established by culture of blood, CSF or other body fluids. The treatment of choice for adult listeriosis is ampicillin plus gentamicin. Co-trimoxazole is also effective but the organism is resistant to cephalosporins.

### Q fever

Q fever is a zoonosis caused by \textit{Coxiella burnetii}. Infection is widespread in domestic, farm and other animals, birds and arthropods; spread is mainly by ticks. Modes of transmission to humans are by dust, aerosol and unpasteurized milk from infected cows. The formation of spores means that \textit{C. burnetii} can survive in extreme environmental conditions for long periods. The infective dose is very small, so that minimal animal contact is required. One reported outbreak occurred among inhabitants of a village through which infected sheep had passed. Infection in the UK is rare and is usually associated with farm and abattoir workers. A large outbreak in the Netherlands (with 4000 human cases) has been linked to intensive goat farming.

### Clinical features

Symptoms begin insidiously 2–4 weeks after infection. Fever is accompanied by influenza-like symptoms with myalgia and headache. The acute illness usually resolves spontaneously but pneumonia or hepatitis may develop. Occasionally, infection can become chronic, with endocarditis, myocarditis, uveitis, osteomyelitis or other focal infections.

\textit{C. burnetii} is an obligate intracellular organism and does not grow on standard culture media. Diagnosis is made serologically using an immunofluorescent assay. Antibody tests for two different bacterial antigens, caused by an antigenic shift, allow distinction between acute and chronic infection. A PCR assay is available but the sensitivity is low.

### Management

Treatment with doxycycline or azithromycin shortens the duration of the acute illness, and there
is emerging evidence that it may reduce the incidence of chronic sequelae. For chronic Q fever, including endocarditis, doxycycline is often combined with rifampicin or hydroxychloroquine. Even prolonged courses of treatment may not clear the infection. A vaccine is available for those at high risk.

**Lyme disease**

Lyme disease is caused by spirochaetes of the genus *Borrelia*. *B. burgdorferi* is the sole cause of Lyme disease in the USA. In Europe, *B. afzelii* and *B. garinii* are also implicated. Lyme disease is a zoonosis of deer and other wild mammals. It has increased in both incidence and detection; it is now known to be widespread in the USA, Europe, Russia and the Far East. About 800 autochthonous cases are seen in England and Wales each year. Infection is transmitted from animal to humans by ixodid ticks and is most likely to occur in rural wooded areas in spring and early summer (*Fig. 11.30*). Co-infection with other organisms, such as ehrlichiosis, occurs.

*FIGURE 11.30* The skin lesion, erythema migrans, at the site of a tick bite.

**Clinical features**

There are three stages of Lyme infection:

- Early localized disease presents about a week after the tick bite with erythema migrans (a macular rash), lymphadenopathy, and associated fever and headache. Many people recover spontaneously at this stage.

- Early disseminated disease occurs days to weeks after the appearance of erythema migrans. Some patients may develop a more widespread rash, and after several weeks or months a small proportion of untreated cases may develop neurological complications such as meningitis, encephalitis, cranial or peripheral neuritis, or radiculopathies. Cardiac involvement is seen in the USA but is rare elsewhere. Myalgia and arthritis may also occur at
this stage.
• Late Lyme disease, which is rare, can cause chronic arthritis, encephalomyelitis and other neurological disorders, and acrodermatitis chronica atrophicans. There is little evidence for persistent infection at this stage and extended antibiotic therapy is unjustified.

### Diagnosis

The clinical features and epidemiological considerations are usually strongly suggestive. The diagnosis can be confirmed only rarely by isolation of the organisms from blood, skin lesions or CSF. IgM antibodies are detectable in the first month and IgG antibodies are invariably present late in the disease. Sensitive antibody detection tests are available but false-positive results occur and an initial positive test should always be followed by a confirmatory immunoblot assay. Even a genuine positive IgG result may be a marker of previous exposure rather than of ongoing infection.

### Management

Amoxicillin or doxycycline given early in the course of the disease shortens the duration of the illness in approximately 50% of patients. Disseminated or late disease should be treated with 2–4 weeks of intravenous ceftriaxone. However, treatment is unsatisfactory and preventative measures are recommended. In tick-infested areas, repellents and protective clothing should be worn. Prompt removal of any tick is essential, as infection is unlikely to take place unless the tick has been attached for more than 48 hours. Ticks should be grasped with forceps near to the point of attachment to the skin and then withdrawn by gentle traction. Antibiotic prophylaxis following a tick bite is not usually justified, even in areas where Lyme disease is common. There is currently no effective vaccine.

### Tularaemia

Tularaemia is due to infection caused by *Francisella tularensis*, a Gram-negative coccobacillus. It is primarily a zoonosis, acquired mainly from rodents. Infection can be transmitted by arthropod vectors or by the handling of infected animals, when the microorganisms enter through minor abrasions or mucous membranes. Occasionally, infection occurs from contaminated water or from uncooked meat. The disease is widely distributed in North America, Northern Europe and Asia, but the particularly virulent type A subspecies is only seen in the USA. It is relatively rare, occurring mainly in hunters, trappers and others in close contact with animals.

The incubation period of 2–7 days is followed by a generalized illness. The most common presentation is ulceroglandular tularaemia. A papule occurs at the site of inoculation. This ulcerates and is followed by tender, suppurative lymphadenopathy. Rarely, this can be followed by bacteraemia, leading to septicaemia, pneumonia or meningitis. These forms of the disease carry a high mortality if untreated.
Diagnosis is by a rising titre seen on a bacterial agglutination test, which is positive after 2 weeks. Routine cultures are often negative. PCR is now becoming the standard diagnostic test. Tularaemia should be treated with streptomycin or gentamicin, although doxycycline is used in mild disease.

Bacterial Infections Seen in Developing and Tropical Countries

Skin, soft tissue and eye disease

Leprosy

Leprosy is caused by the acid-fast bacillus *Mycobacterium leprae*. Unlike other mycobacteria, this does not grow in artificial media or even in tissue culture. Apart from the nine-banded armadillo, humans are the only natural host of *M. leprae*, although it can be grown in the footpads of mice.

The WHO campaign to control leprosy has been hugely successful, more than 14 million people having been cured of the disease. The number of people with active leprosy has fallen from 5.4 million in 1985 to about 190,000 at the end of 2013, largely as the result of supervised multidrug treatment regimens. The majority of the remaining cases are in India and Brazil and, despite the successes, many new infections are occurring in these countries. The WHO has announced a ‘Final Push’ strategy to attempt to eradicate the disease completely.

The precise mode of transmission of leprosy is still uncertain but it is likely that nasal secretions play a role. Infection is related to poverty and overcrowding. Once an individual has been infected, subsequent progression to clinical disease appears to be dependent on several factors. Males appear to be more susceptible than females and there is evidence from twin studies of a genetic susceptibility. The main factor, however, is the response of the host’s cell-mediated immune system.

Two *polar types* of leprosy are recognized (*Fig. 11.31*):
• **Tuberculoid leprosy**, a localized disease that occurs in individuals with a high degree of cell-mediated immunity (CMI). The T-cell response to the antigen releases interferon, which activates macrophages to destroy the bacilli (Th1 response) but with associated destruction of the tissue.

• **Lepromatous leprosy**, a generalized disease that occurs in individuals with impaired CMI ([Fig. 11.31](#)). Here the tissue macrophages fail to be activated and the bacilli multiply intracellularly. Th2 cytokines are produced.

![Clinical spectrum of leprosy with the combined Ridley–Jopling and WHO classification. AFB, acid-fast bacilli; BB, borderline; BL, borderline lepromatous; BT, borderline tuberculoid; CMI, cell-mediated immunity; LL, lepromatous leprosy; MB, multibacillary; PB, paucibacillary; TT, tuberculoid leprosy.](#)

The WHO classification of leprosy depends on the number of skin lesions and the number of bacilli detected on the skin smears: **paucibacillary leprosy** has five or fewer skin lesions with no bacilli; **multibacillary leprosy** has six or more lesions that may have bacilli.

In practice, many patients will fall between these two extremes and some may move along the spectrum as the disease progresses or is treated.

### Clinical features

The incubation period is typically from 2 to 6 years, although it may be as short as a few months or as long as 20 years. The onset of leprosy is generally insidious (although acute onset is known to occur). Patients may present with a transient rash, features of an acute febrile illness, evidence of nerve involvement, or with any combination of these.

The spectrum of disease can be divided into five clinical groups ([Fig. 11.32](#)).
Diagnosis

The diagnosis of leprosy is essentially clinical with:

- hypopigmented/reddish patches with loss of sensation
- thickening of peripheral nerves
- acid-fast bacilli (AFB) seen on skin-slit smears/biopsy. Small slits are made in pinched skin and the fluid obtained is smeared on a slide and stained for AFB.

Patients should be examined for skin lesions in adequate natural light. Occasionally, nerve biopsies are helpful. Detection of *M. leprae* DNA is possible in all forms of leprosy using PCR and can be used to assess the efficacy of treatment.

Management

Multidrug therapy (MDT) is essential because of developing drug resistance (up to 40% of bacilli in some areas are resistant to dapsone). Much shorter courses of treatment are now being used; the current WHO recommended drug regimens for leprosy are shown in *Box 11.45* but longer therapy is required in severe cases. Follow-up, including skin smears, is obligatory. Immunological reactions (‘lepra reactions’) can occasionally occur after treatment is started, especially in borderline and lepromatous disease (*Box 11.46*).
(modified WHO guidelines)

**Box 11.46**

**Lepra reactions following commencement of antimycobacterial treatment**

**Type 1**
- Occurs in borderline disease
- Type IV hypersensitivity reaction
- Lasts for many months
- Upgrading (→ TT) or downgrading (→ BB)
- Abrupt onset of nerve palsy in upgrading
- Treatment:
  - Prednisolone

**Type 2 (erythema nodosum leprosum)**
- Occurs in lepromatous disease
- Type III (immune complex) hypersensitivity reaction
- Last days to weeks:
  - Fever
  - Arthralgia
  - Subcutaneous nodules
  - Iridocyclitis
- Rare since clofazimine included in treatment

BB, borderline; BL, borderline lepromatous; BT, borderline tuberculoid; LL, lepromatous; TT, tuberculoid.
• Treatment:
  – Analgesia
  – Clofazimine (if not already started)
  – Prednisolone if eye involvement
  – Continuation of anti-mycobacterial treatment

Thalidomide no longer has any role in the management of lepra reactions. BB, borderline; TT, tuberculoid.

Patient education is essential. Patients should be taught self-care of their anaesthetic hands and feet to prevent ulcers. If ulcers develop, no weight-bearing should be permitted. Cheap canvas shoes with cushioned insoles are protective.

Leprosy should be treated in specialist centres with adequate physiotherapy and occupational therapy support. Surgery and physiotherapy also play a role in the management of trophic ulcers and deformities of the hands, feet and face.

Prognosis in tuberculoid leprosy is good, even if untreated; lepromatous leprosy is progressive if untreated.

Prevention
The prevention and control of leprosy depend on rapid treatment of infected patients, particularly those with lepromatous and borderline lepromatous types, to decrease the bacterial reservoir.

Anthrax
Anthrax is caused by *Bacillus anthracis*. The spores of these Gram-positive bacilli are extremely hardy and withstand extremes of temperature and humidity. The organism is capable of toxin production and this property correlates most closely with its virulence. The disease occurs worldwide but it is most common in Africa and Southern Asia. Transmission is through direct contact with an infected animal; infection is most frequently seen in farmers, butchers and dealers in wool and animal hides. Spores can also be ingested or inhaled. There have been cases in the USA due to the deliberate release of anthrax spores as a bioterrorist weapon (see p. 60).

Clinical features
The incubation period is 1–10 days.

• **Cutaneous anthrax** is the most common form. The small, erythematous, maculopapular lesion is initially painless. It may subsequently vesiculate and ulcerate, with formation of a central black eschar. The illness is self-limiting in the majority of patients but, occasionally,
perivesicular oedema and regional lymphadenopathy may be marked and toxaemia can occur.

- **Inhalational anthrax** (wool-sorter's disease) follows inhalation of spores. A febrile illness is accompanied by a non-productive cough and retrosternal discomfort; pleural effusions are common. Untreated, the mortality is about 90%; in the bioterrorism cases in the USA, it was 45% despite treatment.

- **Gastrointestinal anthrax** is due to consumption of under-cooked, contaminated meat. It presents as severe gastroenteritis; haematemesis and bloody diarrhoea can occur. Toxaemia, shock and death may follow.

### Diagnosis

The diagnosis is established by demonstration of the organism in smears from cutaneous lesions or by culture of blood and other body fluids. Serological confirmation can be obtained using ELISAs that detect antibodies to both the organism and a toxin.

### Management

Ciprofloxacin is considered the best treatment. In mild cutaneous infections, oral therapy for 2 weeks is adequate but therapy for 60 days was used in the recent outbreaks in the USA. In more severe infections, high doses of intravenous antibiotics are needed, along with appropriate supportive care. The monoclonal antibody, raxibacumab, has been shown in animal studies to improve survival in inhalational anthrax. Any suspected case should be reported to the relevant authority.

### Control

Any infected animal that dies should be burned and the area in which it was housed disinfected. Where animal husbandry is poor, mass vaccination of animals may prevent widespread contamination but needs to be repeated annually. A human vaccine is available for those at high risk, and prophylactic ciprofloxacin is used following exposure. Some countries are establishing public health policies to deal with the deliberate release of anthrax spores.

### Mycobacterial ulcer (buruli ulcer)

Buruli ulcer, caused by *Mycobacterium ulcerans*, is seen in humid rural areas of the tropics, especially in Africa. The mode of transmission is thought to be via infected water bugs living in pools and muddy fields. A small subcutaneous nodule at the site of infection gradually ulcerates, involving subcutaneous tissue, muscle and fascial planes. The ulcers are usually large with undermined edges and markedly necrotic bases due to mycolactone (a toxin produced by the mycobacterium). Smears taken from necrotic tissue generally reveal numerous acid-fast bacilli. The only effective treatment was wide surgical excision with skin grafts, but this is often unavailable in areas where the disease is prevalent. However, there is now good
evidence that combination therapy with rifampicin plus one of streptomycin, clarithromycin or moxifloxacin given for 8 weeks, will heal ulcers in many cases.

### Endemic treponematoses (bejel, yaws and pinta)

These diseases are found in various parts of the tropics and subtropics, mainly in impoverished rural areas. They are easy to treat with antibiotics, and in the absence of an animal reservoir it may be possible to eradicate them completely (India declared itself free of yaws in 2006). Improvements in sanitation and an increase in living standards will speed this process, as organisms are transmitted by bodily contact, usually in children, the organism entering through damaged skin.

### Clinical features

#### Yaws

Yaws (caused by *Treponema pertenue*) is the most widespread and common of the endemic treponemal diseases. It is transmitted by skin-to-skin contact, often in children. After an incubation period of weeks or months, a primary inflammatory reaction occurs at the inoculation site, from which organisms can be isolated. Dissemination of the organism leads to multiple papular lesions containing treponemes; these skin lesions usually involve the palms and soles. There may also be bone involvement, particularly affecting the long bones and those of the hand.

Approximately 10% of those infected go on to develop late yaws. Bony gummatous lesions may progress to cause gross destruction and disfigurement, particularly of the skull and facial bones, the interphalangeal joints and the long bones. Plantar hyperkeratosis is characteristic. As in syphilis, there may be a latent period between the early and late phases of the disease but visceral, neurological and cardiovascular problems do not occur.

#### Bejel (endemic syphilis)

Bejel is seen in Africa, the Middle East and Central Asia. The causative organism (*Treponema endemicum*) enters through abrasions in the skin directly or by mouth-to-mouth or skin-to-skin contact indirectly, often between children. Bejel differs from venereal syphilis in that the primary lesion is small and often in the mouth and not commonly seen. The late stages resemble syphilis but cardiological and neurological manifestations are rare.

#### Pinta

Pinta (caused by *Treponema carateum*) is restricted mainly to Central and South America. It is milder than the other treponematoses and is confined to the skin. The primary lesion is a pruritic red papule, usually on the hand or foot. It may become scaly but never ulcerates, and is generally associated with regional lymphadenopathy. In the later stages, similar lesions can
continue to occur for up to 1 year, associated with generalized lymphadenopathy. Eventually, the lesions heal, leaving hyperpigmented or depigmented patches.

### Diagnosis and management

In endemic areas, the diagnosis is usually clinical. The causative organism can be identified from the exudative lesions under dark-ground microscopy. Serological tests for syphilis are positive and do not differentiate between the conditions.

Single-dose oral azithromycin has now replaced intramuscular benzathine penicillin as the treatment of choice.

Mass treatment with azithromycin is part of the WHO strategy to eradicate yaws.

### Trachoma

Trachoma, caused by the intracellular bacterium *Chlamydia trachomatis*, is the most common infectious cause of blindness in the world. It is estimated that there are 85 million active infections and 8 million people who have been blinded by trachoma. It is a disease of poverty, which is found mainly in the tropics and the Middle East; it is entirely preventable. Trachoma commonly occurs in children and is spread by direct transmission or by flies. Isolated infection is probably self-limiting and it is repeated infection that leads to chronic eye disease.

### Clinical features

Infection is bilateral and begins in the conjunctiva, with marked follicular inflammation and subsequent scarring. Scarring of the upper eyelid causes entropion, leaving the cornea exposed to further damage with the eyelashes rubbing against it (trichiasis). The corneal scarring that eventually occurs leads to blindness.

Trachoma may also occur as an acute ophthalmic infection in the neonate.

### Diagnosis and management

The diagnosis is generally made clinically.

Systemic therapy with a single dose of azithromycin 20 mg/kg is the treatment of choice, but reinfection is common and repeated treatments are often needed. In some endemic areas, routine mass drug administration is used in children. Once infection has been controlled, surgery may be required for eyelid reconstruction and for treatment of corneal opacities.

### Prevention

Community health education, improvements in water supply and sanitation (pit latrines), and earlier case reporting could have a substantial impact on disease prevalence. This is reflected in the ‘SAFE’ approach to trachoma:
• surgery
• antibiotics
• facial cleanliness
• environmental improvement.

The WHO target is global eradication by 2020.

Gastrointestinal infections

Cholera

Cholera is caused by the curved, flagellated, Gram-negative bacillus, Vibrio cholerae. The organism is killed by temperatures of 100°C in a few seconds but can survive in ice for up to 6 weeks. One major pathogenic serogroup possesses a somatic antigen (O1) with two biotypes: classical and El Tor. The El Tor biotype replaced the classical biotype as the major cause of the seventh pandemic, which began in the 1960s and spread into South and Central America. Infection with the El Tor biotype is generally associated with milder symptoms but can still cause severe and life-threatening disease.

The fertile, humid Gangetic plains of West Bengal have traditionally been regarded as the home of cholera. However, a series of pandemics have spread the disease across the world, usually following trade routes. The seventh pandemic currently affects large areas of Asia and sub-Saharan Africa. A new serogroup (O139 Bengal) is responsible for many cases in Bangladesh, India and South-east Asia.

Transmission is by the faeco-oral route. Contaminated water plays a major role in the dissemination of cholera, although contaminated foodstuffs and contact carriers may contribute in epidemics. Achlorhydria or hypochlorhydria facilitates passage of the cholera bacilli into the small intestine. Here they proliferate, elaborating an exotoxin that produces massive secretion of isotonic fluid into the intestinal lumen (see p. 426). Cholera toxin also releases serotonin (5-hydroxytryptamine, 5-HT) from enterochromaffin cells in the gut, which activates a neural secretory reflex in the enteric nervous system. This may account for at least 50% of cholera toxin's secretory activity. V. cholerae also produces other toxins (zona occludens toxin (ZOT) and accessory cholera toxin (ACT)), which contribute to its pathogenic effect.

Clinical features
The incubation period varies from a few hours to 6 days. The majority of patients with cholera have a mild illness that cannot be distinguished clinically from diarrhoea due to other infective causes. In severe cases, there is abrupt onset of profuse painless diarrhoea, followed by vomiting. As the illness progresses, the typical ‘rice water’ stool, flecked with mucus, may be seen. There is massive fluid loss, and if this is not replaced, the features of hypovolaemic shock (cold clammy skin, tachycardia, hypotension and peripheral cyanosis) and dehydration (sunken eyes, hollow cheeks and a diminished urine output) appear. The patient, though apathetic, is usually lucid. Muscle cramps may be severe. Children may present with convulsions owing to hypoglycaemia.

With adequate treatment the prognosis is good, with a gradual return to normal clinical and biochemical parameters in 1–3 days.

### Diagnosis

This is largely clinical. Examination of freshly passed stools may demonstrate rapidly motile organisms (although this is not diagnostic, as *Campylobacter jejuni* may give a similar appearance). A rapid dipstick test is also available. Stool and rectal swabs should be taken for culture to confirm the diagnosis and to establish antibiotic sensitivity. Cholera should always be reported to the appropriate public health authority.

### Management

The mainstay of treatment is rehydration, and with appropriate and effective rehydration therapy, mortality has decreased to less than 1%. Oral rehydration is usually adequate, but intravenous therapy is sometimes required *(Fig. 11.33)*.
Oral rehydration solutions (ORS) are based on the observation that glucose (and other carbohydrates) enhance sodium and water absorption in the small intestine, even in the presence of secretory loss due to toxins. Additions such as amylase-resistant starch to glucose-based ORS have been shown to increase the absorption of fluid. Cereal-based electrolyte solutions have been found to be as effective as sugar/salt ORS and actually reduce stool volume as well as rehydrating. The WHO recommends the use of reduced-osmolarity ORS for all types of diarrhoea, although concerns remain about the risk of hyponatraemia. Suitable solutions for rehydration are listed in Box 11.32.

Immunization is now recommended by the WHO in potential or actual outbreak situations. Two killed oral vaccines are available. The best preventative measures, however, are good hygiene and improved sanitation.
Enteric fever

Over 17 million new cases of enteric fever occur annually worldwide, mainly in India and Africa, causing 600,000 deaths per year. Enteric fever is an acute systemic illness characterized by fever, headache and abdominal discomfort. Typhoid, the typical form of enteric fever, is caused by Salmonella typhi. A similar but generally less severe illness known as paratyphoid is due to infection with S. paratyphi A, B or C. Humans are the only natural host for S. typhi, which is transmitted in contaminated food or water. The incubation period is 10–14 days.

Clinical features

After ingestion, the bacteria invade the small bowel wall via Peyer's patches, from where they spread to the regional lymph nodes and then to the blood. The onset of illness is insidious and non-specific, with intermittent fever, headache and abdominal pain. Physical findings in the early stages include abdominal tenderness, hepatosplenomegaly, lymphadenopathy and a scanty maculopapular rash (‘rose spots’). Without treatment (and occasionally even after treatment), serious complications can arise, usually in the third week of illness. These include meningitis, lobar pneumonia, osteomyelitis, intestinal perforation and intestinal haemorrhage. The fourth week of the illness is characterized by gradual improvement but, in developing countries, up to 30% of those infected will die and 10% of untreated survivors will relapse. This compares with a mortality rate of 1–2% in the USA.

After clinical recovery, 5–10% of patients will continue to excrete S. typhi for several months: these are termed convalescent carriers. Between 1% and 4% will continue to carry the organism for more than a year: this is chronic carriage. The usual site of carriage is the gall bladder and chronic carriage is associated with the presence of gallstones. However, in parts of the Middle East and Africa where urinary schistosomiasis is prevalent, chronic carriage of S. typhi in the urinary bladder is also common.

Paratyphoid fever is associated with a milder and shorter illness, and complications are uncommon.

Diagnosis

The definitive diagnosis of enteric fever requires the culture of S. typhi or S. paratyphi from the patient. Blood culture is positive in most cases in the first 2 weeks. Culture of intestinal secretions, faeces and urine is also used, although care must be taken to distinguish acute infection from chronic carriage. Bone marrow culture is more sensitive than blood culture but is rarely required, except in patients who have already received antibiotics. Leucopenia is common but non-specific. Serological investigations, such as the Widal antigen test, are of little practical value, are easily misinterpreted and should not be used.
Management

Increasing antibiotic resistance is seen in isolates of S. typhi, especially in the Indian subcontinent. Chloramphenicol, co-trimoxazole and amoxicillin may all still be effective in some cases, but quinolones (e.g. ciprofloxacin 500 mg twice daily) are now the treatment of choice. Some resistance is starting to appear to ciprofloxacin; ideally, treatment should be based on known local resistance patterns. Azithromycin is the best choice in quinolone-resistant cases; ceftriaxone has also been shown to be effective. The patient's temperature may remain elevated for several days after antibiotics are started and this alone is not a sign of treatment failure. Prolonged antibiotic therapy may eliminate the carrier state, but in the presence of gall bladder disease it is rarely effective. Cholecystectomy is not usually justified on clinical or public health grounds.

Prevention

This is mainly through improved sanitation and clean water. Travellers should avoid drinking untreated water, taking ice in drinks and eating ice creams. Vaccination with either injectable inactivated or oral live attenuated vaccines gives partial protection.

Systemic infections

Tuberculosis

Tuberculosis (TB) is caused by Mycobacterium tuberculosis and, occasionally, M. bovis or M. africanum. These are slow-growing bacteria and, unlike other mycobacteria, are facultative intracellular organisms. The prevalence of TB increases with poor social conditions, inadequate nutrition and overcrowding. In developing countries, it is most commonly acquired in childhood.

The impact of TB in the developing world has been magnified in the past 20 years by the emergence of the HIV pandemic (see pp. 331–334) (Fig. 11.34).
Widespread misuse of antibiotics, combined with the breakdown of healthcare systems in parts of Africa and Eastern Europe, has led to the emergence of drug-resistant TB. Multidrug-resistant tuberculosis (MDR-TB) is caused by bacteria that are resistant to both rifampicin and isoniazid, two drugs that form the mainstay of treatment. MDR-TB is now widespread in many parts of the world (see Fig. 24.37), including Asia, Eastern Europe and Africa. Extensively drug-resistant tuberculosis (XDR-TB) is additionally resistant to quinolones and injectable second-line agents. MDR-TB and, especially, XDR-TB are very difficult to treat and carry significant mortality, even with the best medical care (see pp. 1111–1112).

In most people, the initial primary TB is asymptomatic or causes only a mild illness. The focus of the disease heals.

Occasionally, the primary infection progresses locally to a more widespread lesion. Haematogenous spread at this stage may give rise to miliary TB.

TB in the adult is usually the result of reactivation of old disease (post-primary TB) but primary infection or, more rarely, reinfection also occurs.

Pulmonary TB is the most common form; this is described on page 1108, along with the chemotherapeutic regimens. TB also affects other parts of the body.

- The gastrointestinal tract, involving mainly the ileocaecal area but occasionally the peritoneum, producing ascites (see p. 436)
- The genitourinary system, most commonly involving the kidneys but also causing painless, craggy swellings in the epididymis and salpingitis, tubal abscesses and infertility in females.
- The central nervous system, causing tuberculous meningitis and tuberculomas (see p. 867).
- The skeletal system, causing septic arthritis and osteomyelitis.
The skin, giving rise to lupus vulgaris.

The eyes, where it can cause choroiditis or iridocyclitis.

The pericardium, producing constrictive pericarditis (see p. 1043).

The adrenal glands, causing destruction and producing Addison's disease.

The lymph nodes, which is a common mode of presentation, especially in young adults and children. Any group of lymph nodes may be involved but hilar and paratracheal lymph nodes are the most common. Initially, the nodes are firm and discrete, but later they become matted and can suppurate with sinus formation. Scrofula is the term used to describe massive cervical lymph node enlargement with discharging sinuses. Mycobacterial lymph node disease may also be caused by non-tuberculous mycobacteria.

Non-tuberculous mycobacterial infections

The majority of mycobacterial species are environmental organisms and are rarely pathogenic. Some have been found to cause disease in humans, particularly in immunocompromised patients or those with pre-existing chronic lung disease (Box 11.47).

Plague

Plague is caused by *Yersinia pestis*, a Gram-negative bacillus. Sporadic cases of plague (as well as occasional epidemics) occur worldwide: about 2000 cases per year are reported to the WHO, with a 10% mortality. The majority of cases are in sub-Saharan Africa, although the disease is occasionally seen in developed countries in people undertaking outdoor pursuits.
The main reservoirs are woodland rodents, which transmit infection to domestic rats (*Rattus rattus*). The usual vector is the rat flea, *Xenopsylla cheopis*. These fleas bite humans when there is a sudden decline in the rat population. Occasionally, spread of the organisms may be through infected faeces being rubbed into skin wounds, or through inhalation of droplets.

### Clinical features

Four clinical forms are recognized: bubonic, pneumonic, septicaemic and cutaneous.

**Bubonic plague**

This is the most common form and occurs in about 90% of infected individuals. The incubation period is 2–7 days. The onset of illness is acute, with high fever, chills, headache, myalgia, nausea, vomiting and, when severe, prostration. This is rapidly followed by the development of lymphadenopathy (buboes), most commonly involving the inguinal region. Characteristically, these are matted and tender, and suppurate in 1–2 weeks.

**Pneumonic plague**

This is characterized by the abrupt onset of features of a fulminant pneumonia with bloody sputum, marked respiratory distress, cyanosis and death in almost all affected patients.

**Septicaemic plague**

This presents as an acute fulminant infection with evidence of shock and disseminated intravascular coagulation (DIC). If it is left untreated, death usually occurs in 2–5 days. Lymphadenopathy is unusual.

**Cutaneous plague**

This presents either as a pustule, eschar or papule, or as extensive purpura, which can become necrotic and gangrenous.

### Diagnosis

This is based on clinical, epidemiological and laboratory findings. Microscopy (on blood or lymph node aspirate) or a rapid antigen detection test can provide a presumptive diagnosis in an appropriate clinical setting. Blood or lymph node culture, or paired serological tests, are required for confirmation. Rapid diagnosis can be made in 15 minutes using *Y. pestis* F1 antigen in serum or sputum.

### Management

Treatment is urgent and should be instituted before the results of culture studies are available. The treatment of choice is gentamicin 1 mg/kg i.v. three times daily for 10 days. Oral doxycycline 500 mg four times daily and chloramphenicol are also effective.
Prevention

Prevention of plague is largely dependent on control of the flea population. Outhouses or huts should be sprayed with insecticides that are effective against the local flea. During epidemics, rodents should not be killed until the fleas are under control, as the fleas will leave dead rodents to bite humans. Tetracycline 500 mg four times daily for 7 days is an effective chemoprophylactic agent. Both killed and attenuated vaccines have been available for many years but have limited efficacy.

Relapsing fevers

These conditions are so named because, after apparent recovery from the initial infection, one or more recurrences may occur after a week or more without fever. They are caused by spirochaetes of the genus *Borrelia*.

Clinical features

**Louse-borne relapsing fever**

This condition (caused by *B. recurrentis*) is spread by body lice and only humans are affected. Classically, it is an epidemic disease of armies and refugees, although it is also endemic in the highlands of Ethiopia, Yemen and Bolivia. Lice are spread from person to person when humans live in close contact in impoverished conditions. Infected lice are crushed by scratching, allowing the spirochaete to penetrate through the skin. Symptoms begin 3–10 days after infection and consist of a high fever of abrupt onset with rigors, generalized myalgia and headache. A petechial or ecchymotic rash may be seen. The patient's general condition then deteriorates, with delirium, hepatosplenomegaly, jaundice, haemorrhagic problems and circulatory collapse. Although complete recovery may occur at this time, the majority experience one or more relapses of diminishing intensity over the weeks following the initial illness. The severity of the illness varies enormously and some cases have only mild symptoms. However, in some epidemics, mortality has exceeded 50%.

**Tick-borne relapsing fever**

This is caused by *B. duttoni* and other *Borrelia* species, spread by soft (argasid) ticks. Rodents are also infected and humans are incidental hosts, acquiring the spirochaete from the saliva of the infected tick. This disease is found mainly in countries where traditional mud huts are the form of shelter and is a common cause of febrile illness in parts of Africa. The illness is generally similar to the louse-borne disease, although neurological involvement is more common.

Diagnosis and management
Spirochaetes can be demonstrated microscopically in the blood during febrile episodes; organisms are more numerous in louse-borne relapsing fever. Treatment is usually with tetracycline or doxycycline. A severe Jarisch–Herxheimer reaction (see p. 329) occurs in many patients.

**Prevention**

Control of infection relies on elimination of the vector. Ticks live for years and remain infected, passing the infection to their progeny. These reservoirs of infection should be controlled by spraying houses with insecticides and by reducing the number of rodents. Post-exposure prophylaxis has been shown to be effective in areas where tick-borne disease is highly endemic. Patients infested with lice should be deloused by washing with a suitable insecticide. All clothes must be thoroughly disinfected.

**Rickettsial diseases**

*Rickettsiae* (and the closely related *Orientiae*) are small, intracellular bacteria that are spread to humans by arthropod vectors, including body lice, fleas, hard ticks and larval mites. Rickettsiae inhabit the alimentary tract of these arthropods and the disease is spread to the human host by inoculation of their faeces through broken human skin, generally produced by scratching (*Fig. 11.35*). Rickettsiae multiply intracellularly and can enter most mammalian cells, although the main lesion produced is a vasculitis caused by invasion of endothelial cells of small blood vessels (*Fig. 11.36*). Multisystem involvement is usual.

*FIGURE 11.35* An eschar developing at the site of the bite in rickettsial disease.
Typhus group

Typhus is the collective name given to a group of diseases caused by *Rickettsia* species. Box 11.48 shows a list of rickettsial diseases; with the advent of molecular techniques, many new species of rickettsia causing human disease have been identified.

### Clinical features

**Typhus fever group**
**Epidemic typhus**

The vector of epidemic typhus is the human body louse and, as with louse-borne relapsing fever, epidemics are associated with war and refugees. Outbreaks have occurred in Africa, Central and South America, and Asia.

The incubation period of 1–3 weeks is followed by an abrupt febrile illness associated with profound malaise and generalized myalgia. Headache is severe and there may be conjunctivitis with orbital pain. A measles-like eruption appears around the fifth day. At the end of the first week, signs of meningoencephalitis appear and CNS involvement may progress to coma. At the height of the illness, splenomegaly, pneumonia, myocarditis and gangrene at the peripheries may be evident. Oliguric acute kidney injury occurs in fulminating disease, which is usually fatal. Recovery begins in the third week but is generally slow. The disease may recur many years after the initial attack owing to rickettsiae that lie dormant in lymph nodes. The recrudescence is known as Brill–Zinsser disease. The factors that precipitate recurrence are not clearly defined, although other infections may play a role.

**Endemic (murine) typhus**

This is an infection of rodents that is inadvertently spread to humans by rat fleas. The disease closely resembles epidemic typhus but is much milder and rarely fatal.

**Scrub typhus**

Found throughout Asia and the Western Pacific, this disease is spread by larval trombiculid mites (chiggers). An eschar (a black, crusted, necrotic papule) can often be found at the site of the bite. The clinical illness is very variable, ranging from a mild illness to fulminant and potentially fatal disease. The more severe cases resemble epidemic typhus. Unlike other types of typhus, the organism is passed on to subsequent generations of mites, which consequently act as both reservoir and vector.

**Spotted fever group**

A variety of *Rickettsia* species, collectively known as the spotted fever group rickettsiae, cause the illnesses known as spotted fevers. In most cases, the vector is a hard tick. Although the causative organism and the name of the illness vary from place to place, the clinical course is common to all.

The typical feature of the spotted fevers is a widespread petechial rash, although a variety of other types of skin lesion are seen especially in Rocky Mountain spotted fever. The form of African tick typhus caused by *R. africae* often presents without a rash.

After an incubation period of 4–10 days, an eschar may develop at the site of the bite in association with regional lymphadenopathy. There is abrupt onset of fever, myalgia and headache, accompanied by a maculopapular rash that may become petechial. Neurological, haematological and cardiovascular complications occur as in epidemic typhus, although these are uncommon.
Diagnosis

The diagnosis is generally made on the basis of the history and clinical course of the illness. It can be confirmed serologically or by PCR.

Management and prevention

Doxycycline or tetracycline given for 5–7 days is the treatment of choice. Ciprofloxacin is also effective. Doxycycline 200 mg weekly protects against scrub typhus; it is reserved for highly endemic areas. Rifampicin is also used when resistance to tetracycline is present. Seriously ill patients need intensive care. Control of typhus is achieved by eradication of the arthropod vectors. Lice and fleas can be eradicated from clothing by insecticides (0.5% malathion or DDT). Control of rodents is necessary in endemic typhus and some of the spotted fevers. Areas of vegetation infested with trombiculid mites can be cleared by chemical spraying from the air. Bites from ticks and mites should be avoided by wearing protective clothing on exposed areas of the body. The likelihood of infection from ticks is related to the duration of feeding; in high-risk areas, the body should be inspected twice a day, as the bites are painless, and any ticks should be removed (see p. 284).

Bartonellosis

*Bartonella* spp. are intracellular bacteria closely related to the rickettsiae. A number of human diseases can be caused by these organisms; as in rickettsial disease, infection is usually spread from animals via an arthropod vector (*Box 11.49*).

*Also known as human granulocytic anaplasmosis.

*Formerly known as *Ehrlichia phagocytophilia.*

**Carrion's disease (*Bartonella bacilliformis*)**

This disease is restricted mainly to the habitat of its main vector, the sandfly, in the river valleys of the Andes mountains at an altitude of 500–3000 m. Two clinical presentations are seen, which may occur alone or consecutively. **Oroya fever** is an acute febrile illness causing myalgia, arthralgia, severe headache and confusion, followed by a haemolytic anaemia. **Verruga peruana** consists of eruptions of reddish-purple haemangiomatous nodules, resembling bacillary angiomatosis. It may follow 4–6 weeks after Oroya fever or be the presenting feature of infection. Spontaneous resolution may occur over a period of months or years. Carrion's disease is frequently complicated by superinfection, especially with *Salmonella* spp.

The diagnosis is made by culturing bacilli from blood or peripheral lesions. Serological tests have been developed but are not widely available.

Treatment with chloramphenicol or tetracycline is very effective in acute disease, but less so in verruga peruana.

**Cat-scratch disease and bacillary angiomatosis (*Bartonella henselae*)**

These are described on page 270.

**Trench fever**

Trench fever is caused by *Bartonella quintana* and transmitted by human body lice. It is mainly seen in refugees and the homeless. It is characterized by cyclical fever (typically, every 5 days), chills and headaches, accompanied by myalgia and pretibial pain. The disease is usually self-limiting but it can be treated with erythromycin or doxycycline if symptoms are severe.

**Ehrlichiosis**
Ehrlichiosis and anaplasmosis are infections caused by tick-borne, rickettsia-like bacteria. At least three species have been implicated: *Ehrlichia chaffeensis*, which causes human monocytic ehrlichiosis (HME), and *E. ewingii* and *Anaplasma phagocytophilum* (formerly known as *E. phagocytophilum*), which cause human granulocytic ehrlichiosis (HGE, also known as human granulocytic anaplasmosis). All cause a rather non-specific febrile illness with fever, myalgia and headache. Treatment is with doxycycline. The vectors are hard ticks and the main reservoir hosts are deer. As with most tick-borne zoonoses, the avoidance of tick bites and the prompt removal of feeding ticks are the best forms of prevention.

### Melioidosis

The term melioidosis refers to infections caused by the Gram-negative bacterium *Burkholderia pseudomallei*. This environmental organism, which is found in soil and surface water, is distributed widely in the tropics and subtropics. The majority of clinical cases of melioidosis occur in South-east Asia. Infection follows inhalation or direct inoculation. More than half of all patients with melioidosis have predisposing underlying disease; it is particularly common in diabetics.

*B. pseudomallei* causes a wide spectrum of disease and the majority of infections are probably subclinical. Illness may be acute or chronic, and localized or disseminated, but one form of the disease may progress to another and individual patients may be difficult to categorize. The most serious form is septicaemic melioidosis, which is often complicated by multiple metastatic abscesses; this is frequently fatal. Serological tests are available but definitive diagnosis depends on isolating the organism from blood or appropriate tissue. *B. pseudomallei* has extensive intrinsic antibiotic resistance. The most effective agent is ceftazidime, which is given intravenously for 2–4 weeks; this should be followed by several months of co-amoxiclav or co-trimoxazole to prevent relapses.

### Actinomycosis

*Actinomyces* spp. are branching, Gram-positive higher bacteria, which are normal mouth and intestine commensals; they are particularly associated with poor mouth hygiene. *Actinomyces* have a worldwide distribution but are a rare cause of disease in the West.
Clinical features

- **Cervicofacial actinomycosis**, the most common form, usually occurs following dental infection or extraction. It is often indolent and slowly progressive, is associated with little pain, and results in induration and localized swelling of the lower part of the mandible. Sinuses and tracts develop, with discharge of ‘sulphur’ granules.

- **Thoracic actinomycosis** follows inhalation of organisms, usually into a previously damaged lung. The clinical picture is not distinctive and is often mistaken for malignancy or tuberculosis. Symptoms such as fever, malaise, chest pain and haemoptysis are present. Empyema occurs in 25% of patients and local extension produces chest-wall sinuses with discharge of ‘sulphur’ granules.

- **Abdominal actinomycosis** most frequently affects the caecum. Characteristically, an indurated mass is felt in the right iliac fossa. Later, sinuses develop. The differential diagnosis includes malignancy, tuberculosis, Crohn's disease and amoeboma. The incidence of pelvic actinomycosis appears to be increasing with wider use of intrauterine contraceptive devices.

  Occasionally, actinomycosis becomes disseminated to involve any site.

Diagnosis and management

Diagnosis is by microscopy and culture of the organism. Treatment often involves surgery, as well as antibiotics. Penicillin is the drug of choice. Intravenous penicillin 2.4 g 4-hourly is given for 4–6 weeks, followed by oral amoxicillin for at least 3–4 months after clinical resolution. Tetracyclines are also effective.

*Nocardia* infections

*Nocardia* spp. are Gram-positive branching bacteria, which are found in soil and decomposing organic matter. *N. asteroides* and, less often, *N. brasiliensis* are the main human pathogens.

Clinical features

*Mycetoma* is the most common illness. This is a result of local invasion by *Nocardia* spp. and presents as a painless swelling, usually on the sole of the foot (Madura foot). The swelling of the affected part of the body continues inexorably. Nodules gradually appear, which eventually rupture and discharge characteristic ‘grains’, which are colonies of organisms. Systemic symptoms and regional lymphadenopathy are rare. Sinuses may occur several years after the onset of the first symptom. A similar syndrome may be produced by other branching bacteria and also by species of eumycete fungi, such as *Madurella mycetomi* (see p. 297).

**Pulmonary disease**, which follows inhalation of the organism, presents with cough, fever and haemoptysis; it is usually seen in the immunocompromised. Pleural involvement and
empyema occur. In severely immunosuppressed patients, initial pulmonary infection may be followed by disseminated disease.

**Diagnosis and management**

The diagnosis is often delayed, partly because of inadequate specimens and partly because *Nocardia* requires prolonged culture on standard media. Severe pulmonary or disseminated infection may require parenteral treatment. Co-trimoxazole, linezolid, ceftriaxone and amikacin have all been used successfully, but *in vitro* sensitivities are variable and there is no consensus on the best treatment.

**Further reading**

**Fungal Infections**

Morphologically, fungi can be grouped into three major categories:

- yeasts and yeast-like fungi, which reproduce by budding
- moulds, which grow by branching and longitudinal extension of hyphae
- dimorphic fungi, which behave as yeasts in the host but as moulds *in vitro*.

Despite the fact that fungi are ubiquitous, systemic fungal infections are relatively rare (in contrast to superficial fungal infections of the skin, nails and orogenital mucosae; see pp. 1345–1347). Systemic mycoses are usually seen in immunocompromised patients and in critical care settings, and are becoming more prevalent as this population of patients increases.

Fungal infections are transmitted by inhalation of spores, contact with the skin or direct inoculation. This last can occur through penetrating injuries, injecting drug use or iatrogenic procedures. Fungi may also produce allergic pulmonary disease. Some fungi, such as *Candida albicans*, are human commensals. Fungal infections are usually divided into systemic, subcutaneous or superficial *(Box 11.50)*. However, these divisions can be misleading, as many fungi that cause superficial infection in the healthy host can cause invasive or disseminated
infection in immunocompromised patients, while ‘deep’ subcutaneous infections can invade other organs to cause systemic disease (see ‘Further reading’).

Box 11.50

Common fungal infections

Systemic

- Histoplasmosis
- Cryptococcosis
- Coccidioidomycosis
- Blastomycosis
- Zygomycosis (mucormycosis)
- Candidiasis
- Aspergillosis
- *Pneumocystis jiroveci* (formerly *P. carinii*)

Subcutaneous

- Sporotrichosis
- Subcutaneous zygomycosis
- Chromoblastomycosis
- Mycetoma

Superficial

- Dermatophytosis
- Superficial candidiasis
- *Malassezia* infections

Systemic Fungal Infections

Candidiasis

Candidiasis is the most common fungal infection in humans and is predominantly caused by *Candida albicans*, although other species of *Candida* are increasingly recognized. *Candida* are small asexual yeasts. They are found worldwide, and most species that are pathogenic to humans are normal oropharyngeal and gastrointestinal commensals.

Clinical features
Most human candidiasis is superficial. Vaginal and oral thrush are the most common forms; these are typically seen in the very young, the elderly, patients on antibiotic therapy and those who are immunosuppressed. Candidal oesophagitis presents with painful dysphagia. Cutaneous candidiasis typically occurs in intertriginous areas. It is also a cause of paronychia.

Invasive candidiasis is usually associated with intravascular devices (especially in intensive care units) and with profound immunosuppression. Dissemination can lead to meningitis, visceral and pulmonary abscesses, endophthalmitis and osteomyelitis.

**Diagnosis and management**

The fungi can be demonstrated in scrapings from infected lesions, tissue secretions or, in invasive disease, from blood cultures.

Treatment varies, depending on the site and severity of infection, and on the sensitivity of the organism. Superficial lesions may respond to topical nystatin or amphotericin B, although systemic agents may be needed for more extensive infection. For invasive infection, parenteral therapy with amphotericin B, fluconazole, voriconazole or echinocandins is necessary. Many non-albicans species are intrinsically resistant to many antifungals, and even *C. albicans* can develop extensive resistance (especially to azoles).

**Histoplasmosis**

Histoplasmosis is caused by *Histoplasma capsulatum* (see p. 348). Spores can survive in moist soil for several years, particularly when it is enriched by bird and bat droppings. Histoplasmosis occurs worldwide but is commonly seen only in Ohio and the Mississippi river valleys, where over 80% of the population have been subclinically exposed. Transmission is mainly by inhalation of the spores, particularly when clearing out attics, barns and bird roosts or exploring caves.

**Clinical features**

**Primary pulmonary histoplasmosis** is usually asymptomatic. Calcification in the lungs, spleen and liver occurs in patients from areas of high endemicity. When symptomatic, primary pulmonary histoplasmosis generally presents as a mild influenza-like illness, with fever, chills, myalgia and cough. The systemic symptoms are pronounced in severe disease.

Complications, such as atelectasis, secondary bacterial pneumonia, pleural effusions, erythema nodosum and erythema multiforme, also occur.

**Chronic pulmonary histoplasmosis** is clinically similar to pulmonary tuberculosis (see p. 1108). It is usually seen in American white males over the age of 50 years. Disseminated histoplasmosis resembles disseminated tuberculosis, with fever, lymphadenopathy, hepatosplenomegaly, weight loss, leucopenia and thrombocytopenia. Rarely, features of meningitis, hepatitis, hypoadrenalism, endocarditis and peritonitis may dominate the clinical picture.
Diagnosis

Definitive diagnosis is possible by culturing the fungi (e.g. from sputum) or by demonstrating them on histological sections. *H. capsulatum* glycoprotein can be detected in the urine and serum in those with acute pulmonary and disseminated infection. Antibodies usually develop within 3 weeks of the onset of illness and are best detected by complement fixation or immunodiffusion (sensitivity of 95% and 90%, respectively).

Management

Only symptomatic acute pulmonary histoplasmosis, chronic histoplasmosis and acute disseminated histoplasmosis require therapy. Itraconazole is effective in mild to moderate disease. Severe infection is treated with intravenous amphotericin B for 1–2 weeks, followed by itraconazole for a total of 12 weeks, or with voriconazole. Surgical excision of histoplasmosmas (pulmonary granuloma due to *H. capsulatum*) or chronic cavitatory lung lesions and release of adhesions following mediastinitis are often required.

African histoplasmosis

This is caused by *Histoplasma duboisii*, the spores of which are larger than those of *H. capsulatum*. Skin lesions (e.g. abscesses, nodules, lymph node involvement and lytic bone lesions) are prominent. Pulmonary lesions do not occur. Treatment is similar to that for *H. capsulatum* infection.

Aspergillosis

Aspergillosis is caused by one of several species of dimorphic fungi of the genus *Aspergillus*. Of these, *A. fumigatus* is the most common, although *A. flavus* and *A. niger* are also recognized. These fungi are ubiquitous in the environment and are commonly found on decaying leaves and trees. Humans are infected by inhalation of the spores. Disease manifestation depends on the dose of the spores inhaled, as well as the immune response of the host. Three major forms of the disease are recognized: bronchopulmonary allergic aspergillosis, aspergilloma and invasive aspergillosis (see p. 1123).

The diagnosis and treatment are described in more detail on pages 1122–1123.

Cryptococcosis

Cryptococcosis is caused by the yeast-like fungus *Cryptococcus neoformans*. It has a worldwide distribution and appears to be spread by birds, especially pigeons, in their droppings. The spores gain entry into the body through the respiratory tract, where they elicit a granulomatous reaction. Pulmonary symptoms are, however, uncommon; meningitis, which usually occurs in those with HIV infection or lymphoma, is the usual mode of presentation and
often develops subacutely. Less commonly, lung cavitation, hilar lymphadenopathy, pleural effusions and, occasionally, pulmonary fibrosis occur. Skin and bone involvement is rare.

### Diagnosis and management

Diagnosis is established by demonstrating the organisms in appropriately stained tissue sections. A positive latex cryptococcal agglutinin test performed on the CSF is diagnostic of cryptococcosis.

Liposomal amphotericin B alone or in combination with flucytosine for 2 weeks is followed by oral fluconazole 400 mg daily. Therapy should be continued for 8 weeks if meningitis is present. Fluconazole has greater CSF penetration and is used when toxicity is encountered with amphotericin B and flucytosine, and as maintenance therapy in immunocompromised patients, especially those with HIV infection (see pp. 349–350).

### Coccidioidomycosis

Coccidioidomycosis is caused by the non-budding spherical form (spherule) of *Coccidioides immitis*. This is a soil saprophyte and is found in the southern USA, Central America and parts of South America. Humans are infected by inhalation of the thick-walled, barrel-shaped spores called arthrospores. Occasionally, epidemics of coccidioidomycosis have been documented following dust storms.

### Clinical features

The majority of patients are asymptomatic and the infection is only detected by the conversion of a skin test using coccidioidin (extract from a culture of mycelial growth of *C. immitis*) from negative to positive. Acute pulmonary coccidioidomycosis presents, after an incubation period of about 10 days, with fever, malaise, cough and expectoration. Erythema nodosum, erythema multiforme, phlyctenular conjunctivitis and, less commonly, pleural effusions may occur. Complete recovery is usual.

Pulmonary cavitation with haemoptysis, pulmonary fibrosis, meningitis, lytic bone lesions, hepatosplenomegaly, skin ulcers and abscesses may occur in severe disease.

### Diagnosis

The organism can be identified in respiratory secretions and can be cultured in specialist laboratories. Serological tests are also widely used for diagnosis. These include the highly specific latex agglutination and precipitin tests (IgM), which are positive within 2 weeks of infection and decline thereafter. Other tests include complement fixation, ELISA and radioimmunoassay.

A complement-fixation test (IgG) performed on the CSF is diagnostic of coccidioidomycosis meningitis; it becomes positive within 4–6 weeks and remains so for many years.
Management

Mild pulmonary infections are self-limiting and require no treatment, but progressive and disseminated disease requires urgent therapy. Ketoconazole, itraconazole or fluconazole for 6 months is the treatment of choice for primary pulmonary disease, with more prolonged courses for cavitating or fibronodular disease. Fluconazole in high dose (600–1000 mg daily) is given for meningitis. Itraconazole provides an alternative. Voriconazole and posaconazole are used for poor responders. Surgical excision of cavitatory pulmonary lesions or localized bone lesions may be necessary.

Blastomycosis

Blastomycosis is a systemic infection caused by the biphasic fungus *Blastomyces dermatitidis*. Although initially believed to be confined to certain parts of North America, it has been reported from South America, India and the Middle East.

Clinical features

Blastomycosis primarily involves the skin, where it presents as non-itchy papular lesions that later develop into ulcers with red verrucous margins. The ulcers are initially confined to the exposed parts of the body but later involve the unexposed parts as well. Atrophy and scarring may occur. Pulmonary involvement presents as a solitary lesion resembling a malignancy or gives rise to radiological features similar to the primary complex of tuberculosis. Systemic symptoms, such as fever, malaise, cough and weight loss, are usually present. Bone lesions are common and present as painful swellings.

Diagnosis and management

The diagnosis is confirmed by demonstrating the organism in histological sections or by culture, although results can be negative in 30–50% of cases. Enzyme immunoassay may be helpful, although there is some cross-reactivity of antibodies to *Blastomyces* with *Histoplasma*.

Itraconazole is preferred for treating mild to moderate disease in the immunocompetent for periods up to 6 months. Ketoconazole or fluconazole is also used. In severe or unresponsive disease and in the immunocompromised, amphotericin B is indicated.

Mucormycosis

The terminology of mucormycosis and zygomycosis is confusing. *Invasive zygomycosis* (also known as *mucormycosis*) is rare and is caused by several fungi, including *Mucor* spp., *Rhizopus* spp. and *Absidia* spp. It usually occurs in immunocompromised or severely ill patients, and has a high mortality. The hallmark of the disease is vascular invasion with marked
haemorrhagic necrosis.

Rhinocerebral mucormycosis is a specific, locally invasive form of the condition. Nasal stuffiness, facial pain and oedema, and necrotic, black nasal turbinates are characteristic. It is rare and is mainly seen in diabetics with ketoacidosis. Other forms of invasive zygomycosis include pulmonary and disseminated infection (in immunosuppressed patients) and gastrointestinal infection (in malnutrition).

Subcutaneous zygomycosis is described below.

Management of locally invasive and systemic disease is with amphotericin B and surgical debridement, but even with the best care, mortality exceeds 50%.

Further reading

Subcutaneous Fungal Infections

Sporotrichosis

Sporotrichosis is caused by the saprophytic fungus Sporothrix schenckii, which is found worldwide. Infection usually follows cutaneous inoculation, at the site of which a reddish, non-tender, maculopapular lesion develops; this is referred to as ‘plaque sporotrichosis’. Pulmonary involvement and disseminated disease rarely occur.

Treatment with itraconazole 100–200 mg/day for 3–6 months is usually curative.

Subcutaneous zygomycosis

Subcutaneous zygomycosis can be seen as a form of mucormycosis in immunocompromised patients, as described above. However, the term is also used to describe a largely tropical condition caused by filamentous fungi of the Basidiobolus genus, and typically associated with inoculation injuries and trauma. The disease usually remains confined to the subcutaneous tissues and muscle fascia. It presents as a brawny, woody infiltration involving the limbs, neck and trunk. Amphotericin B is the drug of choice, usually in combination with surgical debridement. Even the cutaneous/subcutaneous form of the infection carries a significant mortality.

Chromoblastomycosis
Chromoblastomycosis (chromomycosis) is caused by fungi of various genera, including *Phialophora*, *Wangella* and *Fonsecaea*. These are found mainly in tropical and subtropical countries. Chromoblastomycosis presents initially as a small papule, usually at the site of a previous injury, which persists for several months before ulcerating. The lesion later becomes warty and encrusted, and gradually spreads. Satellite lesions may be present. Itching is frequent. The drug of choice is amphotericin B in combination with itraconazole or voriconazole. Cryosurgery is used to remove local lesions.

**Mycetoma (Madura foot)**

Mycetoma may be due to subcutaneous infection with fungi (*Eumycetes* spp.) or bacteria (see p. 294). It is largely confined to the tropics. Infection results in local swelling, which may discharge through sinuses. Bone involvement may follow. **Management** consists of surgical debridement, combined with antimicrobials chosen according to the aetiological agent.

**Pneumocystis jiroveci infection**

Genetic analysis has shown *P. jiroveci* to be homologous with fungi. *Pneumocystis jiroveci* disease is almost invariably associated with immunodeficiency states, particularly AIDS, and is discussed on page 349.

**Further reading**

**Superficial Fungal Infections**

**Dermatophytosis**

Dermatophytoses are chronic fungal infections of keratinous structures, such as the skin, hair or nails. *Trichophyton* spp., *Microsporum* spp., *Epidermophyton* spp. and *Candida* spp. can also infect keratinous structures.

**Malassezia infection**

*Malassezia* spp. are found on the scalp and greasy skin, and are responsible for seborrhoeic dermatitis, pityriasis versicolor (hypo- or hyperpigmented rash on the trunk) and *Malassezia* folliculitis (itchy rash on the back). **Treatment** is with topical antifungals, or oral ketoconazole if infection is refractory or more
Protozoal Infections

Protozoa are unicellular eukaryotic organisms. They are more complex than bacteria and belong to the animal kingdom. Although many protozoa are free-living in the environment, some have become parasites of vertebrates, including humans, often developing complex life cycles involving more than one host species. In order to be transmitted to a new host, some protozoa transform into hardy cyst forms, which can survive harsh external conditions. Others are transmitted by an arthropod vector, in which a further replication cycle takes place before infection of a new vertebrate host.

Blood and Tissue Protozoa

Malaria

Human malaria is usually caused by one of four species of the genus *Plasmodium*: *P. falciparum*, *P. vivax*, *P. ovale* and *P. malariae*. Occasionally, other species of malaria usually found in primates (e.g. *P. knowlesi*) can affect humans. Malaria probably originated from animal malarias in Central Africa but was spread around the globe by human migration. Public health measures and changes in land use have eradicated malaria in most developed countries, although the potential for malaria transmission still exists in many areas. Some 220 million people were infected in 2010, with 650 000 deaths (mainly in African children). Over 25 000 infections per year occur in travellers from non-malarious countries.

Epidemiology

Malaria is transmitted by the bite of female anopheline mosquitoes. The parasite undergoes a temperature-dependent cycle of development in the gut of the insect and its geographical range therefore depends on the presence of the appropriate mosquito species and an adequate temperature. The disease occurs in endemic or epidemic form throughout the tropics and subtropics, except for some areas above 2000 m (*Fig. 11.37*).
In areas of so-called **stable transmission** (including much of sub-Saharan Africa), transmission occurs consistently year round. The bulk of mortality is seen in children, while those who survive to adulthood acquire significant immunity; low-grade parasitaemia is still present but causes few symptoms. **Unstable transmission** occurs when there is erratic, seasonal or low-level transmission (e.g. in the Sahel belt, mosquitoes feed only in the rainy season). In these circumstances, little protective immunity develops and symptomatic malaria occurs at all ages. Changes in environmental or social conditions in such areas can lead to epidemics with substantial mortality in all age groups.

Malaria can also be transmitted in contaminated blood transfusions. It has occasionally been seen in injecting drug users sharing needles and in patients with a hospital-acquired infection related to contaminated equipment. Rare cases are acquired outside the tropics when mosquitoes are transported from endemic areas (‘airport malaria’), or when the local mosquito population becomes infected by a returning traveller.

### Parasitology

The female mosquito becomes infected after taking a blood meal containing gametocytes, the sexual form of the malarial parasite (**Fig. 11.38**). The developmental cycle in the mosquito usually takes 7–20 days (depending on temperature), culminating in the migration of infective sporozoites to the insect's salivary glands. The sporozoites are inoculated into a new human
host and those not destroyed by the immune response are rapidly taken up by the liver. Here they multiply inside hepatocytes as merozoites: this is pre-erythrocytic (or hepatic) sporogony. After a few days, the infected hepatocytes rupture, releasing merozoites into the blood, from where they are rapidly taken up by erythrocytes. In the case of *P. vivax* and *P. ovale*, a few parasites remain dormant in the liver as hypnozoites. These may reactivate at any time subsequently, causing relapsing infection.

![Diagram of Plasmodium vivax life cycle](image)

**FIGURE 11.38** A schematic life cycle of *Plasmodium vivax*.

Inside the red cells, the parasites again multiply, changing from merozoite, to trophozoite, to schizont and finally appearing as 8–24 new merozoites. The erythrocyte ruptures, releasing the merozoites to infect further cells. Each cycle of this process, which is called erythrocytic schizogony, takes about 48 hours in *P. falciparum*, *P. vivax* and *P. ovale* disease and about 72 hours in *P. malariae* disease. *P. vivax* and *P. ovale* mainly attack reticulocytes and young erythrocytes, while *P. malariae* tends to attack older cells; *P. falciparum* will parasitize any stage of erythrocyte.
A few merozoites develop not into trophozoites but into gametocytes. These are not released from the red cells until taken up by a feeding mosquito to complete the life cycle.

Pathogenesis

The pathology of malaria is related to anaemia, cytokine release and, in the case of *P. falciparum*, widespread organ damage due to impaired microcirculation. The anaemia seen in malaria is multifactorial ([Box 11.51](#)). In *P. falciparum* malaria, red cells containing schizonts adhere to the lining of capillaries in the brain, kidneys, gut, liver and other organs. As well as causing mechanical obstruction, these schizonts rupture, releasing toxins and stimulating further cytokine release.

**Box 11.51**

**Causes of anaemia in malaria infection**

- Haemolysis of infected red cells
- Haemolysis of non-infected red cells (blackwater fever)
- Dyserythropoiesis
- Splenomegaly and sequestration
- Folate depletion

After repeated infections, partial immunity develops, allowing the host to tolerate parasitaemia with minimal ill effects. This immunity is largely lost if there is no further infection for a couple of years. Certain genetic traits also confer some immunity to malaria. People who lack the Duffy antigen on the red cell membrane (a common finding in West Africa) are not susceptible to infection with *P. vivax*. Certain haemoglobinopathies (including sickle cell trait) also give some protection against the severe effects of malaria; this may account for the persistence of these otherwise harmful mutations in tropical countries. Iron deficiency may also have some protective effect. The spleen appears to play a role in controlling infection and splenectomized people are at risk of overwhelming malaria. Some individuals appear to have a genetic predisposition for developing cerebral malaria following infection with *P. falciparum*. Pregnant women are especially susceptible to severe disease.

Clinical features

Typical malaria is seen in non-immune individuals. This includes children in any area, adults in areas of unstable transmission, and any visitors from a non-malarious region.

The normal incubation period is 10–21 days but can be longer. The most common symptom is fever, although malaria may present initially with general malaise, headache, vomiting or diarrhoea. At first, the fever may be continual or erratic; the classical tertian or quartan fever
appears only after some days. The temperature often reaches 41°C and is accompanied by rigors and drenching sweats.

**P vivax or P. ovale infection**

The illness is usually relatively mild (although *P. vivax* can occasionally cause severe disease). Anaemia develops slowly and there may be tender hepatosplenomegaly. Spontaneous recovery usually occurs within 2–6 weeks but hypnozoites in the liver can cause relapses for many years after infection. Repeated infections often cause chronic ill health due to anaemia and hyper-reactive splenomegaly.

**P malariae infection**

This also causes a relatively mild illness but tends to run a more chronic course. Parasitaemia may persist for years, with or without symptoms. In children, *P. malariae* infection is associated with glomerulonephritis and nephrotic syndrome.

**P falciparum infection**

This causes, in many cases, a self-limiting illness similar to the other types of malaria, although the paroxysms of fever are usually less marked. However, it may also cause serious complications ([Fig. 11.39](#)) and the vast majority of malaria deaths are due to *P. falciparum*. Patients can deteriorate rapidly, and children in particular progress from reasonable health to coma and death within hours. A high parasitaemia (>1% of red cells infected) is an indicator of severe disease, although patients with apparently low parasite levels may also develop complications (peripheral parasite counts can be misleading, as many parasitized cells are sequestered in the microcirculation). **Cerebral malaria** is marked by diminished consciousness, confusion and convulsions, often progressing to coma and death. Untreated, it is universally fatal. **Blackwater fever** is due to widespread intravascular haemolysis, affecting both parasitized and unparasitized red cells, giving rise to dark urine.
Hyper-reactive malarial splenomegaly (tropical splenomegaly syndrome)

This is seen in older children and adults in areas where malaria is hyperendemic. It is associated with an exaggerated immune response to repeated malaria infections and is characterized by anaemia, massive splenomegaly and elevated IgM levels. Malaria parasites are scanty or absent. Tropical splenomegaly syndrome usually responds to prolonged treatment with prophylactic antimalarial drugs.

**Diagnosis**

Malaria should be in the differential diagnosis of anyone who presents with a febrile illness in, or having recently left, a malarious area. *Falciparum* malaria is unlikely to present more than 3 months after exposure, even if the patient has been taking prophylaxis, but *vivax* malaria may
cause symptoms for the first time up to a year after leaving a malarious area. Diagnosis is usually made by identifying parasites on a Giemsa-stained thick or thin blood film (thick films are more difficult to interpret and it may be difficult to speciate the parasite, but they have a higher yield). At least three films should be examined before malaria is declared unlikely. Rapid antigen detection tests are available for near-patient use. In many endemic areas, malaria is over-diagnosed on clinical grounds and a definite diagnosis should be made wherever possible. Serological tests are of no diagnostic value.

Parasitaemia is common in endemic areas and the presence of parasites does not necessarily mean that malaria is the cause of the patient's symptoms. Further investigation, including a lumbar puncture, may be needed to exclude bacterial infection.

Management

Uncomplicated malaria

Chloroquine is still widely used to treat non-*falciparum* malaria (*Box 11.52*), and in many areas it remains effective. However, there is increasing resistance to chloroquine in some strains of *P. vivax*, and co-infection with *P. falciparum* is common in some parts of the world. It is therefore sensible to use oral artemisinin combination therapy, where available, for all cases of malaria. Following successful treatment of *P. vivax* or *P. ovale* malaria, it is necessary to give a 2- to 3-week course of primaquine (0.25–0.5 mg daily) to eradicate the hepatic hypnozoites and prevent relapse. This drug can precipitate haemolysis in patients with glucose-6-phosphate dehydrogenase deficiency (see pp. 541–543).

<sup>a</sup>10 mg/kg in children.

<sup>b</sup>5 mg/kg in children.

<sup>c</sup>Only use ACT if quinine not available. ACT, artemisinin-based combination therapy; SP, sulfadoxine–pyrimethamine.

The artemisinin-based drugs are the most effective treatment for both uncomplicated and severe infections with *P. falciparum*, in adults and in children. Artemisinin-based combination therapy (ACT) is the recommended oral treatment for uncomplicated *falciparum* malaria worldwide. These drugs are now quite widely available, partly through the efforts of the Global Fund (see ‘Further reading’). Five different fixed-dose combinations are recommended by the WHO (Box 11.53); the choice should be based on local resistance to the ‘partner’ drug (see ‘Further reading’). In order to limit the development of resistance, artemisinin derivatives should never be given as monotherapy; some resistance has already been reported in parts of South-east Asia, although, at present, this can usually be overcome by using longer courses of treatment. The WHO recommends that a single dose of primaquine should be given as a gametocide, to decrease transmission.

\(^c\) Not suitable for *P. vivax* or mixed infections. Different fixed-dose combinations available.

**Severe *falciparum* malaria**

Severe malaria, indicated by the presence of any of the complications discussed above, or a parasite count >1% in a non-immune patient, is a medical emergency (*Box 11.54*). Anyone involved in managing patients with malaria should be familiar with the latest WHO guidelines.

- Intravenous artesunate is more effective than intravenous quinine and should be used where available. Absorption from intramuscular injection is less reliable than that from intravenous injection.
- Intensive care facilities may be needed, including mechanical ventilation and dialysis.
- Severe anaemia may require transfusion.
- Careful monitoring of fluid balance is essential; both pulmonary oedema and pre-renal failure are common.
- Hypoglycaemia can be induced both by the infection itself and by quinine treatment.
- Superadded bacterial infection is common.

*Box 11.54*

**Drug treatment of severe *falciparum* malaria in adults and children**
Severe malaria is an emergency: after rapid assessment and confirmation of diagnosis, if possible, treatment should be started with whatever parenteral treatment is available. The options, in order of preference, are:

<table>
<thead>
<tr>
<th>Drug/route</th>
<th>Immediate dose</th>
<th>Subsequent doses</th>
</tr>
</thead>
<tbody>
<tr>
<td>Intravenous artesunate</td>
<td>2.4 mg/kg</td>
<td>2.4 mg/kg at 12 and 24 h, then daily (up to 7 days)</td>

*10 mg/kg if patient has already received oral quinine or mefloquine. ACT, artemisinin-based combination therapy.

## Prevention and control

Malaria is a priority for the WHO, which announced its ‘Roll Back Malaria campaign’ in 1998. This has had considerable success, and global malaria-specific mortality decreased by 25% between 2000 and 2010. Some countries either have eradicated malaria or plan to do so soon, but for much of Africa the aim remains control rather than eradication. A three-part strategy is now widely endorsed and supported by governments and non-governmental organizations (Box 11.55).

### Box 11.55

**Strategy for controlling malaria**

1. Aggressive control in highly endemic countries, to reduce mortality and decrease transmission
2. Progressive eradication at the endemic margins, to shrink the ‘malaria map’
3. Research into new vaccines, new drugs, new diagnostics and better ways of delivering malaria care

As with many vector-borne diseases, control of malaria relies on a combination of case treatment, vector eradication and personal protection from vector bites, such as that provided by insecticide (permethrin)-treated nets. Mosquito eradication is usually achieved by a combination of insecticide use (e.g. house spraying with DDT) and manipulation of the habitat (e.g. marsh drainage). Alongside these elements, there has been renewed interest in chemoprevention, in which children in endemic areas are given monthly doses of antimalarials during the rainy season. This has been shown to reduce the incidence of malaria but may lead
to an increased risk of drug resistance. Pregnant women, who are at greater risk of complications from malaria, may also be offered chemoprevention (although drug options are limited). Enormous effort (and resource) has been devoted to the search for a malaria vaccine. A new vaccine may soon be available, as it has shown benefit in a phase 3 study.

**Non-immune travellers** to malarious areas should take measures to avoid insect bites, such as using insect repellent (diethyltoluamide (DEET) 20–50% in lotions and sprays) and sleeping under mosquito nets. Antimalarial prophylaxis should also be taken in most cases, although this is never 100% effective *(Box 11.56)*. The precise choice of prophylactic regimen depends both on the individual traveller and on the specific itinerary; further details can be found in national formularies or travel advice centres.

---

**Trypanosomiasis**

**African trypanosomiasis (sleeping sickness)**

Sleeping sickness is caused by trypanosomes transmitted to humans by the bite of the tsetse fly (*genus Glossina*). It is endemic in a belt across sub-Saharan Africa, extending to about 14°N and 20°S: this marks the natural range of the tsetse fly. Two subspecies of trypanosome cause human sleeping sickness: *Trypanosoma brucei gambiense* (‘Gambian sleeping sickness’) and *T. b. rhodesiense* (‘Rhodesian sleeping sickness’).

**Epidemiology**

*Sleeping sickness due to T. b. gambiense* is found in an area stretching from Uganda in Central Africa, west to Senegal and south as far as Angola. Humans are the major reservoir
and infection is transmitted by riverine Glossina species (e.g. G. palpalis).

**Sleeping sickness due to T. b. rhodesiense** occurs in East and Central Africa from Ethiopia to Botswana. It is a zoonosis of both wild and domestic animals. In endemic situations, it is maintained in game animals and transmitted by savannah flies such as G. morsitans. Epidemics are usually related to cattle and the vectors are riverine flies.

Political upheavals during the 1990s disrupted established treatment and control programmes, resulting in major epidemics in Angola, the Democratic Republic of Congo (DRC) and Uganda. By 1997, as many as 500 000 people were affected by sleeping sickness. A concerted control programme has brought this number down to below 30 000, most of whom are in DRC and the Central African Republic.

### Parasitology

Tsetse flies bite during the day and, unlike most arthropod vectors, both males and females take blood meals. An infected insect may deposit metacyclic trypomastigotes (the infective form of the parasite) into the subcutaneous tissue. These cause local inflammation (‘trypanosomal chancre’) and regional lymphadenopathy. Within 2–3 weeks, the organisms invade the bloodstream, subsequently spreading to all parts of the body, including the brain.

### Clinical features

*T. b. gambiense* causes a chronic, slowly progressive illness. Episodes of fever and lymphadenopathy occur over months or years and hepatosplenomegaly may develop. Eventually, infection reaches the CNS, causing headache, behavioural changes, confusion and daytime somnolence. As the disease progresses, patients may develop tremors, ataxia, convulsions and hemiplegias; eventually, coma and death supervene. Histologically, there is a lymphocytic meningoencephalitis, with scattered trypanosomes visible in the brain substance.

*T. b. rhodesiense* sleeping sickness is a much more acute disease. Early systemic features may include myocarditis, hepatitis and serous effusions, and patients can die before the onset of CNS disease. If they survive, cerebral involvement occurs within weeks of infection and is rapidly progressive.

### Diagnosis

Trypanosomes may be seen on Giemsa-stained smears of thick or thin blood films, or of lymph node aspirate. Blood films are usually positive in *T. b. rhodesiense* infection but may be negative in *T. b. gambiense* disease; concentration techniques may increase the yield. Serological tests are useful for screening for infection; the card agglutination test for trypanosomiasis (CATT) is a robust and easy-to-use field assay. Examination of CSF is essential in patients with evidence of trypanosomal infection. CNS involvement causes lymphocytosis and elevated protein in the CSF, and parasites may be seen in concentrated specimens.
Management

The treatment of sleeping sickness had remained largely unchanged for more than 40 years, but better drugs are now available for *T. b. gambiense* infection and further new agents are undergoing clinical trials. In both forms of disease, treatment is usually effective if given before the onset of CNS involvement (*Box 11.57*). A single dose of suramin should be given to patients with parasitaemia prior to lumbar puncture, to avoid inoculation into the CSF. The treatment of choice for second-stage (CNS) disease in *T. b. gambiense* is a combination of eflornithine and nifurtimox, a therapy introduced in 2009 and provided free of charge via the WHO. Melarsoprol remains the only treatment for CNS infection with *T. b. rhodesiense*. It is extremely toxic: 2–10% of patients develop an acute encephalopathy, with a 50–75% mortality; peripheral neuropathy and hepatorenal toxicity are also common. Between 3% and 6% of patients relapse following melarsoprol treatment.

Control

Control programmes coordinated by the WHO have been effective in many areas. As in many vector-borne diseases, prevention depends largely on elimination, control or avoidance of the vector.

South American trypanosomiasis (Chagas' disease)

Chagas' disease is widely distributed in rural areas of South and Central America, where up to 8 million people are infected. It is caused by *Trypanosoma cruzi*, which is transmitted to humans in the faeces of blood-sucking reduviid bugs (also called cone-nose or assassin bugs). Faeces infected with *T. cruzi* trypomastigotes are rubbed in through skin abrasions, mucosa or conjunctiva. The bugs, which live in mud or thatch buildings, feed on a variety of vertebrate hosts (e.g. rats, opossums) at night, defecating as they do so.

The parasites spread in the bloodstream before entering host cells and multiplying. Cell rupture releases them back into the circulation, where they can be taken up by a feeding bug.
Further multiplication takes place in the insect gut, completing the trypanosome life cycle. Human infection can also occur via contaminated blood transfusion or, occasionally, by transplacental spread.

### Clinical features

#### Acute infection

This usually occurs in children and often passes unnoticed. A firm, reddish papule is sometimes seen at the site of entry, associated with regional lymphadenopathy. In the case of conjunctival infection, there is swelling of the eyelid, which may close the eye (Román's sign). There may be fever, lymphadenopathy, hepatosplenomegaly and, rarely, meningoencephalitis. Acute Chagas' disease is occasionally fatal in infants but normally there is full recovery within a few weeks or months.

#### Chronic infection

Some 10–30% of people go on to develop chronic Chagas' disease after a latent period of many years. The pathogenesis is unclear: it is possibly due to an autoimmune response triggered by the initial infection, although some evidence has thrown doubt on this mechanism. The heart is commonly affected, with conduction abnormalities, arrhythmias, aneurysm formation and cardiac dilatation. Gastrointestinal involvement leads to progressive dilatation of parts of the gastrointestinal tract; this commonly results in mega-oesophagus (causing dysphagia and aspiration pneumonia) and megacolon (causing severe constipation).

### Diagnosis

Trypanosomes may be seen on a stained blood film during the acute illness. PCR is also sensitive in diagnosis in the acute phase. In chronic disease, parasites may be detected by xenodiagnosis; infection-free reduviid bugs are allowed to feed on the patient and the insect gut subsequently examined for parasites. Serological tests can detect both acute and chronic Chagas' disease.

### Management and control

Nifurtimox and benznidazole are the main drugs used in Chagas' disease. Both are highly effective in acute infection, with a cure rate of over 90%, but much less so in chronic disease. They are relatively toxic, with adverse reactions in up to 40% of patients, and new drugs are urgently needed. Antiarrhythmic drugs and pacemakers may be needed in cardiac disease and surgical treatment is sometimes required for gastrointestinal complications.

In the long term, prevention of Chagas' disease relies on improved housing and living conditions. Several coordinated multinational vector control programmes have been implemented, with some success in reducing transmission.
**Leishmaniasis**

This group of diseases is caused by protozoa of the genus *Leishmania*, which are transmitted by the bite of the female phlebotomine sandfly (Box 11.58). Leishmaniasis is seen in localized areas of Africa, Asia (particularly India and Bangladesh), Europe, the Middle East and South and Central America. Certain parasite species are specific to each geographical area. The clinical picture is dependent on the species of parasite and on the host's cell-mediated immune response. Asymptomatic infection, in which the parasite is suppressed or eradicated by a strong immune response, is common in endemic areas, as demonstrated by a high incidence of positive leishmanin skin tests. Symptomatic infection may be confined to the skin (sometimes with spread to the mucous membranes; *Fig. 11.40*) or widely disseminated throughout the body (visceral leishmaniasis). Relapse of previously asymptomatic infection is seen in patients who become immunocompromised, especially those with HIV infection.

</tbody>
</table>
In some areas, leishmaniasis is primarily zoonotic, whereas in others humans are the main reservoir of infection. In the vertebrate host, the parasites are found as oval amastigotes (Leishman–Donovan bodies). These multiply inside the macrophages and cells of the reticuloendothelial system and are then released into the circulation as the cells rupture. Parasites are taken into the gut of a feeding sandfly (genus *Phlebotomus* in the Old World, genus *Lutzomyia* in the New World), where they develop into the flagellate promastigote form. These migrate to the salivary glands of the insect, where they can be inoculated into a new host.

**Visceral leishmaniasis**

**Clinical features**

Visceral leishmaniasis (kala azar) is caused by *L. donovani*, *L. infantum* or *L. chagasi*, and is prevalent in localized areas of Asia, Africa, the Mediterranean littoral and South America. In parts of India, where humans are the main host, the disease occurs in epidemics. In most other areas, it is endemic, and it is mainly children and visitors to the area who are at risk. The main animal reservoirs in Europe and Asia are dogs and foxes, while in Africa it is carried by various rodents. About 300 000 people are currently infected, with more than 20 000 deaths per year.

The incubation period is usually 1–2 months but may be several years. The onset of symptoms is insidious and the patient may feel quite well, despite markedly abnormal physical findings. Fever is common and, although usually low-grade, may be high and intermittent. The liver and especially the spleen become enlarged; lymphadenopathy is common in African kala azar. The skin becomes rough and pigmented. If the disease is not treated, profound pancytopenia develops and the patient becomes wasted and immunosuppressed. Death usually
occurs within a year and is normally due to bacterial infection or uncontrolled bleeding.

**Diagnosis**

Specific diagnosis is made by demonstrating the parasite in stained smears of aspirates of bone marrow, lymph node, spleen or liver. The organism can also be cultured from these specimens. Specific serological tests are positive in 95% of cases. Pancytopenia, hypoalbuminaemia and hypergamma globulinaemia are common. The leishmanin skin test is negative, indicating a poor cell-mediated immune response.

**Management**

The most widely used drugs for visceral leishmaniasis remain the pentavalent antimony salts (e.g. sodium stibogluconate and meglumine antimoniate), despite toxicity and increasing resistance. Intravenous amphotericin B (preferably liposomal, which may be curative as a single-dose treatment) is effective but expensive; intramuscular paromomycin is cheaper and also has a good cure rate. The oral drug miltefosine has been shown in India to be highly effective, especially in combination with liposomal amphotericin; this and other combination therapies are being increasingly used to shorten treatment courses and limit resistance.

Successful treatment may be followed in a small proportion of patients by a skin eruption called post-kala azar dermal leishmaniasis (PKDL). It starts as a macular or maculopapular nodular rash, which spreads over the body. It is most often seen in Sudan and India, and is difficult to treat, although it may improve with miltefosine.

**HIV co-infection**

Visceral leishmaniasis is strongly associated with HIV-related immunosuppression, and the two infections may be passed on together through injecting drug use. In Southern Europe, anti-retroviral therapy has largely controlled the problem, but increasing numbers of cases are being seen in Brazil and India (see p. 350).

**Cutaneous leishmaniasis**

Cutaneous leishmaniasis is caused by a number of geographically localized species, which may be zoonotic or anthropo notic. Following a sandfly bite, Leishmania amastigotes multiply in dermal macrophages. The local response depends on the species of Leishmania, the size of the inoculum and the host immune response. Single or multiple painless nodules occur on exposed areas 1 week to 3 months following the bite. These enlarge and ulcerate with a characteristic erythematous raised border. An overlying crust may develop. The lesions heal slowly over months or years, sometimes leaving a disfiguring scar.

*L. major* and *L. tropica* are found in Russia and Eastern Europe, the Middle East, Central Asia, the Mediterranean littoral and sub-Saharan Africa. The reservoir for *L. major* is desert rodents, while *L. tropica* has a mainly urban distribution with dogs and humans as reservoirs.
L. aethiopica is found in the highlands of Ethiopia and Kenya, where the animal reservoir is the hyrax. The skin lesions usually heal spontaneously with scarring; this may take a year or more in the case of L. tropica. Leishmaniasis recidivans is a rare chronic relapsing form caused by L. tropica.

L. mexicana is found predominantly in Mexico, Guatemala, Brazil, Venezuela and Panama; infection usually runs a benign course with spontaneous healing within 6 months. L. braziliensis infections (which are seen throughout tropical South America) also usually heal spontaneously but may take longer.

L. mexicana amazonensis and L. aethiopica may occasionally cause diffuse cutaneous leishmaniasis. This is rare and is characterized by diffuse infiltration of the skin by Leishman–Donovan bodies. Visceral lesions are absent.

---

### Diagnosis and management

The diagnosis can often be made clinically in a patient who has been in an endemic area. Giemsa stain on a split-skin smear will demonstrate Leishmania parasites in 80% of cases. Biopsy tissue from the edge of the lesion can be examined histologically and parasites identified by PCR; culture is less often successful. The leishmanin skin test is positive in over 90% of cases but does not distinguish between active and resolved infection. Serology is unhelpful.

Small lesions usually require no treatment. Large lesions or those in cosmetically sensitive sites can sometimes be treated locally by curettage, cryotherapy or topical antiparasitic agents. In other cases, systemic treatment (as for visceral leishmaniasis) is required.

---

### Mucocutaneous leishmaniasis

Mucocutaneous leishmaniasis occurs in 3–10% of infections with L. b. braziliensis and is most common in Bolivia and Peru. The cutaneous sores are followed months or years later by indurated or ulcerating lesions affecting mucosa or cartilage, typically on the lips or nose (‘espundia’). The condition can remain static, or there may be progression over months or years affecting the nasopharynx, uvula, palate and upper airways.

---

### Diagnosis and management

Biopsies usually show only very scanty organisms, although parasites can be detected by PCR; serological tests are frequently positive.

Amphotericin B is the treatment of choice, if available, although systemic antimonial compounds are widely used; miltefosine may also be effective. Relapses are common following treatment. Patients may die because of secondary bacterial infection or, occasionally, laryngeal obstruction.
Prevention

Prevention of leishmaniasis relies on control of vectors and/or reservoirs of infection. Insecticide spraying, control of host animals and treatment of infected humans may all be helpful. Personal protection against sandfly bites is also necessary, especially in travellers visiting endemic areas. Sandflies are poor fliers and sleeping off the ground helps prevent bites.

Other protozoal diseases of the blood and tissues

Toxoplasmosis

Toxoplasmosis is caused by the intracellular protozoan parasite *Toxoplasma gondii*. The sexual form of the parasite lives in the gut of the definitive host, the cat, where it produces oocysts. After a period of maturing in the environment, these oocysts become the source of infection for secondary hosts, which may ingest them. In the secondary hosts (which include humans, cattle, sheep, pigs, rodents and birds), there is disseminated infection. Following a successful immune response, the infection is controlled, but dormant parasites remain encysted in host tissue for many years. The life cycle is completed when carnivorous felines eat infected animal tissue. Humans are infected either from contaminated cat faeces, or by eating undercooked infected meat; transplacental infection may also occur.

Clinical features

Toxoplasmosis is common: seroprevalence in adults in the UK is about 25%, rising to 90% in some parts of Europe. Most infections are asymptomatic or trivial. Symptomatic patients usually present with lymphadenopathy, mainly in the head and neck. There may be fever, myalgia and general malaise; occasionally, there are more severe manifestations, including hepatitis, pneumonia, myocarditis and choroidoretinitis. Lymphadenopathy and fatigue can sometimes persist for months after the initial infection.

Congenital toxoplasmosis may also be asymptomatic but can produce serious disease. Clinical manifestations include microcephaly, hydrocephalus, encephalitis, convulsions and mental retardation. Choroidoretinitis is common; occasionally, this may be the only feature.

Immunocompromised patients, especially those with HIV infection, are at risk of serious infections with *T. gondii*. In acquired immunodeficiency states, this is usually due to reactivation of latent disease (see p. 350).

Diagnosis

Diagnosis is usually made serologically. IgG antibodies detectable by the Sabin–Feldman dye test remain positive for years; acute infection can be confirmed by demonstrating a rising titre of specific IgM.
Management

Acquired toxoplasmosis in an immunocompetent host rarely requires treatment. In those with severe disease (especially eye involvement), sulfadiazine 2–4 g daily and pyrimethamine 25 mg daily are given for 4 weeks, along with folinic acid. The management of pregnant women with toxoplasmosis aims to decrease the risk of fetal complications. However, there is little good evidence that giving spiramycin, either alone or in combination with sulfadiazine (which is the recommended treatment), has any significant effect on the frequency or severity of fetal damage. Infected infants should be treated from birth. The treatment of toxoplasmosis in HIV-positive patients is covered on page 350.

Babesiosis

Babesiosis is a tick-borne parasitic disease, diagnosed most commonly in North America and Europe. It is a zoonosis of rodents and cattle, and is occasionally transmitted to humans; infection is more common and more severe in those who are immunocompromised following splenectomy. The causative organisms are the Plasmodium-like Babesia microti (rodents) and B. divergens (cattle).

The incubation period averages 10 days. In patients with normal splenic function, the illness is usually mild. In splenectomized individuals, systemic symptoms are more pronounced and haemolysis is associated with haemoglobinuria, jaundice and acute kidney injury. Examination of a peripheral blood smear may reveal the characteristic Plasmodium-like organisms.

The standard treatment of severe babesiosis is a combination of quinine 650 mg and clindamycin 600 mg orally three times daily for 7 days. Atovaquone and azithromycin plus doxycycline are used for persistent or relapsing disease.

Gastrointestinal Protozoa

The major gastrointestinal parasites of humans are shown in Box 11.59.

Box 11.59

Pathogenic human intestinal protozoa

Amoebae

• Entamoeba histolytica

Flagellates

• Giardia intestinalis

Ciliates

• Balantidium coli

Coccidia

• Cryptosporidium parvum
• Isospora belli
• Sarcocystis spp.
• Cyclospora cayetanensis
**Microspora**

- *Enterocytozoon bieneusi*
- *Encephalitozoon spp.*

**Amoebiasis**

Amoebiasis is caused by *Entamoeba histolytica*. There are three morphologically identical species of amoeba, which can be distinguished by molecular techniques after culture of the trophozoite: *E. histolytica*, which is pathogenic; *E. dispar*, which is non-pathogenic; and *E. moshkovskii*, which is of uncertain significance. Amoebiasis occurs worldwide, although much higher incidence rates are found in the tropics and subtropics.

The organism exists both as a motile trophozoite and as a cyst that can survive outside the body. Cysts are transmitted by ingestion of contaminated food or water, or spread directly by person-to-person contact. Trophozoites emerge from the cysts in the small intestine and then pass on to the colon, where they multiply.

**Clinical features**

It is believed that many individuals can carry the pathogen without obvious evidence of clinical disease (asymptomatic cyst passers). However, this may be due, in some cases, to the misidentification of non-pathogenic *E. dispar* as *E. histolytica*, and it is not clear how often true *E. histolytica* infection is symptomless. In affected people, *E. histolytica* trophozoites invade the colonic epithelium, probably with the aid of their own cytotoxins and proteolytic enzymes. The parasites continue to multiply and, finally, frank ulceration of the mucosa occurs. If penetration continues, trophozoites may enter the portal vein, via which they reach the liver and cause intrahepatic abscesses. This invasive form of the disease is serious and may even be fatal.

The incubation period of intestinal amoebiasis is highly variable and may be as short as a few days or as long as several months. The usual course is chronic, with mild intermittent diarrhoea and abdominal discomfort. This may progress to bloody diarrhoea with mucus and is sometimes accompanied by systemic symptoms, such as headache, nausea and anorexia. Less commonly, infection may present as acute amoebic dysentery, resembling bacillary dysentery or acute ulcerative colitis.

Complications are unusual but include toxic dilatation of the colon, chronic infection with stricture formation, severe haemorrhage, amoeboma and amoebic liver abscess. Amoebic liver abscesses often develop in the absence of a recent episode of colitis. Tender hepatomegaly, a high swinging fever and profound malaise are characteristic, although early in the course of the disease both symptoms and signs may be minimal. The clinical features are described in more detail on page 484.
Diagnosis

Microscopic examination of fresh stool or colonic exudate obtained at sigmoidoscopy is the simplest way of diagnosing colonic amoebic infection. To confirm the diagnosis, motile trophozoites containing red blood cells must be identified; the presence of amoebic cysts alone does not imply disease. Sigmoidoscopy and barium enema examination may show colonic ulceration but are rarely diagnostic.

The amoebic fluorescent antibody test is positive in at least 90% of patients with liver abscess and in 60–70% with active colitis. Seropositivity is low in asymptomatic cyst passers.

Management

Metronidazole 800 mg three times daily for 5 days is given in amoebic colitis; a lower dose (400 mg three times daily for 5 days) is usually adequate in liver abscess. Tinidazole is also effective. After treatment of the invasive disease, the bowel should be cleared of parasites with a luminal amoebicide such as diloxanide furoate.

Prevention

Amoebiasis is difficult to eradicate because of the substantial human reservoir of infection. The only progress will be through improved standards of hygiene, sanitation and better access to clean water. Cysts are destroyed by boiling but chlorine and iodine sterilizing tablets are not always effective.

Giardiasis

*Giardia intestinalis* is a flagellate (*Fig. 11.41*) that is found worldwide. It causes small intestinal disease, with diarrhoea and malabsorption. Prevalence is high in many developing countries and it is the most common parasitic infection in travellers returning to the UK. In certain parts of Europe and in some rural areas of North America, large water-borne epidemics have been reported. Person-to-person spread may occur in day nurseries and residential institutions. The organism exists as both a trophozoite and a cyst, the latter being the form in which it is transmitted.
The organism sometimes colonizes the small intestine and may remain there without causing detriment to the host. In other cases, severe malabsorption may occur, which is thought to be related to morphological damage to the small intestine. The changes in villous architecture are usually mild partial villous atrophy; subtotal villous atrophy is rare. The mechanism by which the parasite causes alteration in mucosal architecture and produces diarrhoea and intestinal malabsorption is unknown; there is evidence that the morphological damage is immune-mediated. Bacterial overgrowth has also been found in association with giardiasis and may contribute to fat malabsorption.

**Clinical features**

Many individuals excreting *Giardia* cysts have no symptoms. Others become ill within 1–3 weeks of ingesting cysts; symptoms include diarrhoea, often watery in the early stage of the illness, nausea, anorexia, and abdominal discomfort and bloating. In most people affected, these symptoms resolve after a few days, but in some they persist. Stools may then become paler, with the characteristic features of steatorrhoea. If the illness is prolonged, weight loss occurs and can be marked. Chronic giardiasis, frequently seen in developing countries, can result in growth retardation in children.

**Diagnosis**

Both cysts and trophozoites can be found in the stool, but negative stool examination does not
exclude the diagnosis since the parasite may be excreted at irregular intervals. The parasite can also be seen in duodenal aspirates (obtained with either an endoscope or a luminal capsule) and in histological sections of jejunal mucosa.

Management

Metronidazole 2 g as a single dose on three successive days will cure the majority of infections, although sometimes a second or third course is necessary. Alternative drugs include tinidazole, mepacrine and albendazole. Preventative measures are similar to those outlined above for *E. histolytica*.

Cryptosporidiosis

This organism is found worldwide, cattle being the major natural reservoir. It has also been demonstrated in supplies of drinking water in the UK. The parasite is able to reproduce both sexually and asexually; it is transmitted by oocysts excreted in the faeces.

In healthy individuals, cryptosporidiosis is a self-limiting illness. Acute watery diarrhoea is associated with fever and general malaise lasting for 7–10 days. In immunocompromised patients, especially those with HIV, diarrhoea is severe and intractable (see p. 350).

Diagnosis is usually made by faecal microscopy, although the parasite can also be detected in intestinal biopsies. There is no reliable treatment but nitazoxanide may be of benefit.

Balantidiasis

*Balantidium coli* is the only ciliate that produces clinically significant infection in humans. It is found throughout the tropics, particularly in Central and South America, Iran, Papua New Guinea and the Philippines. It is usually carried by pigs, and infection is most common in those communities that live in close association with swine. Its life cycle is identical to that of *E. histolytica*. *B. coli* causes diarrhoea and sometimes a dysenteric illness with invasion of the distal ileal and colonic mucosa. Trophozoites rather than cysts are found in the stool. Treatment is with tetracycline or metronidazole.

*Blastocystis hominis* infection

*B. hominis* is a strictly anaerobic protozoan pathogen that inhabits the colon. The pathogenicity for humans remains controversial, despite many studies indicating response to chemotherapy.

*Cyclospora cayetanensis* infection

*C. cayetanensis*, a coccidian protozoal parasite, was originally recognized as a cause of diarrhoea in travellers to Nepal. It has been detected in stool specimens from immunocompetent and immunodeficient people worldwide. Infection is usually self-limiting
but can be treated with co-trimoxazole.

**Microsporidiosis**

Protozoa of the phylum *Microsporea* can cause diarrhoea in patients with HIV/AIDS (see p. 350).

**Further reading**

**Helminthic Infections**

Worm infections are very common in developing countries, causing much disease in both humans and domestic animals. Worms are frequently imported into industrialized countries. The most common human helminth infections are listed in *Box 11.60*. Three in particular – ascariasis, hookworm and trichuriasis – are included in a list of 13 ‘neglected tropical diseases’, which the WHO has identified as causing major disability among the poorest people in the world.

Helminths are the largest internal human parasite. They reproduce sexually, generating millions of eggs or larvae. **Nematodes** and **trematodes** have a mouth and intestinal tract, while **cestodes** absorb nutrients directly through the outer tegument. All worms are motile, although once the adults are established in their definitive site, they rarely migrate further. Adult helminths may be very long-lived: up to 30 years in the case of the schistosomes.

Many helminths have developed complex life cycles, involving more than one host. Both primary and intermediate hosts are often highly specific to a particular species of worm. In
some cases of human infection, humans are the primary host, while in others, humans are a non-specific intermediary or are coincidentally infected. Multiple infections with different helminths are common in endemic areas. Mass treatment programmes, in which one or more anthelmintic drugs are given on a regular (usually annual) basis, are used to keep the total worm load down, and the WHO recommends treating all schoolchildren at regular intervals in areas where helminth infections are common (Box 11.61).

**Nematodes**

Human infections can be divided into:

- **Tissue-dwelling worms**, including the filarial worms and the Guinea worm *Dracunculus medinensis*.

- **Human intestinal worms**, including the human hookworms, the common roundworm (*Ascaris lumbricoides*) and *Strongyloides stercoralis*, which are the most common helminthic parasites of humans. The adult worms live in the human gut and do not usually invade tissues, but many species have a complex life cycle involving a migratory larval stage.

- **Zoonotic nematodes**, which accidentally infect humans and are not able to complete their normal life cycle. They often become ‘trapped’ in the tissues, causing a potentially severe local inflammatory response.

**Tissue-dwelling worms**

**Filariaasis**

Several nematodes belonging to the superfamily Filarioidea can infect humans. The adult worms are long and thread-like, ranging from 2 cm to 50 cm in length; females are generally
much larger than males. Larval stages are inoculated into humans by various species of biting flies (each specific to a particular parasite). The adult worms that develop from these larvae mate, producing millions of offspring (microfilariae), which migrate in the blood or skin. These are ingested by feeding flies, in which the remainder of the life cycle takes place. Disease, which may be caused either by the adult worms or by microfilariae, is caused by the host immune response to the parasite and is characterized by massive eosinophilia. Adult worms are long-lived (10–15 years) and re-infection is common, so that disease tends to be chronic and progressive.

**Lymphatic filariasis**

Lymphatic filariasis, which may be caused by different species of filarial worm, has a scattered distribution in the tropics and subtropics (Box 11.62). More than 1 billion people in developing countries are at risk. *Wuchereria bancrofti* is transmitted to humans by a number of mosquito species, mainly *Culex fatigans*. Adult female worms (which are 5–10 cm long) live in the lymphatics, releasing large numbers of microfilariae into the blood. Generally, this occurs at night, coinciding with the nocturnal feeding pattern of *C. fatigans*. Non-periodic forms of *W. bancrofti*, transmitted by day-biting species of mosquito, are found in the South Pacific. *Brugia malayi* (and the closely related *B. timori*) is very similar to *W. bancrofti*, exhibiting the same nocturnal periodicity. The usual vectors are mosquitoes of the genus *Mansonia*, although other mosquitoes have been implicated.

Many filarial worms coexist with symbiotic *Wolbachia* bacteria, which are, in themselves, a cause of inflammation in the human host.
Clinical features

Following the bite of an infected mosquito, the larvae enter the lymphatics and are carried to regional lymph nodes. Here, they grow and mature for 6–18 months.

Adult worms produce allergic lymphangitis. The clinical picture depends on the individual immune response, which in turn may depend on factors such as age at first exposure. In endemic areas, many people have asymptomatic infection. Sometimes, early infection is marked by bouts of fever accompanied by pain, tenderness and erythema along the course of affected lymphatics. Involvement of the spermatic cord and epididymis are common in Bancroftian filariasis. These acute attacks subside spontaneously in a few days but usually recur. Recurrent episodes cause intermittent lymphatic obstruction, which in time can become fibrotic and irreversible. Obstructed lymphatics may rupture, causing cellulitis and further fibrosis; there may also be chylous pleural effusions and ascites. Over time, there is progressive enlargement, coarsening and fissuring of the skin, leading to the classical appearances of elephantiasis. The limbs or scrotum may become hugely swollen. Eventually, the adult worms will die, but the lymphatic obstruction remains and tissue damage continues. Elephantiasis takes many years to develop and is only seen in association with recurrent infection in endemic areas.

Occasionally, the predominant features of filarial infection are pulmonary. Microfilariae become trapped in the pulmonary capillaries, generating an intense local allergic response. The resulting pneumonitis causes cough, fever, weight loss and shifting radiological changes, associated with a high peripheral eosinophil count. This is known as tropical pulmonary eosinophilia.

Diagnosis

The clinical picture in established disease is usually diagnostic, although similar lymphatic damage may occasionally be caused by silicates absorbed through the feet from volcanic soil (podoconiosis). Parasitological diagnosis has traditionally relied on detecting microfilariae in blood films or skin snips, but rapid and sensitive near-patient antigen detection tests are now available.

Management

Diethylcarbamazine (DEC) kills both adult worms and microfilariae. Serious allergic responses may occur as the parasites are killed and particular care is needed when using DEC in areas endemic for loiasis. Mass treatment programmes using combinations of DEC, ivermectin and albendazole to target various helminthic infections are used in many parts of the world; the exact regimens depend on local situations. Over 500 million people have already received such treatment. There is currently much interest in using doxycycline to kill the symbiotic Wolbachia bacteria, without which the adult worm will eventually die. However, the best way of incorporating this into the overall management strategy remains unclear. Vector
control with insecticide bed nets is helpful in certain areas.

**Loiasis**

Loiasis is found in the humid forests of West and Central Africa. The causative parasite, *Loa loa*, is a small (3–7 cm) filarial worm, which is found in the subcutaneous tissues. The microfilariae circulate in the blood during the day but cause no direct symptoms. The vectors are day-biting flies of the genus *Chrysops*.

Adult worms migrate around the body in subcutaneous tissue planes. Worms may be present for years, frequently without causing symptoms. From time to time, localized, tender, hot, soft tissue swellings occur due to hypersensitivity (Calabar swellings), often near to a joint. These are produced in response to the passage of a worm and usually subside over a few days or weeks. There may also be more generalized urticaria and pruritus. Occasionally, a worm may be seen crossing the eye under the conjunctiva; it may also enter retro-orbital tissue, causing severe pain. Short-term residents of endemic areas often have more severe manifestations of the disease.

Microfilariae may be seen on stained blood films, although these are often negative. Serological tests are relatively insensitive and cross-react with other microfilariae. There is usually massive eosinophilia. DEC may cause severe allergic reactions associated with parasite killing and is being replaced by newer agents. Ivermectin in single doses of 200–400 µg/kg is effective: it may occasionally cause severe reactions. Albendazole, which causes a more gradual reduction in microfilarial load, may be preferable in heavily infected patients. Mass treatment with either DEC or ivermectin can decrease the transmission of infection but the mainstay of prevention is vector avoidance and control.

**Onchocerciasis**

Onchocerciasis (river blindness) affects 37 million people worldwide, of whom 250 000 are blind and 500 000 visually impaired; most of these are in West and Central Africa, with small foci in the Yemen, and in Central and South America. It is the result of infection with *Onchocerca volvulus*. Infection is transmitted by day-biting flies of the genus *Simulium*.

**Pathogenesis**

Infection occurs when larvae are inoculated into humans by the bite of an infected fly. The worms mature in 2–4 months and can live for more than 15 years. Adult worms, which can reach lengths of 50 cm (although they are <0.5 mm in diameter), live in the subcutaneous tissues. They may form fibrotic nodules, especially over bony prominences and sites of trauma. Huge numbers of microfilariae are distributed in the skin and may invade the eyes. Live microfilariae cause relatively little harm, but dead parasites may cause severe allergic reactions, with hyaline necrosis and loss of tissue collagen and elastin. In the eye, a similar process causes conjunctivitis, sclerosing keratitis, uveitis and secondary glaucoma.
Choroidoretinitis is also occasionally seen.

### Clinical features
Symptoms usually start about a year after infection. Initially, there is generalized pruritus, with urticaria and fleeting oedema. Subcutaneous nodules (which can be detected by ultrasound) start to appear, and in dark-skinned individuals, there is hypo- and hyperpigmentation from excoriation and inflammatory changes. Over time, more chronic inflammatory changes appear, with roughened, inelastic skin. Superficial lymph nodes become enlarged and, in the groin, may hang down in loose folds of skin (‘hanging groin’). Eye disease, which is associated with chronic heavy infection, usually first manifests as itching and conjunctival irritation. This gradually progresses to more extensive eye disease and eventually to blindness.

### Diagnosis
In endemic areas, the diagnosis can often be made clinically, especially if supported by finding eosinophilia on a blood film. In order to identify parasites, skin snips taken from the iliac crest or shoulder are placed in saline under a cover slip. After 4 hours, microscopy will show microfilariae wriggling free on the slide. If this is negative, DEC can be applied topically under an occlusive dressing and will provoke an allergic rash in the majority of infected people (modified Mazzotti reaction); this should not be routinely performed, as it is unpleasant. Slit-lamp examination of the eyes may reveal the microfilariae. Rapid near-patient serological card tests are under evaluation.

### Management and prevention
Ivermectin, in a single dose of 150 μg/kg, kills microfilariae and prevents their return for 6–12 months. There is little effect on adult worms, so annual (or more frequent) retreatment is needed. In patients co-infected with *Loa loa*, ivermectin may occasionally induce severe allergic reactions, including a toxic encephalopathy.

The WHO Onchocerciasis Control Programme (OCP), which started in 1974, had a considerable impact on onchocerciasis in West Africa. A combination of vector control measures and, more recently, mass treatment with ivermectin led to a decrease in both infection rates and progression to serious disease. The control programme has been handed over to local governments by the WHO, and local mass treatment programmes are still running in most endemic countries. Eradication may eventually be possible, as humans are the only host, but measures are required over a long period because of the longevity of the worm (10–15 years).

### Mansonellosis
*Mansonella perstans* is a filarial worm transmitted by biting midges of the genus *Culicoides*. Small numbers of microfilariae are found in the blood, and although they do not cause serious
disease, there may be minor allergic reactions and an eosinophilia.

## Dracunculiasis

Infection with the Guinea worm, *Dracunculus medinensis*, occurs when water fleas (copepods) containing the parasite larvae are swallowed in contaminated drinking water. Ingested larvae mature and the female worm, which can reach over 1 metre in length, migrates through connective and subcutaneous tissue for 9–18 months before surfacing on the skin. The uterus of the worm ruptures, releasing larvae that are ingested by the small crustacean water fleas, and the cycle is completed.

The *diagnosis* is clinical. The traditional *management*, extracting the worm over several days by winding it round a stick, is probably still the most effective. The worm should not be damaged. Antibiotics may be needed to control secondary infection.

Prevention and control of dracunculiasis has been one of the success stories in tropical medicine. Large-scale eradication programmes (involving removal of water fleas, and thus infective larvae, by chemical treatment or simple filtration) have been in place for several years. The number of reported cases has fallen from over 3 million in 1985 to just 148 in 2013. The disease is now confined to a handful of small areas of Africa, mainly in south Sudan. Humans are the only host of *D. medinensis* and it should therefore be possible to eradicate this parasite completely.

## Human intestinal nematodes

Adult intestinal nematodes (also sometimes referred to as soil-transmitted helminths, or geohelminths) live in the human gut. There are two main types of life cycle, both usually including a soil-based stage. In some species, infection is spread by ingestion of eggs (which often require a period of maturation in the environment); in others, the eggs hatch in the soil and larvae penetrate directly through the skin of a new host. *Strongyloides* is unusual, in that it is the only nematode that is able to complete its life cycle in humans. Larvae may hatch before leaving the colon and so are able to re-infect the host by penetrating the intestinal wall and entering the venous system.

## Ascariasis (roundworm infection)

*Ascaris lumbricoides* is a pale yellow worm, 20–35 cm in length (*Fig. 11.42*). It is found worldwide but is particularly common in poor rural communities, where there is heavy faecal contamination of the immediate environment. Larvae hatch and penetrate the duodenum, migrating through the tissues to the lungs before being expectorated and swallowed. The adult worms live in the small intestine. Ova are deposited in faeces and require a 2–4-month maturation in the soil before they are infective.
Ascaris lumbricoides. The worm is approximately 20 cm long.

Infection is usually asymptomatic, although heavy infections are associated with nausea, vomiting, abdominal discomfort and anorexia. Worms can sometimes obstruct the small intestine, the most common site being the ileo-caecal valve. They may also occasionally invade the appendix, causing acute appendicitis, or the bile duct, resulting in biliary obstruction and suppurative cholangitis. Larvae in the lung may produce pulmonary eosinophilia. Heavy infection in children, especially those who are already malnourished, may have significant effects on nutrition and development. Serious morbidity and mortality are rare in ascariasis, but the huge number of people infected means that, on a global basis, roundworm infection causes a significant burden of disease, especially in children.

Ascaris eggs can be identified in the stool and, occasionally, adult worms emerge from the mouth or the anus. They may also be seen on barium enema studies. Appropriate drug treatments are shown in Box 11.63. Very rarely, surgical or endoscopic intervention may be required for intestinal or biliary obstruction.

++, highly effective; +, moderately effective; –, ineffective; n/a, drug not used for this indication/no data available.

<sup>a</sup>Single dose unless otherwise stated. <sup>b</sup>Twice daily for 3 days in strongyloidiasis. <sup>c</sup>WHO recommended dose for developing countries; in the UK, commonly given as 100 mg single dose for threadworm or 100 mg twice daily for 3 days for whipworm. <sup>d</sup>Once daily for 2 days.
Threadworm (Enterobius vermicularis)

*E. vermicularis* is a small (2–12 mm) worm, which is common throughout the world. Larval development takes place mainly in the small intestine and adult worms are normally found in the colon. The gravid female deposits eggs around the anus, causing intense itching, especially at night. Unlike those of *A. lumbricoides*, the eggs do not require a maturation period in soil, and infection is often directly transmitted from anus to mouth via the hands. Eggs may also be deposited on clothing and bed linen, and are subsequently either ingested or inhaled. Apart from discomfort and local excoriation, infection is usually harmless.

Ova can be collected either by using a moistened perianal swab, or by applying adhesive cellophane tape to the perianal skin. They can then be identified by microscopy.

The most commonly used drugs are mebendazole and piperazine (*Box 11.63*). However, isolated treatment of an affected person is often ineffective. Other family members (especially small children) may also need to be treated and the whole family should be given advice about personal hygiene. Two courses of treatment 2 weeks apart may break the cycle of autoinfection.

Whipworm (Trichuris trichiura)

Infections with whipworm are common worldwide, especially in poor communities with inadequate sanitation. Adult worms, which are 3–5 cm long, inhabit the terminal ileum and caecum, although in heavy infection they are found throughout the large bowel. The head of the worm is embedded in the intestinal mucosa. Ova are deposited in the faeces and require a maturation period of 3–4 weeks in the soil before becoming infective.

Infection is usually asymptomatic, but mucosal damage can occasionally be so severe that there is colonic ulceration, dysentery or rectal prolapse.

Diagnosis is made by finding ova on stool microscopy, or occasionally by seeing adult worms on sigmoidoscopy. Drug treatment is shown in *Box 11.63*.

Hookworm

Hookworm infections, caused by the human hookworms *Ancylostoma duodenale* and *Necator americanus*, are found worldwide. They are relatively rare in developed countries but very common in areas with poor sanitation and hygiene; overall, about 25% of the world's population is affected. Hookworm infection is a major contributing factor to anaemia in the tropics. *A. duodenale* is found mainly in East Asia, North Africa and the Mediterranean, while *N. americanus* is the predominant species in South and Central America, South-east Asia and sub-Saharan Africa.

Adult worms (which are about 1 cm long) live in the duodenum and upper jejunum, where they are often found in large numbers. They attach firmly to the mucosa using the buccal plate, feeding on blood. Eggs passed in the faeces develop in warm, moist soil, producing infective filariform larvae. These penetrate directly through the skin of a new host and are carried in the bloodstream to the lungs. Having crossed into the alveoli, the parasites are expectorated and
then swallowed, thus arriving at their definitive home.

### Clinical features

Local irritation as the larvae penetrate the skin (‘ground itch’) may be followed by transient pulmonary signs and symptoms, often accompanied by eosinophilia. Light infections, especially in a well-nourished person, are often asymptomatic. Heavier worm loads may be associated with epigastric pain and nausea, resembling peptic ulcer disease. Chronic heavy infection, particularly on a background of malnourishment, may cause iron deficiency anaemia and hypoproteinaemia. Heavy infection in children is associated with delays in physical and mental development.

### Diagnosis and management

The diagnosis is made by finding eggs on faecal microscopy. In infections heavy enough to cause anaemia, these will be present in large numbers. The aim of treatment in endemic areas is reduction of worm burden rather than complete eradication; albendazole given as a single dose is the best drug (Box 11.63). The WHO is promoting mass treatment programmes for schoolchildren in many parts of the world, together with treatment for schistosomiasis where appropriate.

### Strongyloidiasis

*Strongyloides stercoralis* is a small (2 mm long) worm that lives in the small intestine. It is found in many parts of the tropics and subtropics, and is especially common in Asia. Eggs hatch in the bowel and larvae are found in the stool. Usually, these are non-infective rhabditiform larvae, which require a further period of maturation in the soil before they can infect a new host, but sometimes this maturation can occur in the large bowel. Infective filariform larvae can therefore penetrate directly through the perianal skin, re-infecting the host. In this way, autoinfection may continue for years or even decades. Some war veterans who were imprisoned in the Far East during the Second World War were found to have active strongyloidiasis over 50 years later. After skin penetration, the life cycle is similar to that of the hookworm, except that the adult worms may burrow into the intestinal mucosa, causing a local inflammatory response.

### Clinical features

*S. stercoralis*, following skin penetration, causes a similar local dermatitis to hookworm. In autoinfection, this manifests as a migratory linear weal around the buttocks and lower abdomen (cutaneous larva currens). In heavy infections, damage to the small intestinal mucosa can cause malabsorption, diarrhoea and even perforation. There is usually a persistent eosinophilia.

In patients who are *immunosuppressed* (e.g. by corticosteroid therapy or intercurrent
illness), filariform larvae may penetrate directly through the bowel wall in huge numbers, causing an overwhelming and usually fatal generalized infection (the strongyloidiasis hyperinfestation syndrome). This condition is often complicated by Gram-negative septicaemia due to bowel organisms.

### Diagnosis and management

Motile larvae may be seen on stool microscopy, especially after a period of incubation. Serological tests are also useful. The best drug for treating strongyloidiasis is ivermectin (200 µg/kg daily for 2 days); albendazole (15 mg/kg 12-hourly for 3 days) is also effective. In hyperinfection, antibiotics against Gram-negative organisms should be given.

### Zoonotic nematodes

A number of nematodes that are principally parasites of animals may also affect humans. The most common are described below.

#### Trichinosis

The normal hosts of *Trichinella spiralis*, the cause of trichinosis, include pigs, bears and warthogs. Humans are infected by eating undercooked meat from these animals. Ingested larvae mature in the small intestine, where adults release new larvae that penetrate the bowel wall and migrate through the tissues. Eventually, these larvae encyst in striated muscle.

Light infections are usually asymptomatic. Heavier loads of worms produce gastrointestinal symptoms as the adults establish themselves in the small intestine, followed by systemic symptoms as the larvae invade. The latter include fever, oedema and myalgia. Massive infection may occasionally be fatal but usually the symptoms subside once the larvae encyst.

The diagnosis can usually be made from the clinical picture, associated eosinophilia and serological tests. If necessary, it can be confirmed by muscle biopsy a few weeks after infection. Longstanding infection may be revealed by the presence of numerous calcified cysts on X-ray. Albendazole (20 mg/kg for 7 days), given early in the course of the illness, will kill the adult worms and decrease the load of larvae reaching the tissues. Analgesia and steroids may be needed for symptomatic relief.

#### Toxocariasis (visceral larva migrans)

Eggs of the dog roundworm, *Toxocara canis*, are occasionally ingested by humans, especially children. The eggs hatch and the larvae penetrate the small intestinal wall and enter the mesenteric circulation, but are then unable to complete their life cycle in a ‘foreign’ host. Many are held up in the capillaries of the liver, where they generate a granulomatous response, but some may migrate into other tissues, including lungs, striated muscle, heart, brain and eye. In most cases, infection is asymptomatic and the larvae die without causing serious problems. In heavy infections, there may be generalized symptoms (fever and urticaria) and eosinophilia, as
well as focal signs related to the migration of the parasites. Pulmonary involvement may cause bronchospasm and chest X-ray changes. Ocular infection may produce a granulomatous swelling mimicking a retinoblastoma, while cardiac or neurological involvement is occasionally fatal. Rarely, larvae survive in the tissues for many years, causing symptoms long after infection.

Isolation of the larvae is difficult and the diagnosis is usually made serologically. Albendazole 400 mg daily (5–10 mg/kg in children) for a week is the most effective treatment.

### Cutaneous larva migrans
Cutaneous larva migrans is caused by the larvae of the non-human hookworms, *Ancylostoma braziliense* and *A. caninum*. Like human hookworms, these hatch in warm, moist soil and then penetrate the skin. In humans, they are unable to complete a normal life cycle and instead migrate under the skin for days or weeks until they eventually die. The wandering of the larva is accompanied by a clearly defined, serpiginous, itchy rash, which progresses at the rate of about 1 cm per day. There are usually no systemic symptoms. The diagnosis is purely clinical. Single larvae may be treated with a 15% solution of topical tiabendazole; multiple lesions require systemic therapy with a single dose of albendazole 400 mg or ivermectin 150–200 µg/kg.

### Trematodes
Trematodes (flukes) are flat, leaf-shaped worms. They have complex life cycles, often involving fresh-water snails and intermediate mammalian hosts. Disease is caused by the inflammatory response to eggs or to the adult worms.

### Water-borne flukes

#### Schistosomiasis
Schistosomiasis affects nearly 240 million people in the tropics and subtropics, mostly in sub-Saharan Africa. Chronic infection causes significant morbidity and, after malaria, it has the most socioeconomic impact of any parasitic disease. Schistosomiasis is largely a disease of the rural poor but has also been associated with major development projects, such as dams and irrigation schemes.

#### Parasitology and pathogenesis
There are three species of schistosome that commonly cause disease in humans: *Schistosoma mansoni*, *S. haematobium* and *S. japonicum*. *S. mekongi* and *S. intercalatum* also affect humans but have a very restricted distribution (*Fig. 11.43*). Eggs are passed in the urine or faeces of an infected person and hatch in fresh water to release the miracidia. These ciliated
organisms penetrate the tissue of the intermediate host, a species of water snail specific to each species of schistosome. After multiplying in the snail, large numbers of fork-tailed cercariae are released back into the water, where they can survive for 2–3 days. During this time, the cercariae can penetrate the skin or mucous membranes of the definitive host, humans. Transforming into schistosomulae, they pass through the lungs before reaching the portal vein, where they mature into adult worms (the male is about 20 mm long and the female a little larger). Worms pair in the portal vein before migrating to their final destination: mesenteric veins in the case of *S. mansoni* and *S. japonicum*, and the vesicular plexus for *S. haematobium*. Here, they may remain for many years, producing vast numbers of eggs. The majority of these are released in urine or faeces, but a small number become embedded in the bladder or bowel wall and a few are carried in the circulation to the liver or other distant sites.

The pathology of schistosome infection varies with species and stage of infection. In the early stages, there may be local and systemic allergic reactions to the migrating parasites. As eggs start to be deposited, there may be a local inflammatory response in the bowel or bladder, while ectopic eggs may produce granulomatous lesions anywhere in the body. Chronic heavy infection, in which large numbers of eggs accumulate in the tissues, leads to fibrosis, calcification and, in some cases, dysplasia and malignant change. Morbidity and mortality are related to duration of infection and worm load, as well as to the species of parasite. Children in endemic areas tend to have the heaviest worm load because of both increased exposure to infection and differences in the immune response between adults and children.
Clinical features

Cercarial penetration of the skin may cause local dermatitis (‘swimmer’s itch’). After a symptom-free period of 3–4 weeks, systemic allergic features may develop, including fever, rash, myalgia and pneumonitis (Katayama fever). These allergic phenomena are common in non-immune travellers but are rarely seen in local populations, who are usually exposed to infection from early childhood onwards. If infection is sufficiently heavy, symptoms from egg deposition may start to appear 2–3 months after infection.

*S haematobium infection (bilharzia)*

The earliest symptom is usually painless terminal haematuria. As bladder inflammation progresses, there is increased urinary frequency and groin pain. Obstructive uropathy develops, leading to hydronephrosis, chronic kidney disease and recurrent urinary infection. There is a strong association between chronic urinary schistosomiasis and squamous cell bladder carcinoma. The genitalia may also be affected and ectopic eggs may cause pulmonary or neurological disease.

*S mansoni*

This usually affects the large bowel. Early disease produces superficial mucosal changes, accompanied by blood-stained diarrhoea. Later, the mucosal damage becomes more marked, with the formation of rectal polyps, deeper ulceration and, eventually, fibrosis and stricture formation. Ectopic eggs are carried to the liver, where they cause an intense granulomatous response. Hepatitis is followed by progressive periportal fibrosis, leading to portal hypertension, oesophageal varices and splenomegaly (see p. 484). Hepatocellular function is usually well preserved.

*S japonicum*

Unlike the other species, *S. japonicum* infects numerous other mammals apart from humans. It is similar to *S. mansoni* but infects both large and small bowel and produces a greater number of eggs. Disease therefore tends to be more severe and rapidly progressive. Hepatic involvement is more common and neurological involvement is seen in about 5% of cases.

Diagnosis

Schistosomiasis is suggested by relevant symptoms following fresh-water exposure in an endemic area. In the early allergic stages, the diagnosis can only be made clinically. When egg deposition has started, the characteristic eggs (with a terminal spine in the case of *S. haematobium* and a lateral spine in the other species) can be detected on microscopy. In *S. haematobium* infection, the best specimen for examination is a filtered midday urine sample. Parasites may also be found in semen and in rectal snip preparations. *S. mansoni* and *S. japonicum* eggs can usually be found in faeces or in a rectal snip. Serological tests are
available and may be useful in the diagnosis of travellers returning from endemic areas, although the test may not become positive for 12 weeks after infection; a parasitological diagnosis should always be made, if possible. In chronic disease, X-rays, ultrasound examinations and endoscopy may show abnormalities of the bowel or urinary tract, although these are non-specific. Liver biopsy may show the characteristic periportal fibrosis.

### Management

The aim of treatment in endemic areas is to decrease the worm load and therefore minimize the chronic effects of egg deposition. It may not always be possible (or even desirable) to eradicate adult worms completely and re-infection is common. However, a 90% reduction in egg output has been achieved in mass treatment programmes, and in light infections where there is no risk of re-exposure, the drugs are usually curative. The most widely used is praziquantel (*Box 11.64*), which is effective against all species of schistosome, well tolerated and reasonably cheap.

<sup>a</sup> May be split to minimize nausea.

<sup>b</sup> Repeated if necessary.

<sup>c</sup> Depending on worm load.

### Prevention

Prevention of schistosomiasis is difficult and relies on a combination of approaches. Mass treatment of the population (especially children) will decrease the egg load in the community. Health education programmes, the provision of latrines and access to a safe water supply should decrease contact with infected water. Attempts to eradicate the snail host have generally been unsuccessful, although man-made bodies of water can often be made less ‘snail-
friendly’. Travellers should be advised to avoid potentially infected water.

**Food-borne flukes**

Many flukes infect humans via ingestion of an intermediate host, often fresh-water fish.

---

**Paragonimiasis**

Over 20 million people are infected with lung flukes of the genus *Paragonimus*. The adult worms (of which the major species is *P. westermani*) live in the lungs, producing eggs that are either expectorated, or swallowed and passed in the faeces. Miracidia emerging from the eggs penetrate the first intermediate host, a fresh-water snail. Larvae released from the snail seek out the second intermediate host, fresh-water crustacea, in which they encyst as metacercariae. Humans and other mammalian hosts become infected after consuming uncooked shellfish. Cercariae penetrate the small intestinal wall and migrate directly from the peritoneum to the lungs across the diaphragm. Having established themselves in the lung, the adult worms may survive for 20 years.

The common clinical features are fever, cough and mild haemoptysis. In heavy infections, the disease may progress, sometimes mimicking pneumonia or pulmonary tuberculosis. Ectopic worms may cause signs in the abdomen or the brain.

The diagnosis is made by detection of ova on sputum or stool microscopy. Radiological appearances are variable and non-specific. Treatment is with praziquantel and prevention involves avoidance of inadequately cooked shellfish.

---

**Liver flukes**

The human liver flukes, *Clonorchis sinensis*, *Opisthorchis felineus* and *O. viverrini*, are almost entirely confined to East and South-east Asia, where they infect more than 20 million people. Adults live in the bile ducts, releasing eggs into the faeces. The parasite requires two intermediate hosts, a fresh-water snail and a fish, and humans are infected by consumption of raw fish. The cycle is completed when excysted worms migrate from the small intestine into the bile ducts.

Infection is often asymptomatic but may be associated with cholangitis and biliary carcinoma. The diagnosis is made by identifying eggs on stool microscopy. Treatment is with praziquantel, and infection can be avoided by cooking fish adequately.

---

**Other fluke infections**

Humans can also be infected with a variety of animal flukes: notably, the liver fluke, *Fasciola hepatica*, and the intestinal fluke, *Fasciolopsis buski*. Both require a water snail as an intermediate host; cercariae encyst on aquatic vegetation and then are consumed by animals or humans. After ingestion, *F. hepatica* penetrates the intestinal wall before migrating to the liver: during this stage, it causes systemic allergic symptoms. After reaching the bile ducts, it causes
similar problems to those caused by the other liver flukes. *F. buski* does not migrate after it excysts and causes mainly bowel symptoms.

### Management of trematode infections

For treatment, see [Box 11.64](#).

## Cestodes

Cestodes (tapeworms) are ribbon-shaped worms, which vary from a few millimetres to several metres in length. Adult worms live in the human intestine, where they attach to the epithelium using suckers on the anterior portion (scolex). From the scolex arises a series of progressively developing segments, called proglottids. The mature distal segments contain eggs, which either may be released directly into the faeces, or are carried out with an intact detached proglottid. The eggs are consumed by intermediate hosts, after which they hatch into larvae (oncospheres). These penetrate the intestinal wall of the host (pig or cattle) and encyst in the tissues. Humans ingest the cysts in undercooked meat and the cycle is completed when the parasites excyst in the stomach and develop into adult worms in the small intestine. Infections are usually solitary but several adult tapeworms may coexist. The exceptions to this life cycle are the dwarf tapeworm, *Hymenolepis nana*, which has no intermediate host and is transmitted from person to person by the faeco-oral route; and *Taenia solium*, which can cause either normal tapeworm infection (when humans are the definitive host) or cysticercosis (when humans are the intermediate host).

### Taenia saginata

*T. saginata*, the beef tapeworm, may reach a length of several metres. It is found in all countries where under-cooked beef is eaten. The adult worm causes few, if any, symptoms. Infection is usually discovered when proglottids are found in faeces or on underclothing, often causing considerable anxiety. Ova may also be seen on stool microscopy. Infection can be cleared with a single dose of praziquantel (10 mg/kg). It can be prevented by careful meat inspection or by thorough cooking of beef.

### Taenia solium and cysticercosis

*T. solium*, the pork tapeworm, is generally smaller than *T. saginata*, although it can still reach 6 metres in length. It is particularly common in South America, South Africa, China and parts of South-east Asia. As with *T. saginata*, infection is usually asymptomatic. The ova of the two species are identical but the proglottids can be distinguished on inspection.

**Pork tapeworm infection** is acquired by eating uncooked pork. **Treatment** is with praziquantel or niclosamide. Drug treatment should not be accompanied by a purgative, as was previously believed.
Cysticercosis occurs when humans become the intermediate host of the parasite, and is caused by cysts rather than the adult worm. It follows the ingestion of eggs from contaminated food and water. Faeco-oral autoinfection can occur but is rare. Patients with tapeworms do not usually develop cysticercosis and individuals with cysticercosis do not usually harbour tapeworms. Following the ingestion of eggs, the larvae are liberated, penetrate the intestinal wall, and are carried to various parts of the body where they develop into cysticerci. These are cysts, 0.5–1 cm in diameter, containing the scolex of a new adult worm. Common sites for cysticerci include subcutaneous tissue, skeletal muscle and brain.

Superficial cysts may be felt under the skin but usually cause no significant symptoms. Cysts in the brain can cause a variety of problems, including epilepsy, personality change, hydrocephalus and focal neurological signs (see pp. 866-867). These may only appear many years after infection.

Muscle cysts tend to calcify and are often visible on X-rays. Cutaneous cysts can be excised and examined. Brain cysts are less prone to calcification and are often seen only on CT or MRI scan. Serological tests may support the diagnosis.

Management of cysticercosis

Following years of controversy, recent studies do suggest that anthelminthic drugs are of benefit in most cases of neurocysticercosis, although the role of these drugs in other forms of cysticercosis remains unproven. Albendazole 15 mg/kg daily for 8–20 days is the drug of choice; the alternative is praziquantel 50 mg/kg daily (in divided doses) for 15 days.

Successful treatment is accompanied by increased local inflammation, and corticosteroids should be given during and after the course of anthelminthic. Prevention of cysticercosis depends mainly on good hygiene.

Cerebral cysticercosis

Anticonvulsants should be given for epilepsy, and surgery may be indicated if there is hydrocephalus (see pp. 870–871).

Diphyllobothrium latum

Infection with the fish tapeworm, *D. latum*, is common in Northern Europe and Japan, owing to the consumption of raw fish. The adult worm reaches a length of several metres but, like the other tapeworms, usually causes no symptoms. A megaloblastic anaemia (due to competitive utilization of vitamin $B_{12}$ by the parasite) may occur. Diagnosis and treatment are the same as for *Taenia* species.

Hydatid disease

Hydatid disease occurs when humans become an intermediate host of the dog tapeworm, *Echinococcus granulosus*. The adult worm lives in the gut of domestic and wild canines and
the larval stages are usually found in sheep, cattle and camels. Humans may become infected either from direct contact with dogs, or from food or water contaminated with dog faeces. After ingestion, the parasites excyst, penetrate the small intestine wall, and are carried to the liver and other organs in the bloodstream. A slow-growing, thick-walled cyst is formed, inside which further larval stages of the parasite develop. The life cycle cannot be completed unless the cyst is eaten by a dog. Hydatid disease is prevalent in areas where dogs are used in the control of livestock, especially sheep. It is common in Australia, Argentina, the Middle East and parts of East Africa.

Symptoms depend mainly on the site of the cyst. The liver is the most common organ affected (60%), followed by the lung (20%), kidneys (3%), brain (1%) and bone (1%). The symptoms are those of a slowly growing benign tumour. Pressure on the bile ducts may cause jaundice. Rupture into the abdominal cavity, pleural cavity or biliary tree may occur. In the latter situation, intermittent jaundice, abdominal pain and fever associated with eosinophilia result. A cyst rupturing into a bronchus may result in its expectoration and spontaneous cure, but if secondary infection supervenes, a chronic pulmonary abscess will form. Focal seizures can occur if cysts are present in the brain. Renal involvement produces lumbar pain and haematuria. Calcification of the cyst occurs in about 40% of cases.

A related parasite of foxes, *E. multilocularis*, causes a similar but more severe infection, alveolar hydatid disease. These cysts are invasive and metastases may occur.

The diagnosis and treatment of hydatid liver disease are described on page 484.

**Further reading**

[http://www.plosntds.org](http://www.plosntds.org) *PLoS Neglected Tropical Diseases: the Anti-Wolbachia*
Arthropod Ectoparasites
Arthropods, which include the arachnid ticks and mites as well as insects, may be responsible for human disease in several ways.

Local hypersensitivity reactions
Local lesions may be caused by hypersensitivity to allergens in arthropod saliva. This common reaction, known as papular urticaria, is non-specific and is seen in the majority of people in response to the bite of a variety of blood-sucking arthropods, including mosquitoes, bugs, ticks, lice and mites (Fig. 11.44). Occasionally, tick bites may cause a more severe systemic allergic response, especially in previously sensitized individuals.

Most of these parasites alight on humans only to feed but some species of lice live in very close proximity to the skin: body lice in clothing, and head and pubic lice on human hairs (see p. 331).

Resident ectoparasite infections
Other ectoparasites are actually resident within the skin, causing more specific local lesions.

Scabies
See page 1347.

Jiggers
Jiggers is due to infection with the jigger flea, Tunga penetrans, and is common throughout
South America and Africa. The pregnant female flea burrows into the sole of the foot, often between the toes. The egg sac grows to about 0.5 cm in size, before the eggs are discharged onto the ground. The main danger is bacterial infection or tetanus. The flea should be removed with a needle or scalpel and the area kept clean until it heals.

**Myiasis**

Myiasis is caused by invasion of human tissue by the larva of certain flies, principally the Tumbu fly, *Cordylobia anthropophaga* (found in sub-Saharan Africa), and the human botfly, *Dermatobia hominis* (Central and South America). The larvae, which hatch from eggs laid on laundry and linen, burrow into the skin to form boil-like lesions; a central breathing orifice may be visible. Again, the main risk is secondary infection. It is not always easy to extract the larva; covering it with petroleum jelly may bring it up in search of air.

**Systemic envenoming**

Many arthropods can cause local or systemic illness through envenoming: that is, injection of venom.

The main role of arthropods in causing human disease is as vectors of parasitic and viral infections. Some of these infections are shown in *Box 11.4* and discussed in detail elsewhere.

Sexually Transmitted Infections

Sexually transmitted infections (STIs) are among the most common causes of illness in the world and remain endemic in all societies. They have a profound impact on sexual and reproductive health, and rank among the top five disease categories for which adults seek healthcare worldwide.

The World Health Organization (WHO) estimated that in 2008 there were over 498 million new cases of the four major curable STIs in adults aged 15–49 throughout the world. These included 10.6 million cases of syphilis, 106.1 million of gonorrhoea, 105.7 million of chlamydia and 276.4 million of trichomoniasis. The estimates suggest that the vast majority of these infections were in low-income countries. The pattern of STIs is usually different in high-income countries: for example, in England in 2013, the most common STIs were chlamydia (208 755; 47%), genital warts (73 418; 17%), genital herpes (32 279; 7%) and gonorrhoea (29 291; 7%). The public health, social and economic consequences of STIs are extensive, both for acute infections and for their longer-term sequelae. The inflammation caused by one STI can increase the risk of acquisition of others, and most infections increase the acquisition and transmission of the human immunodeficiency virus (HIV).

The highest prevalence of STIs is in young people, men having sex with men (MSM) and bisexual men, and black and ethnic minority populations. STIs are associated with high-risk sexual behaviour, more frequent partner change and inconsistent use of condoms. Increased travel, both within and between countries, recreational drug use and alcohol are also implicated.

All STIs can be asymptomatic and multiple infections frequently coexist; hence many people without symptoms attend sexual health clinics to seek sexual health checks and advice.

Clinical Approach to the Patient with an STI

Patients presenting with possible STIs are frequently anxious, embarrassed and concerned about confidentiality. Staff must be alert to these issues and respond sensitively. The clinical setting must ensure privacy and reinforce confidentiality.

History

The history of the presenting complaint usually focuses on genital symptoms, the most common being:

- urethral discharge in males (*Box 12.1*)
Causes of urethral discharge

- Urethritis in men usually presents with a urethral discharge and dysuria
- Usually divided into gonococcal (due to *N. gonorrhoeae*) or non-gonococcal urethritis (NGU)

**Infective causes**

- *Chlamydia trachomatis*
- *Mycoplasma genitalium*
- *Ureaplasma urealyticum*
- *Neisseria gonorrhoeae*
- *Trichomonas vaginalis (TV)*
- Herpes simplex virus (HSV)
- Urinary tract infection (UTI)
- Adenoviruses (often associated with conjunctivitis)

**Non-infective causes**

- Non-specific urethritis (where no cause can be identified)
- Physical or chemical trauma
- Urethral stricture

**Questions that help discriminate between causes**

- Colour of discharge
- Any dysuria, urinary frequency, nocturia or haematuria?
- Any testicular pain or swelling?
- Any other symptoms, e.g. genital sores or rash, sore eyes?

**Investigations**

- Microscopy of urethral discharge, nucleic acid amplification test (NAAT) and culture for *N. gonorrhoeae*, NAAT for *C. trachomatis*, serology for syphilis and HIV
- Tests for TV and HSV are not usually performed routinely
- There are no commercial tests available for *M. genitalium* and *U. urealyticum*
- A mid-stream specimen of urine (MSU) should be taken if symptoms are suggestive of UTI

---

*vMost common cause of NGU. \*Second most common cause of NGU. \*Rarer causes of NGU. \*Most frequent non-sexually transmitted cause of NGU.

• vaginal discharge (Box 12.2)
Box 12.2

Causes of vaginal discharge

**Inf ective causes**

**Vaginal infections**
- Bacterial vaginosis (BV)\(^a\)
- *Candida albicans*\(^a\)
- *Trichomonas vaginalis* (TV)\(^b\)

**Cervical infections**
- *Chlamydia trachomatis*
- *Neisseria gonorrhoeae*
- Herpes simplex virus

**Non-inf ective causes**
- Physiological discharge/cervical ectopy\(^c\)
- Cervical polyps
- Neoplasms
- Retained products (e.g. of conception, tampons)
- Chemical irritation

**Questions that help discriminate between causes**
- Does the discharge have an offensive odour?
- Any vulval itching or soreness?
- Any other symptoms, e.g. dysuria, intermenstrual or postcoital bleeding, abdominal pain?

**Investigations**
- Microscopy of vaginal discharge for BV, candida and TV, culture for candida, nucleic acid amplification test (NAAT; if available) or culture for TV, NAAT for *N. gonorrhoeae* and *C. trachomatis*, serology for syphilis and HIV

\(^a\)The most common causes of altered vaginal discharge but *C. trachomatis* and *N. gonorrhoeae* infections must also be considered. \(^b\)The most common cause worldwide but rarer in high-income countries. \(^c\)Also a common cause (diagnosis usually made on the basis of exclusion of infective causes).

- lower abdominal pain (*Box 12.3*) in females
Causes of lower abdominal pain

Infective causes

• Pelvic inflammatory disease (PID)\textsuperscript{a,b}
  – *Chlamydia trachomatis*\textsuperscript{c}
  – *Neisseria gonorrhoeae*
  – *Mycoplasma genitalium*
  – Bacterial vaginosis (BV)
• Urinary tract infection (UTI)

Non-infective causes

• Ectopic pregnancy
• Acute appendicitis
• Endometriosis
• Irritable bowel syndrome
• Neoplasms
• Torsion or haemorrhage of ovarian cyst

Questions that help discriminate between causes

• Site, character and duration of pain?
• Any vaginal discharge, postcoital or intermenstrual bleeding, or deep dyspareunia?
• Date of last menstrual period (LMP) and contraception used? Is pregnancy possible?
• Any dysuria, urinary frequency, nocturia or haematuria?
• Any nausea, vomiting, diarrhoea or constipation?

Investigations

• Microscopy of vaginal discharge for BV and TV, nucleic acid amplification test (NAAT; if available) or culture for TV, NAAT and culture for *N. gonorrhoeae*, NAAT for *C. trachomatis*, serology for syphilis and HIV
• There are no commercial tests available for *M. genitalium*
• A pregnancy test should be performed, as ectopic pregnancy is a differential diagnosis
• A mid-stream specimen of urine (MSU) should be taken if symptoms are suggestive of UTI

\textsuperscript{a}Most common in young (under 25 years) sexually active women. \textsuperscript{b}Symptoms of abnormal vaginal discharge and/or abnormal bleeding are usually present with PID, and BV is also often present. \textsuperscript{c}The most common cause of PID.

• genital lumps (Box 12.4)
Causes of genital lumps

Infective causes

• Human papillomavirus (HPV; anogenital warts)\textsuperscript{a,b}
• Molluscum contagiosum
• \textit{Sarcoptes scabiei} (scabies – excoriated lesions)\textsuperscript{c}
• \textit{Treponema pallidum}
  – Secondary condylomata lata\textsuperscript{d}

Non-infective causes

• Normal anatomical variants (e.g. papillae, sebaceous glands and skin tags)
• Sebaceous cysts
• Neoplasms

Questions that help discriminate between causes

• Where are the lumps?
• Are they single or multiple?
• Are they itchy or painful?
• How long have they been present?
• Are there any lumps or rashes elsewhere on the skin?

Investigations

• Nucleic acid amplification test (NAAT) for \textit{N. gonorrhoeae} and NAAT for \textit{C. trachomatis}, serology for syphilis and HIV
• Diagnoses of anogenital warts and molluscum contagiosum are made on clinical appearances; HPV testing is not appropriate for diagnosing anogenital warts

\textsuperscript{a}Most common infective causes, followed by molluscum contagiosum. \textsuperscript{b}Lumps present on the mucous membranes are more likely to be anogenital warts, as molluscum contagiosum does not occur there. \textsuperscript{c}Can present with excoriated papules on the genital area due to excessive scratching. \textsuperscript{d}Moist papules present in secondary syphilis – rare but easily misdiagnosed as anogenital warts.

• genital ulceration (\textit{Box 12.5})

Causes of genital ulceration

\textit{Box 12.5}
Infective causes

- Herpes simplex virus (HSV) types 1 and 2:
  - Primary
  - Recurrent
- Treponema pallidum
  - Primary chancre
  - Secondary mucous patches
  - Tertiary gumma
- Herpes zoster
- Lymphogranuloma venereum (LGV)
- Chancroid
- Donovanosis (granuloma inguinale)

Non-infective causes

- Trauma
- Aphthous ulceration (e.g. as in Behçet syndrome)
- Lichen sclerosus
- Erosive lichen planus
- Fixed drug eruptions
- Stevens–Johnson syndrome
- Crohn's disease
- Neoplasms

Questions that help distinguish between causes

- Are the ulcers painful?
- Are they single or multiple?
- How long have they been present?
- Is there any external dysuria?
- Are there any ulcers or rash elsewhere on the skin?
- Are there any systematic symptoms?

Investigations

- Ulcer swab for HSV polymerase chain reaction (PCR). Some laboratories also test these swabs for *T. pallidum* using PCR. Nucleic acid amplification test (NAAT) for *N. gonorrhoeae*, NAAT for *C. trachomatis*, serology for syphilis and HIV. Syphilis serology should be repeated after the 3-month window period if appropriate
- In men who have sex with men (MSM), consider an ulcer swab for *C. trachomatis* and NAAT with genotyping for LGV if positive
Most common cause of multiple painful ulcers. Syphilis ulcers are usually single and non-painful. Much rarer than HSV and characterized by unilateral presentation. LGV rare except in MSM; chancroid and donovanosis extremely rare. Most common non-infective cause; usually, there is a history of similar lesions in the mouth.

- genital itching *(Box 12.6)*

**Box 12.6**

**Causes of genital itching**

**Infective causes**

- *Candida albicans*\(^a\)
- *Trichomonas vaginalis* (TV)
- *Phthirius pubis* (pubic lice)\(^b\)
- *Sarcoptes scabiei* (scabies)\(^c\)

**Non-infective causes**\(^d\)

- Irritant dermatitis
- Genital eczema
- Lichen sclerosus
- Lichen planus

**Questions that help distinguish between causes**

- Site and duration of itching?
- Any vaginal discharge, offensive odour or vulval swelling?
- Any itching or rash elsewhere on the skin, or any known skin problems?

**Investigations**

- Microscopy of vaginal discharge for candida and TV, culture for candida, nucleic acid amplification test (NAAT; if available) or culture for TV, NAAT for *N. gonorrhoeae* and *C. trachomatis*, serology for syphilis and HIV

\(^a\)The most frequent symptom in females is vulval itching rather than vaginal discharge.

\(^b\)Relatively rare but easily visible in the hair area. Can cause genital itching and may present with excoriated papules due to excessive scratching.

\(^c\)Genital dermatoses are common causes of genital itching and are frequently misdiagnosed as candida.

- rectal symptoms *(Box 12.7).*
Causes of rectal symptoms

- Symptoms of proctitis are rectal pain, mucopurulent anal discharge, rectal bleeding, constipation and tenesmus
- Proctoscopy may reveal mucosal erythema, oedema, contact bleeding and a mucopurulent discharge, with ulceration in severe cases

Infective causes

Rectal infections
- Neisseria gonorrhoeae
- Chlamydia trachomatis
- Lymphogranuloma venereum (LGV)
- Herpes simplex virus (HSV)
- Treponema pallidum

Intestinal infections
- Shigella spp.
- Campylobacter spp.
- Entamoeba histolytica
- Salmonella spp.
- Escherichia coli
- Cryptosporidium spp.

Non-infective causes
- Ulcerative colitis
- Crohn's disease
- Neoplasms

Questions that help distinguish between causes
- Any irritation or pain around the anus or in the rectum?
- Any discharge or bleeding from the anus?
- Any abdominal pain, diarrhoea or blood in the stool?
- Any feeling of incomplete bowel evacuation or constipation?
- Any systematic symptoms?

Investigations
- Microscopy of a rectal smear, rectal culture and nucleic acid amplification test (NAAT) for N. gonorrhoeae, NAAT for C. trachomatis, serology for syphilis and HIV. If positive
for *C. trachomatis*, genotyping for LGV should be requested

- If there is severe proctitis, a swab for HSV and *T. pallidum* polymerase chain reaction (PCR) should be performed

- LGV should be considered in MSM with suspected inflammatory bowel disease, as the clinical presentation can be very similar

- Cultures for enteric pathogens should be performed if symptoms of enteritis are present

Most common causes of proctitis in women and MSM. Outbreaks occurring in Europe in MSM. Rarer causes than *N. gonorrhoeae* and *C. trachomatis*; mainly seen in MSM.

Details should be obtained of any associated pain, malodour, genital swelling and any abnormal bleeding. Systemic symptoms of fever, skin rash, joint pains and eye symptoms may also be present. Enquiries should be made as to any previous STIs, including dates and treatment received, HIV testing and results, and hepatitis B vaccination status if appropriate (see pp. 320–321).

A full general medical history should be obtained, including a history of allergies and a drug history, particularly of any recent antibacterial or antiviral treatment. In women, a menstrual, obstetric and cervical cytology screening history should be obtained, as well as details of current contraception. Any past or current history of drug (including recreational use) and/or alcohol misuse should be explored.

A sexual history should be taken that includes:

- number and types of recent sexual contacts with dates
- gender of partners
- whether the partner is regular or casual; if regular, how long the couple has been having sex
- use of condoms
- any known symptoms or STI diagnosis in the partner
- sexual practices, e.g. insertive or receptive vaginal, insertive or receptive anal, insertive or receptive pharyngeal, and insertive or receptive oroanal sex
- number of partners over the past 3 months, particularly in people who frequently change partners
- number of sexual partners over the past 12 months, in those at higher risk of STIs, such as young people and men having sex with men (MSM)
- whether the patient has ever paid, or has been paid, for sex
- country of origin of any sexual partners, in view of the differences in prevalence of HIV, hepatitis B and C, certain STIs such as chancroid and donovanosis, and the patterns of gonococcal antibiotic resistance worldwide.

An STI and HIV acquisition risk assessment should be routinely undertaken. Those identified as being at high risk of STIs (e.g. frequent partner change, unprotected sex, use of drugs and/or alcohol to a level that reduces safer sex) and those with ongoing higher risk of
HIV (e.g. MSM, sexual partners from countries with high HIV prevalence) should be offered risk reduction advice based on motivational interview techniques and be made aware of the availability of post-exposure HIV prophylaxis following sexual exposure (PEPSE). See page 347 for more details.

**Examination**

The inguinal, genital and perianal areas should be examined using a good light source. The groins should be palpated for lymphadenopathy, and the pubic hair and skin examined for nits and lice and any skin rashes or lumps. The external genitalia and perianal area should be examined for signs of erythema, fissures, lumps, ulcers, pigmented or hypopigmented areas. A rectal examination/proctoscopy should be performed in patients with rectal symptoms, in those with perianal warts extending into the anal canal, and in men with prostatic symptoms.

*In men,* the skin of the penile shaft (retracting the prepuce if present) should be examined for rashes, lumps, or ulcers, and the urethral meatus should be inspected for erythema and discharge (*Fig. 12.1*). The scrotal contents should be palpated, noting any tenderness or lumps, as well as the consistency of the testes.

![Mucopurulent urethral discharge.](image)

**FIGURE 12.1** Mucopurulent urethral discharge.

*In women,* the labia majora, labia minora, clitoris, urethra, introitus and perineum should be examined for rashes, lumps or ulcers. Any evidence of female genital mutilation (FGM) should be documented. A bivalve vaginal speculum should be inserted and the vagina examined for erythema, discharge, lumps or ulcers. The cervix should be inspected and any ectopy noted, as well as any discharge (*Fig. 12.2A*), contact bleeding (*Fig. 12.2B*), ulceration or raised lesions. A bimanual pelvic examination should be performed in those complaining of abdominal pain to determine the size and any tenderness of the uterus, as well as any cervical motion or adnexal tenderness and the presence of any masses.
If systemic symptoms have been identified, a general examination should be performed with inspection of the skin, mouth, pharynx and lymph nodes. Signs of HIV infection are covered on p. 336.

**Investigation of STIs**

Although the history and examination will guide investigations, it should be remembered that multiple infections may coexist and may be asymptomatic. Tests for all STIs are indicated in any patient with a known STI or in those who have been in contact with an STI. The recommended tests for specific infections are indicated in the sections below.

**Asymptomatic STI screening**

The minimum investigations should include tests for chlamydia, gonorrhoea, syphilis and HIV. HIV antibody testing should be performed on an ‘opt out’ basis. If it is declined, the reasons why should be documented. Screening for hepatitis viruses should be performed in those at increased risk, as indicated below.

**Screening for hepatitis A and vaccination.** Test for antibodies to hepatitis A (with vaccination if negative) should be performed in injecting drug users, people with chronic hepatitis B or C, or HIV, and MSM in areas where an outbreak of hepatitis A has been reported.

**Screening for hepatitis B and vaccination.** The recommended screening test in those who have not been immunized is immunoglobulin G (IgG) anti-hepatitis B core (anti-HBc), which is a marker of past infection. If positive, hepatitis B surface antigen (HBsAg) testing should be
performed, as this identifies currently infected individuals. Screening is recommended for the following: sexual partners of those who are HBsAg-positive, MSM and their sexual partners, people who have been sexually assaulted, sex workers, injecting drug users and their sexual partners, individuals or those with a sexual partner from countries with a high prevalence of hepatitis B (which are countries outside Western Europe, North America and Australasia), needle-stick recipients, people with chronic hepatitis C or HIV, and those born to a mother infected with hepatitis B. Patients who are negative and have ongoing increased risk should be offered vaccination.

**Screening for hepatitis C** (HCV). Screening for antibodies to hepatitis C is recommended in the sexual partners of HCV-positive people, injecting drug users, needle-stick recipients, people with chronic hepatitis B or HIV, and those born to a mother infected with HCV.

**Investigations for symptomatic patients**

The investigations will depend on the clinical presentation but should always include tests for chlamydia, gonorrhoea, syphilis and HIV. The recommended investigations for these presentations are shown in **Boxes 12.1–12.7**.

**Management, prevention and control**

The treatment of specific conditions is covered in the appropriate sections. Most sexual health clinics give directly observed therapy where possible or dispense medication directly to the patient to improve adherence in order to prevent onward transmission.

Tracing the sexual partners of patients is crucial in controlling the spread of STIs. The aims are to identify and treat those with infections (particularly those with asymptomatic infections) in order to prevent the spread within the community. Also, appropriate antibiotic therapy is usually offered to recent sexual partners of those known to have an active infection (epidemiological treatment). Interviewing people about their sexual partners requires considerable tact and sensitivity, and specialist health advisers are available in sexual health clinics.

Many STI diagnoses are in young adults (16–24 years). Prevention starts with education and information. People begin sexual activity at ever-younger ages and education programmes need to include school pupils, as well as young adults. Education of health professionals is also crucial. Primary public health prevention aimed at informing groups at particular risk in order to modify sexual behaviour should be implemented at a national level. Secondary interventions include the prompt diagnosis and appropriate management of STIs in order to reduce complications and onward transmission. The National Chlamydia Screening Programme (NCSP) in England aims to provide earlier detection and treatment for chlamydia by providing easy access for under-25-year-olds to chlamydia testing in community settings.

Reducing the numbers of sexual partners, avoiding overlapping relationships, using condoms correctly and consistently, and avoiding sex if symptoms are present can reduce the risks of acquiring and transmitting an STI. For those who change their sexual partners frequently, regular check-ups (approximately 3-monthly) are advisable. Once people develop symptoms,
they should be encouraged to seek medical advice as soon as possible to reduce complications and spread to others.

British Association for Sexual Health and HIV (BASHH). BASHH Clinical Effectiveness Guidelines. BASHH; available online at http://www.bashh.org/.

Specific Infections

HIV/AIDS

This is discussed on pages 331–355.

Hepatitis B

This is discussed on pages 454-457. Sexual contacts should be screened and immunized if they are not immune.

Chlamydia trachomatis

C. trachomatis (CT) is the most common STI in the UK; up to 10% of sexually active people below the age of 25 years are infected. It infects the urethra, endocervix, rectum, pharynx and conjunctiva, and is transmitted by direct inoculation of infected secretions from one mucous membrane to another. As up to 80% of women and 50% of men may be asymptomatic, it is frequently unrecognized and therefore untreated. Pelvic inflammatory disease, the main complication of CT, can result in tubal infertility, ectopic pregnancy and chronic pelvic pain, causing significant morbidity and cost to health services.

Clinical features

The exact incubation period is unclear but is thought to be between 7 and 21 days.
**In men**, it can cause an anterior urethritis with a mucoid or mucopurulent urethral discharge (which may be worse on waking, when there may be crusting at the meatus) and dysuria. The infection can ascend along the vas deferens, leading to epididymo-orchitis.

**In women**, the most common site of infection is the endocervix but the urethra can also be infected. Symptoms may include increased vaginal discharge, dysuria, postcoital or intermenstrual bleeding, and lower abdominal pain. Examination of the cervix may reveal mucopurulent cervicitis and/or contact bleeding. Ascending infection into the uterus and fallopian tubes causes endometritis and acute salpingitis (pelvic inflammatory disease). In pregnancy, CT is associated with preterm birth, postpartum infection, and neonatal mucopurulent conjunctivitis and pneumonia due to vertical transmission during vaginal delivery.

Rectal infection, through receptive anal sex, may be asymptomatic but can cause proctitis. Reactive arthritis (see p. 686) can occur with CT infection, particularly in human leucocyte antigen (HLA)-B27-positive individuals.

### Diagnosis

Nucleic acid amplification tests (NAATs) are the diagnostic tests of choice for CT, as they have sensitivities of 90–99%. In men, first-voided urine (FVU) samples or urethral swabs, and in women vulvovaginal swabs (VVSs) or endocervical swabs, are taken. Self-taken VVSs are as sensitive at detecting CT as clinician-taken VVSs but FVU samples in women are less sensitive than VVSs and endocervical swabs. The advantages of male FVU samples and self-taken VVSs is that they are non-invasive (meaning they can be obtained by the patient without the need for an examination), so are ideal for asymptomatic chlamydia screening.

MSM who practise receptive anal sex and receptive oral sex should have rectal and pharyngeal swabs for CT NAAT performed.

### Management

Macrolide or tetracycline antibiotics are most commonly used to treat CT. Azithromycin 1 g as a single dose or doxycycline 100 mg ×2 daily for 7 days is the recommended regimen for uncomplicated infection. Both of these drugs have similar efficacies of more than 95%. Azithromycin 1 g as a single dose is recommended in pregnant or lactating women by WHO, USA, UK and Australian guidelines but the manufacturers advise use only if adequate alternatives are not available. Tetracyclines are contraindicated in pregnancy. Longer courses of antibiotics are required for complicated infections (see pelvic inflammatory disease and epididymo-orchitis below). Epidemiological treatment pending test results is usually offered to those who have had recent sexual intercourse with someone who has confirmed CT infection, as the infection rate can be up to 50%. Abstinence from sex for at least 7 days, or until treatment is completed, should be advised. Sexual contacts must be traced, notified and treated, particularly as many infections are asymptomatic.

A follow-up interview (possibly by telephone) should be held in order to assess adherence.
to therapy and partner notification. A routine test of cure is not necessary after treatment with azithromycin or doxycycline, except in pregnant women or where symptoms persist or re-infection is suspected. NAATs may remain positive for some time after treatment, as they detect non-viable organisms, so a test of cure should be deferred until 6 weeks after the start of treatment.

### Gonorrhea

*Neisseria gonorrhoeae* is a Gram-negative intracellular diplococcus (*Fig. 12.3*), which infects the urethra, endocervix, rectum, pharynx and conjunctiva. It is transmitted by direct inoculation of infected secretions from one mucous membrane to another. Up to 50% of infected women and 10% of infected men are asymptomatic. Co-infection with CT is common, occurring in 20% of men and 40% of women with gonorrhoea (GC).

![Gonorrheaea](https://example.com/gonorrheaea.png)

**FIGURE 12.3 Neisseria gonorrhoeae. Gram-negative intracellular diplococci.** (Courtesy of Dr B. Goh.)

### Clinical features

The incubation period is 2–14 days, with most symptoms in males occurring between 2 and 5 days.

**In men**, GC can cause anterior urethritis with mucopurulent or purulent urethral discharge and dysuria (*Fig. 12.4*). The discharge can be profuse, causing staining of underwear. Complications include ascending infection, leading to epididymo-orchitis and acute prostatitis.
In women, symptoms may include increased vaginal discharge, dysuria, postcoital or intermenstrual bleeding, and lower abdominal pain. Examination of the cervix may reveal mucopurulent or purulent cervicitis and/or contact bleeding. Complications include Bartholin's abscesses, and ascending infection into the uterus and fallopian tubes causes endometritis and acute salpingitis (pelvic inflammatory disease). In pregnancy, GC is associated with preterm birth, postpartum infection, and neonatal purulent conjunctivitis due to vertical transmission during vaginal delivery.

Rectal infection, through receptive anal sex, may be asymptomatic but can cause proctitis. GC septicaemia (disseminated gonococcal infection, DGI) is a rare complication presenting as fever, tenosynovitis, arthritis and characteristic erythematous skin lesions with necrotic centres.

Diagnosis

NAATs are the diagnostic test of choice for N. gonorrhoeae, as they have better sensitivity than culture. However, as N. gonorrhoeae antimicrobial resistance is increasing, culture on selective media should be performed prior to any treatment for GC being given. In men, FVU samples or urethral swabs, and in women VVSs or endocervical swabs, are the specimens of choice for GC NAATs. Self-taken VVSs are as sensitive at detecting GC as clinician-taken VVSs. FVU samples in women should not be used as they are less sensitive than VVSs and endocervical swabs. As male FVU samples and self-taken VVSs are non-invasive samples, they are ideal for asymptomatic screening. MSM who practise receptive anal sex and receptive oral sex should have rectal and pharyngeal swabs for GC NAATs performed. A urethral swab in men, an endocervical swab in women, and rectal and pharyngeal swabs in both are the specimens to use for culture.

Microscopy of Gram-stained urethral and endocervical secretions may demonstrate intracellular, Gram-negative diplococci, allowing rapid diagnosis. The sensitivity ranges from 90% in urethral specimens from symptomatic men to 50% in endocervical specimens. Microscopy should not be used for pharyngeal specimens. The sensitivity of blood and
synovial fluid cultures is poor, so NAATs from the genital tract, rectum and pharynx remain the tests of choice for investigations of DGI.

Management

Treatment should be given to those who have positive microscopy, a positive NAAT or a positive culture for GC. Antibiotic-resistant strains of *N. gonorrhoeae* are increasing and dual antibiotic therapy should always be used in order to reduce development of further resistance. Single-dose ceftriaxone 500 mg i.m. with azithromycin 1 g is recommended in the UK. If there is a history of penicillin anaphylaxis or established cephalosporin allergy, spectinomycin 2 g i.m. with azithromycin 1 g should be used. Both of these regimens can be used in pregnancy. Epidemiological treatment pending test results is usually offered to those who have had recent sexual intercourse with someone with confirmed GC infection, as the infection rate is usually about 50%. Longer courses of antibiotics are required for complicated infections (see pelvic inflammatory disease and epididymo-orchitis below). Abstinence from sex for at least 7 days, or until treatment has been completed, should be advised. All sexual contacts should be notified, examined and treated.

A follow-up assessment and test of cure using GC NAAT should take place 14 days after treatment.

Non-gonococcal urethritis

Non-gonococcal urethritis (NGU) in men is usually characterized by a urethral discharge and dysuria. There are a number of causes, many of which are sexually transmitted; the most common of these is *C. trachomatis*, which is discussed above. Other causes are *Mycoplasma genitalium*, *Ureaplasma urealyticum*, *Trichomonas vaginalis* (TV), herpes simplex virus (HSV) 1 and 2, and adenoviruses, in that order of frequency. Studies investigating the aetiology of NGU have consistently identified no known cause in over 60% of cases. Non-sexually transmitted causes of NGU may be urinary tract infections (UTIs), foreign bodies and strictures.

Clinical features

The incubation period is usually 2–3 weeks. The main symptom is a mucoid or mucopurulent urethral discharge, which may be worse on waking, when there may be crusting at the meatus. Dysuria is common but not universal. Discomfort or itching within the urethra may be present.

Diagnosis

NAAT for *N. gonorrhoeae* and for *C. trachomatis* should be performed in all men with symptoms of urethritis on either an FVU sample or urethral swab. Microscopy of Gram-stained urethral secretion showing five or more polymorphonuclear leucocytes per high-power (×1000
oil-immersion lens) field is diagnostic. Men who are symptomatic but have no objective evidence of urethritis should be re-examined and tested after holding their urine overnight. Testing for TV and HSV is not routinely performed and there are no commercial tests available for *M. genitalium* and *U. urealyticum*. A mid-stream specimen of urine (MSU) should be taken if symptoms are suggestive of a UTI (urinary frequency, nocturia, urgency, haematuria).

### Management

Therapy for NGU is with either doxycycline 100 mg ×2 daily for 7 days or azithromycin 1 g orally as a single dose. Abstinence from sex for at least 7 days should be advised. All sexual contacts should be notified, examined and treated. Follow-up is only indicated if CT is confirmed or if symptoms persist.

#### Recurrent/persistent NGU

This is defined as persistent or recurrent symptomatic urethritis occurring 30–90 days following treatment of acute NGU, and occurs in 10–20% of cases. The aetiology is probably multifactorial but *M. genitalium* and *T. vaginalis* are likely causes. It is necessary to ensure that there is still objective evidence of urethritis, that there was good adherence to NGU treatment with sexual abstinence, and that sexual partners were also treated. If there is no objective evidence of urethritis, patients should be reassured and further antibiotic therapy avoided. Subsequent treatment needs to cover *M. genitalium* and *T. vaginalis*. The recommended treatment is azithromycin 500 mg orally as a single dose, followed by 250 mg daily for 4 days with metronidazole 400 mg ×2 daily for 5 days.

#### Pelvic inflammatory disease

Pelvic inflammatory disease (PID) results when infections ascend from the cervix or vagina into the upper genital tract. It is most frequent in young (under 25 years) sexually active women. It includes endometritis, salpingitis, tubo-ovarian abscess and pelvic peritonitis. The main causes are *C. trachomatis* and *N. gonorrhoeae*, but these are identified in less than half of the cases of PID in the UK. *M. genitalium* has been associated with PID and anaerobes have also been implicated. Even in women with laparoscopically proven PID, often no bacterial cause is found. PID has serious long-term sequelae due to tubal damage and pelvic adhesions, resulting in tubal infertility, increased risk of ectopic pregnancy and chronic pelvic pain. The risk of sequelae increases with more severe and multiple episodes of PID. Tubal infertility occurs in 10–12% of women after one episode of PID and increases to 50–60% after three or more episodes. The risk of ectopic pregnancy is increased 6–10-fold and abdominal or pelvic pain for longer than 6 months occurs in 18% of women.

#### Clinical features

The onset of symptoms often occurs in the first part of the menstrual cycle. Lower abdominal
pain, usually bilateral, is the most common symptom, with increased vaginal discharge, irregular bleeding, deep dyspareunia and dysuria being present in some women. There may be a mucopurulent cervical discharge with contact bleeding. Lower abdominal tenderness and adnexal and cervical motion tenderness on bimanual examination are the most common signs.

**Diagnosis**

The diagnosis is usually made on the clinical findings of lower abdominal pain, with supportive symptoms of increased vaginal discharge and abnormal bleeding, and cervical motion and/or adnexal tenderness on bimanual examination. However, such a clinical diagnosis has a specificity of only 65–70%. The differential diagnosis includes ectopic pregnancy, acute appendicitis, endometriosis, UTI and irritable bowel disease.

Investigations should include microscopy of Gram-stained vaginal discharge for bacterial vaginosis (BV), NAAT and culture for *N. gonorrhoeae*, and NAAT for *C. trachomatis*. There are no commercial tests available for *M. genitalium*. A pregnancy test should be performed on all women suspected of having PID, as ectopic pregnancy is a differential diagnosis. An MSU should be taken if symptoms are suggestive of a UTI (urinary frequency, nocturia, urgency, haematuria).

**Management**

Early diagnosis and treatment reduce the risk of long-term sequelae, so empirical treatment should be started before microbiology results are known. A broad-spectrum antibiotic regimen is needed to cover the main bacterial causes. The recommended regimens are: single-dose ceftriaxone 500 mg i.m. with doxycycline 100 mg ×2 daily and metronidazole 400 mg ×2 daily for 14 days; or ofloxacin 400 mg ×2 daily and metronidazole 400 mg ×2 daily for 14 days. Abstinence from sex for at least 14 days should be advised. All sexual contacts should be notified, examined and treated.

Those with moderate or severe clinical findings should be reviewed within 2–3 days to ensure they are improving on treatment. Lack of response requires further investigation and possible admission for intravenous therapy and/or surgical intervention. All women should be seen after 2 weeks in order to assess symptom resolution, adherence to therapy and partner notification.

**Epididymo-orchitis**

Acute epididymo-orchitis is a clinical syndrome consisting of pain, swelling and inflammation of the epididymis that can extend into the testis. It is caused mainly by extension of infection from the urethra or the bladder. In men under 35 years, *C. trachomatis* and *N. gonorrhoeae* are the main causes, but in men over 35 years, it is more commonly a complication of a UTI. Mumps is another cause of epididymo-orchitis in non-immune men. The most common differential diagnosis is torsion of the spermatic cord, which is a urological emergency.
### Clinical features

The typical presentation is subacute onset of unilateral scrotal pain and swelling. There may also be symptoms of a urethral discharge and dysuria but these are often absent. On examination, there is tenderness and usually palpable swelling of the epididymis. There may also be some tenderness and swelling of the testicle, with oedema and erythema of the overlying scrotal skin. A urethral discharge may be present.

### Diagnosis

The diagnosis is usually made on the above clinical findings. The main differential diagnosis is testicular torsion.

**Investigations** include a NAAT and culture for *N. gonorrhoeae* and a NAAT for *C. trachomatis*. If microscopy of Gram-stained urethral secretions shows five or more polymorphonuclear leucocytes per high-power (×1000 oil-immersion lens) field, this indicates the diagnosis of NGU. If intracellular Gram-negative diplococci are present, this is suggestive of GC. An MSU should be taken if symptoms are suggestive of a UTI (urinary frequency, nocturia, urgency, haematuria) and in older men.

### Management

As empirical treatment should be started before microbiology results are known, a broad-spectrum antibiotic regimen is needed to cover the main bacterial causes. In younger men, where an STI is the likely diagnosis, the recommended regimen is single-dose ceftriaxone 500 mg i.m. with doxycycline 100 mg ×2 daily for 14 days. Where a UTI is the more likely diagnosis, ofloxacin 200 mg ×2 daily for 14 days should be prescribed. Abstinence from sex for at least 14 days should be advised. All sexual contacts should be notified, examined and treated.

Patients should be reassessed after 3 days if there is no improvement in their symptoms, as such lack of response requires further investigations. All should be seen after 2 weeks in order to assess symptom resolution, adherence to therapy and partner notification.

### Bacterial vaginosis

Bacterial vaginosis (BV) is the most frequent cause of vaginal discharge among women of childbearing age. A BV prevalence of 9% has been reported in women attending general practice for cervical cytology screening and in 15% of pregnant women in the UK. BV develops when the normal *Lactobacilli*-dominant vaginal flora are replaced by an overgrowth of other bacteria, including *Gardnerella vaginalis*, anaerobes, mycoplasmas and *Mobiluncus* spp. It is not regarded as a sexually transmitted disease. BV in pregnancy is associated with an increased risk of miscarriage and preterm birth. It also increases the risk of acquisition and transmission of HIV. Up to 50% of women with BV have no symptoms and, as it is not
regarded as an STI, it is not necessary to look for or treat asymptomatic BV.

### Clinical features

The symptoms are an increased vaginal discharge and offensive fishy odour. On examination, there is a creamy-white homogeneous discharge, which may be slightly frothy (due to the volatile amine production by the bacteria, and which is responsible for the characteristic odour) and adherent to the vaginal walls (Fig. 12.5). Visible inflammatory changes are not seen with BV, so there should be no vaginal inflammation.

![FIGURE 12.5](image)

**FIGURE 12.5** Bacterial vaginosis. Homogenous creamy-white vaginal discharge, which may be slightly frothy and adherent to the vaginal walls.

### Diagnosis

The most accurate method of diagnosis is microscopy of Gram-stained vaginal discharge, as the characteristic pattern of the BV bacteria is easily distinguished from the normal *Lactobacilli*-dominant vaginal flora. It is possible to diagnose BV just on clinical criteria but this is less specific. All three of the following should be present for the diagnosis to be made:

- characteristic creamy-white homogeneous vaginal discharge
- raised vaginal pH of >4.5 (measured using narrow-range pH paper)
- characteristic fishy odour, which can be released by mixing the vaginal discharge with 10% potassium hydroxide.

### Management

The recommended treatment is oral metronidazole 400 mg ×2 daily for 5–7 days. A single dose of metronidazole 2 g can also be used but this is slightly less effective. Alternative topical treatments are intravaginal metronidazole 0.75% gel for 5 nights, or intravaginal clindamycin 2% cream for 7 nights. High-dose metronidazole should be avoided in pregnancy but the 5–7-
day oral course can be safely prescribed, as can either of the intravaginal regimens.

BV recurrences are frequent, with about 50% of women experiencing a recurrence within 12 months of completing metronidazole therapy. Simultaneous treatment of the male partner does not reduce the rate of recurrence, and treatment of male partners is not indicated.

**Candidiasis**

*Candida* is a ubiquitous organism and is not classified as an STI. Vulvovaginal *Candida* infection is extremely common; about 75% of women have at least one episode of symptomatic candidiasis in their lifetime. About 20% of asymptomatic women are colonized with *Candida*, and this figure rises to 30–40% in pregnancy and uncontrolled diabetes. Predisposing factors for symptomatic infection include pregnancy, diabetes, the use of broad-spectrum antibiotics and corticosteroids, and immunosuppression. *Candida albicans* causes 90% of vaginal yeast infections, with *Candida glabrata* and other *Candida* species causing the remainder. Male sexual partners of women with candidiasis can contract transient penile colonization (and may develop penile rashes) following sex due to direct inoculation from the vagina.

**Clinical features**

*In women*, the main symptom is vulval itching, which is present in nearly all symptomatic women. An increased thick, white vaginal discharge, vulval burning, external dysuria and superficial dyspareunia may also be present. On examination, vulval erythema, fissuring and oedema may be present. There may be the typical white, curdy, adherent plaques on the vaginal walls (*Fig. 12.6*) but the discharge may be minimal.

![Candidiasis. Adherent plaques of discharge on the vaginal walls.](image)

*In men*, there may be a transient penile irritation and rash immediately following sex, but some men experience more persistent balanoposthitis. On examination, there may be erythema of the foreskin and glans penis, or a spotty, red, itchy rash on the glans, with an accumulation of white discharge under the foreskin. In severe cases, there may be fissuring and phimosis of the foreskin.
Diagnosis

Microscopy of a Gram-stained vaginal smear, or a sub-preputial smear, identifies the fungal pseudohyphae and spores in 50% of cases of candidiasis. Culture of vaginal, or sub-preputial, swabs has almost 100% sensitivity. Diabetes should be excluded in men with severe balanoposthitis.

Management

There are a number of short-course oral and intravaginal antifungal agents available, all with efficacies of 80–85%. Recommended treatments are the oral triazole drugs, such as fluconazole 150 mg as a single dose or itraconazole 200 mg ×2 daily for 1 day, and intravaginal imidazole pessaries or creams such as clotrimazole pessary 500 mg as a single dose, miconazole vaginal ovule 1.2 g as a single dose or econazole pessary 150 mg nightly for 1–3 nights. These treatments can be supplemented with antifungal cream applied to the vulva. Males can be treated with either oral therapy or topical antifungal cream. Nystatin pessaries 200 000 units nightly for 14 nights are the treatment of choice for C. glabrata and other non-albicans yeasts. Intravaginal treatment is safe in pregnancy but oral therapies should not be used.

Recurrent candidiasis (four or more symptomatic episodes in 1 year) occurs in up to 5% of healthy women of reproductive age. It frequently requires weekly oral fluconazole 150 mg, or clotrimazole pessary 500 mg, for up to 6 months in order to prevent recurring symptoms. There is no evidence that treatment of male partners reduces recurrences in women, so male partners do not need treatment unless they also have symptoms.

Trichomoniiasis

*Trichomonas vaginalis* (TV) is the most common STI worldwide but it is much rarer in Western Europe and Australasia. The organism is a flagellated protozoon that is sexually transmitted. In women, it infects the vagina and urethra; in men, it infects the urethra and sub-preputial sac. Nearly all infected men are asymptomatic, as are 10–50% of women. TV in pregnancy is associated with an increased risk of preterm birth and low birth weight, and it increases the risk of acquisition of HIV.

Clinical features

In women, the most common symptoms are an increased purulent vaginal discharge and malodour. There may also be vulval pruritus, external dysuria and dyspareunia. On examination, there may be vulval erythema and the vaginal mucosa is often inflamed. The discharge is yellow or grey and frothy, and can be profuse. The cervix may have multiple small haemorrhagic areas, which have given rise to the description ‘strawberry cervix’.

In men, the majority have no symptoms, although they may complain of urethral discharge,
irritation and dysuria.

**Diagnosis**

Phase-contrast microscopy of vaginal discharge identifies the motile protozoa in 50% of infected females. The sensitivity of microscopy of urethral discharge in males is much lower. Culture will detect 70–80% of infections but NAATs of vaginal swabs in women, and first-pass urine (FPU) or urethral swabs in males, will detect over 90%.

**Management**

The treatment of choice is metronidazole 2 g orally as a single dose or 400 mg ×2 daily for 7 days. Single-dose treatment has the advantage of improved adherence. However, in women who are HIV-positive, the 7-day course of metronidazole has better efficacy than single-dose treatment. As TV infects areas beyond the vagina (e.g. the urethra), intravaginal metronidazole gel has poor cure rates and should not be used. High-dose metronidazole should be avoided in pregnancy but the 7-day oral course can be safely prescribed.

Abstinence from sex for at least 7 days should be advised. All sexual contacts should be notified, examined and treated. Tests of cure are only recommended if the patient remains symptomatic following treatment, or if symptoms recur.

Occasionally, TV can become resistant to metronidazole and other nitroimidazoles. This is usually relative rather than absolute and may be overcome by high-dose metronidazole or tinidazole therapy.

**Human papillomavirus – anogenital warts**

Anogenital warts are painless, benign, epithelial tumours and are a common STI. The causative agent is human papillomavirus (HPV) types 6 and 11. Genital HPV infection is acquired by direct skin-to-skin contact during sex with a person who has either clinical or subclinical infection. Subclinical infection is very common in young sexually active people, with rates of up to 20%. Anogenital warts are the ‘tip of the iceberg’, occurring in only about 1% of those with subclinical infection.

Warts due to HPV 6 and 11 do not undergo malignant transformation. The main oncogenic HPV types are 16 and 18. These lead to subclinical infection, not genital warts, and cause the majority of cases of cervical and other anogenital cancers (see p. 265). Neonates may acquire HPV from an infected birth canal, which may result either in anogenital warts or in laryngeal papillomatosis.

**Clinical features**

Anogenital warts have a long incubation period; the average is 3 months but it can extend to years. The warts first appear at sites of trauma during sex, so in males they tend to appear
around the prepuce and glans; from there, they can spread to the urethra and down the penile shaft. In women, they usually start at the fourchette and then spread to the vulva and perineum (Fig. 12.7). Perianal lesions are common in both sexes but are more common in MSM. Warts on mucous membranes tend to be soft and non-keratinized, whereas those on the hair-bearing skin tend to be firm and keratinized.

![Genital warts on the fourchette and perineum.](image)

Warts tend to increase in size and number during pregnancy or in immunosuppressed patients.

**Diagnosis**

The diagnosis is made on the clinical appearances. HPV testing is not appropriate for diagnosing anogenital warts. The main differential diagnoses are molluscum contagiosum and the condylomata lata of secondary syphilis. Atypical lesions should be biopsied, particularly in older patients, as pre-malignant and malignant lesions can look similar to warts. Investigations should include NAAT for *N. gonorrhoeae* and NAAT for *C. trachomatis*, serology for syphilis and HIV, as co-infection with other STIs is common.

**Management**

There are a number of treatments available for anogenital warts but all of them have significant failure and relapse rates. The choice of treatment depends on the number, type and distribution of lesions. Topical podophyllotoxin (0.5% solution or 0.15% cream used twice daily for 3 consecutive days per week) acts as a cytotoxic agent and is useful for non-keratinized warts; keratinized warts respond better to ablative therapy, such as cryotherapy or electrocautery. Imiquimod enhances the local immune response when applied to skin infected with HPV (5% cream used daily, three times a week) and is effective in both types of warts. Podophyllotoxin
and imiquimod have the advantage of being self-applied home therapies. Podophyllotoxin and imiquimod should not be used in pregnancy. Pregnant women, those co-infected with HIV and those with other causes of immunosuppression may have a poorer response to treatment. The use of condoms should be advised in new relationships, as they protect against the transmission of HPV infection and genital warts. Current sexual partners may have undetected genital warts so may benefit from a sexual health assessment. Follow-up is recommended in order to monitor the response to treatment and to assess the need for any change of therapy.

### Prevention and vaccination

There are two very effective vaccines against HPV. One protects against HPV types 16 and 18 (the bivalent vaccine, which covers the most common high-risk types) and the other protects against types 6, 11, 16 and 18 (the quadrivalent vaccine, which covers the most common high-risk types and those that cause genital warts). They are given over 6 months in three divided doses and have excellent safety profiles, with almost 100% serological response that is maintained over a number of years. Vaccination is most beneficial in those who have not yet been exposed to HPV infection; hence most programmes target those aged 12–13 years. The best evidence of the effect of HPV vaccination is from Australia, where there has been a school-based quadrivalent HPV vaccination programme in girls since 2007. The programme has recently been extended to include boys. There has been a rapid reduction of more than 90% in genital warts and a reduction of high-grade cervical lesions.

### Molluscum contagiosum

Molluscum contagiosum (see pp. 1344–1345) is a large DNA virus. It causes small (typically 2–5 mm in diameter), benign, smooth papules with central umbilication. It is spread via direct skin-to-skin contact. When it is transmitted sexually, the lesions are usually multiple and present on the labia majora, penile shaft, pubic region, lower abdomen and upper inner thighs.

### Diagnosis

The diagnosis is made on the characteristic clinical appearance. As it is a sexually acquired condition, investigations for other STIs should include NAAT for *N. gonorrhoeae* and NAAT for *C. trachomatis*, and serology for syphilis and HIV.

### Management

Molluscum infection is often self-limiting, resolving naturally. Treatment options, if required, are cryotherapy, podophyllotoxin cream or imiquimod cream. The creams have the advantage of being self-applied home therapies. Podophyllotoxin and imiquimod should be avoided in
pregnancy. Patients should be advised about the risks of autoinoculation of the virus and discouraged from shaving or waxing the pubic hair in order to prevent further spread. No routine follow-up or partner notification is required unless any other STIs are identified.

## Herpes simplex

Genital herpes (also see pp. 247–249) is the most common cause of genital ulceration in all countries worldwide. The peak incidence for primary infection is in 16–24-year-olds. Women acquire the infection more frequently than men, probably because of the larger surface area of susceptible mucous membrane on the vulva. Transmission occurs from the mucous membrane of a person who is shedding herpes simplex virus (HSV), many of whom will be asymptomatic. Only about 20% of people with serological evidence of genital herpes give a clinical history of herpes, suggesting that many individuals have subclinical infection.

Genital herpes can be due to HSV type 1 or type 2. It is possible to be co-infected with both HSV-1 and HSV-2. HSV-1 infection may be spread from an infected genital tract or from orolabial lesions via orogenital sex. HSV-2 is almost always transmitted via genital-to-genital contact. In the UK, more than 50% of primary HSV is due to HSV-1.

During the primary infection, the virus ascends the peripheral sensory nerves supplying the area of inoculation and establishes latency in the dorsal root ganglia, thus allowing future reactivation and recurrences.

## Clinical features

**Initial episode** is the first occurrence of either HSV-1 or HSV-2. This is sub-divided as below, depending on whether or not the person has had prior exposure to the other HSV type.

**Primary genital infection** is the first ever exposure to either HSV type 1 or 2. It typically presents with multiple painful, shallow ulcers *(Fig. 12.8).* There is usually tender inguinal lymphadenopathy and systemic symptoms of viraemia, including fever, myalgia and headache. In women, external dysuria and vulval pain are the main symptoms. Ulcers may be present on the cervix and can have the appearance of a malignancy. Rectal infection may lead to severe proctitis with pain and bleeding (this is mainly seen in MSM). The lesions start to heal over a period of 10–21 days, even without treatment. Neurological complications can include aseptic meningitis and autonomic neuropathy leading to urinary retention. However, primary infection can be asymptomatic.
Non-primary genital infection occurs in people with previous HSV-1 or HSV-2 who then acquire the other type of genital HSV. There is some cross-protection from the prior HSV infection, resulting in a milder illness than in primary infection. Non-primary genital infections are more likely to be asymptomatic than primary infections.

Recurrent genital herpes is due to reactivation of previous HSV-1 or HSV-2 infection. HSV-2 recurs more frequently than HSV-1. The median recurrence rate in the subsequent year following a primary or non-primary infection is about one recurrence for HSV-1 and about four recurrences for HSV-2. The recurrences may be preceded by a prodrome of tingling, itching or pain in the area. On examination, there are usually a few ulcers confined to a small area and systemic symptoms are rare. Recurrences are not always noticed and asymptomatic, subclinical viral shedding can occur. However, all of these reactivated episodes are potentially infectious. Long-term studies show that symptomatic recurrences and subclinical viral shedding gradually decrease with time.

The clinical presentation of primary infection in immunosuppressed patients (including those with HIV and pregnant women) is usually more severe, with increased frequency of symptomatic and subclinical recurrences. Rarely, the infection can disseminate, causing a systemic life-threatening condition.

Genital herpes increases the acquisition and transmission of HIV and is an attributable risk in the spread of HIV. Many people with recurrent HSV develop psychological and psychosexual problems and fear rejection on disclosure of their infection to sexual partners.

Diagnosis

HSV DNA detection using polymerase chain reaction (PCR) on a swab taken from the ulcer is the diagnostic method of choice. This can distinguish between HSV-1 and HSV-2. Tests for other STIs should be performed, including NAAT for *N. gonorrhoeae* and NAAT for *C. trachomatis*, NAAT (if available) or culture for TV, and serology for syphilis and HIV.

Blood tests for HSV type-specific antibodies can be used to diagnose prior HSV-1 and HSV-2 infections when the clinical history is suggestive of genital herpes but confirmation by
HSV DNA detection has not been possible. The presence of HSV-2 antibodies is indicative of genital herpes but the presence of HSV-1 antibodies cannot differentiate between genital and orolabial infections.

**Management**

**Initial episode**
Saltwater bathing or sitting in a warm bath is soothing and may allow women to pass urine more comfortably. Topical anaesthetic agents can also be used to ease micturition. Recommended antiviral therapies are aciclovir 400 mg ×3 daily, valaciclovir 500 mg ×2 daily or famciclovir 250 mg ×3 daily, all for 5 days. Aciclovir is the drug of choice in pregnancy and breast-feeding. If lesions are already healing, antiviral therapy will have little added effect. Secondary bacterial infection occasionally occurs and should be treated.

The natural history of HSV infection should be explained, including recurrences, subclinical viral shedding, and the potential for sexual transmission with both of these infections. Patients should be advised to avoid sex during the prodrome and recurrences. Subclinical viral shedding is most common during the first 12 months following initial HSV-2 infection and in those with frequent symptomatic recurrences. Condoms and suppressive treatment reduce the risk of transmission from subclinical viral shedding but neither completely prevents it. Consequently, disclosure should be advised in all relationships.

**Recurrence**
The appropriate management will depend on the number and severity of recurrences. As recurrences tend to be less severe and self-limiting, they can sometimes be managed with saltwater bathing and topical anaesthetic agents.

**Episodic treatment**
When recurrences are infrequent but severe, episodic antiviral therapy, started early by the patient, will reduce the duration and severity but will not reduce the number of recurrences. Recommended episodic regimens are aciclovir 400 mg ×3 daily, valaciclovir 500 mg ×2 daily, or famciclovir 250 mg ×3 daily, all for 5 days. Shorter-course therapies are also effective: aciclovir 800 mg ×3 daily for 2 days, famciclovir 1 g ×2 daily for 1 day or valaciclovir 500 mg ×2 daily for 3 days can be used.

**Suppressive treatment**
In those with six or more recurrences per year, long-term suppressive therapy is effective at stopping, or reducing, the recurrences. The decision whether to start suppressive treatment depends on the number of recurrences and the inconvenience of taking daily treatment. Recommended regimens are aciclovir 400 mg ×2 daily, valaciclovir 500 mg daily or famciclovir 250 mg ×2 daily for a maximum of 12 months. Therapy should then be discontinued
in order to assess the frequency of recurrences. If they are still frequent, suppressive treatment can be restarted.

Frequent recurrences are associated with psychological and psychosexual morbidity; support and counselling are often needed.

**HSV in pregnancy**

The main risk of HSV in pregnancy is vertical transmission. Despite antiviral treatment, neonatal HSV has a high mortality rate and high morbidity in those who survive. The primary episode of genital HSV in late pregnancy poses the highest risk of transmission, and women within 6 weeks of the expected delivery date should be offered caesarean section. Women who present with an initial episode of HSV in the first or second trimester can be given suppressive aciclovir from 36 weeks' gestation. This reduces recurrences and subclinical viral shedding, and therefore the need for a caesarean section. The dose of suppressive treatment should be aciclovir 400 mg ×3 daily due to the altered pharmacokinetics of the drug in late pregnancy.

The risk of neonatal herpes with recurrent HSV is small, even if lesions are present at the time of delivery. The Royal College of Obstetricians and Gynaecologists in the UK suggests that caesarean section is not indicated in such women, but daily suppressive aciclovir from 36 weeks' gestation should be started.

**Syphilis**

Syphilis is a chronic systemic disease caused by *Treponema pallidum* (TP), a motile spirochaete. It is mainly transmitted by direct contact with an infectious lesion and enters the new host through breaches in squamous or columnar epithelium, usually during sex. Primary infection of non-genital sites may occur but is rare. It can also be transmitted by infected blood products or from mother to child during pregnancy. Hence syphilis is classified as acquired or congenital. **Acquired syphilis** is further subdivided into primary, secondary and early latent (all are also referred to as early or infectious syphilis, and indicate that infection has been acquired during the last 2 years), late latent (infection for more than 2 years) and tertiary syphilis (the most destructive stage, which includes cardiovascular and neurological syphilis and gummatous lesions of any organ). **Congenital syphilis** is also further subdivided into early (diagnosed within the first 2 years of life) and late (diagnosed over the age of 2).

The incidence varies significantly with geographic location. It is more common in low- and middle-income countries; in high-income countries, it is mainly confined to MSM. For instance, diagnoses of infectious syphilis in England between 2004 and 2013 increased by 36% in men with 74% of the infections being in MSM, whereas they decreased by 37% in women. However, syphilis still affects large numbers of pregnant women worldwide. It was estimated that, in 2008, 1.4 million pregnant women were infected worldwide, causing approximately 520,000 adverse pregnancy outcomes, including 215,000 stillbirths, 90,000 neonatal deaths, 65,000 preterm or low-birth-weight babies, and 150,000 babies with congenital infections. Antenatal screening for syphilis, followed by adequate treatment during
pregnancy, can prevent many of these adverse outcomes.

Clinical features

Primary syphilis
Between 10 and 90 days (mean 21 days) after exposure, a papule develops at the site of inoculation. This ulcerates to become a painless, firm ulcer (chancre). There is usually also a painless regional lymphadenopathy. The primary lesion may go unnoticed, especially if it is on the cervix or within the rectum. Healing occurs spontaneously within 2–6 weeks.

Secondary syphilis
Between 6 and 10 weeks after the appearance of the primary lesion, constitutional symptoms with fever, sore throat, malaise and arthralgia may appear due to septicaemia. Hence, any organ may be affected and hepatitis, nephritis, arthritis and meningitis have all been described.

Common signs include:
• widespread skin rash (present in 75%), which can involve the whole body, including the palms and soles – typically, a non-itchy, maculopapular rash that may have a coppery colour (Fig. 12.9)

![Rash of secondary syphilis on the palms. (Courtesy of Dr B. Goh.)](image)

• generalized lymphadenopathy (present in 50%)
• condylomata lata, which are moist, wart-like plaques found in the perianal area and other moist body sites
• mucosal lesions in the mouth and on the genitalia presenting as distinct mucous patches or becoming confluent to form ‘snail-track ulcers’.

Without treatment, the symptoms and signs of secondary syphilis resolve but may recur, especially in the first year of infection.
Latent syphilis
Latent syphilis is diagnosed on the basis of reactive syphilis serology in someone who has no symptoms and has not been treated. It is divided into early latent (defined as within 2 years of acquiring the infection, or within 1 year in USA) and late latent syphilis (present for 2 or more years), as sexual transmission can occur in early latency but not in late latent disease. Latent syphilis may persist for years or may even be life-long.

Tertiary syphilis
About one-third of people with untreated latent syphilis will develop tertiary syphilis within 2 to 30 or more years of contracting the infection. Gummatous syphilis (with inflammatory, granulomatous, destructive lesions) is the most benign and commonly involves the skin and bones, but lesions can occur in any organ. Cardiovascular syphilis causes aortitis, aortic regurgitation, aneurysm of the ascending aorta and stenosis of the coronary artery ostia. Neurosyphilis causes chronic meningovascular damage and endarteritis of the small vessels of the brain and spinal cord, presenting as ‘general paralysis of the insane’ and tabes dorsalis.

Syphilis in pregnancy and congenital syphilis
Syphilis can be transmitted transplacentally at any stage of pregnancy. The risk of transmission is dependent on the stage of maternal infection and can be up to 100% in early syphilis, and even up to 10% with late infection. The WHO estimates that untreated early syphilis in pregnancy results in rates of second-trimester miscarriage or stillbirth of 25%, preterm birth before 32 weeks' gestation of 13%, neonatal death of 11% and congenital syphilis amongst the infants born of 20%. Detection and treatment of syphilis early in pregnancy prevent congenital syphilis and neonatal death at term, and reduce adverse pregnancy outcomes.

Signs of early congenital syphilis occur in the neonatal period and include a rash, condylomata lata, mucous patches, nasal discharge, hepatosplenomegaly and periostitis. Late syphilis (occurring after 2 years of age) can present with neurological or gummatous lesions but also includes the ‘stigmata of congenital syphilis’, resulting from early damage to developing structures, particularly teeth and bones. These are Hutchinson's teeth, sabre tibia, bossing of the frontal and parietal bones, and saddle nose.

Diagnosis
*T. pallidum* cannot be cultured but it can be identified by dark-ground microscopy of secretions from a primary chancre or condylomata lata; however, sensitivity is dependent on highly skilled microscopists. Some laboratories are able to test swabs for TP using PCR but serological testing remains the main laboratory diagnosis.

Most laboratories use a treponemal enzyme immunoassay (EIA) to detect IgG and IgM as a screening test. If this is positive, a further treponemal test and a non-treponemal test are performed.
**Treponemal tests**

*T. pallidum* haemagglutination (TPHA) and *T. pallidum* particle agglutination (TPPA) assays are highly specific for treponemal disease but usually remain positive for life, even after treatment, so are unable to differentiate between prior treated infection and re-infection.

**Non-treponemal tests**

The Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR) tests become positive within 3–4 weeks of the primary infection. They are quantifiable tests that can be used to monitor treatment response and evidence of re-infection. These tests are not specific to syphilis and false-positive results may occur in other conditions, particularly in other infections and autoimmune diseases.

Examination of the cerebrospinal fluid (CSF) for evidence of neurosyphilis is indicated in those patients with positive syphilis serology who demonstrate neurological signs and symptoms.

**Management**

Treponemocidal levels of an antibiotic are required for at least 7 days in early syphilis to cover the slow division time of the organism (30 h). In late syphilis, treponemes may divide even more slowly, so longer therapy is required. Ideally, a long-acting penicillin should be given intramuscularly.

**Early syphilis (primary, secondary and early latent)**

- Benzathine penicillin G 2.4 MU i.m. single dose.
  - **In penicillin allergy:**
    - Doxycycline 100 mg ×2 daily for 14 days.

  The **Jarisch–Herrxheimer reaction** is caused by release of inflammatory cytokines and occurs in 50% of patients with primary syphilis and up to 90% with secondary syphilis. It occurs about 8 hours after the injection and usually consists of mild fever, malaise and headache lasting several hours.

**Late latent, cardiovascular and gummatous syphilis**

- Benzathine penicillin G 2.4 MU i.m. three doses at weekly intervals.
  - **In penicillin allergy:**
    - Doxycycline 100 mg ×2 daily for 28 days.

**Neurosyphilis**

- Procaine penicillin 2.4 MU i.m. daily plus probenecid 500 mg orally ×4 daily for 14–17 days.
  - **In penicillin allergy:**
    - Doxycycline 200 mg ×2 daily for 28 days.
Pregnancy

- Penicillin can be safely used in pregnancy but doxycycline should not be used.

Syphilis and HIV

The diagnosis and management of syphilis in HIV-co-infected patients remains unaltered; however, if untreated, it may advance more rapidly than in HIV-negative patients and has a higher incidence of neurosyphilis.

Prognosis and follow-up

Those being treated for early syphilis should abstain from sex for at least 14 days and sexual contacts must be traced and investigated. There should be regular follow-up within the first year using repeat VDRL/RPR titres to establish the ‘fourfold fall’, which demonstrates adequately treated syphilis.

The prognosis of syphilis depends on the stage at which the infection is treated. Early syphilis has an excellent outlook, but once permanent damage has occurred in tertiary syphilis, the damage will not be reversed, although further progression will be halted.

Lymphogranuloma venereum

Lymphogranuloma venereum (LGV) is an STI caused by the invasive serovars, L1, L2 and L3, of Chlamydia trachomatis. It is endemic in several tropical areas, including southern Africa, India, South-east Asia and the Caribbean. It used to be rare in Western Europe but since 2003 it has become hyper-endemic among MSM, particularly those with HIV. It is frequently associated with other STIs and acute hepatitis C infection. The main presentation in MSM is with rectal symptoms. LGV should be considered in MSM with suspected inflammatory bowel disease, as the clinical presentation can be very similar and the histological findings of LGV proctitis are similar to other causes of granulomatous proctitis, such as Crohn's disease.

Clinical features

There are three clinical stages. The primary lesion may be transient and is frequently unnoticed. In the genital area, it takes the form of a painless papule or shallow ulcer appearing at the area of inoculation, 3–30 days after exposure. The main presentation in MSM is proctitis with symptoms of rectal pain, mucopurulent discharge, rectal bleeding, constipation and tenesmus. Some also report systemic symptoms, such as fever and malaise.

The secondary lesions are enlarged, tender regional lymph nodes. With genital LGV, they are usually unilateral and affect the inguinal and femoral nodes. When both are involved, the ‘groove sign’ develops due to the inguinal ligament separating the two enlarged lymph node systems. The nodes may become matted with bubo formation, which may rupture.

The tertiary stage is a chronic inflammatory response with tissue destruction. In the rectum, it can cause fistulae, strictures and granulomatous fibrosis, mimicking Crohn's disease. There
may also be scarring of the genital area, and destruction of local lymph nodes can lead to genital lymphoedema.

## Diagnosis

### Genital LGV

A swab should be taken from the ulcer base for *C. trachomatis* NAAT. If this is positive for *C. trachomatis*, genotyping for LGV should be requested. Testing for the other causes of genital ulcers should be undertaken (see Box 12.5) and should include an ulcer swab for HSV and TP PCR, and serology for syphilis, which should be repeated after the 3-month window period. A NAAT for *N. gonorrhoeae*, NAAT for *C. trachomatis* and serology for HIV should also be carried out.

### Rectal LGV

A swab should be taken from the rectal mucosa for *C. trachomatis* NAAT. If this is positive for *C. trachomatis*, genotyping for LGV should be requested. Swabs should also be taken for *N. gonorrhoeae* NAAT, and HSV and TP PCR. Serology for syphilis and HIV should be performed, and serology for hepatitis C should be considered in view of the frequent co-infection of acute hepatitis C with LGV.

## Management

First-choice treatment is doxycycline 100 mg ×2 daily for 21 days or erythromycin 500 mg ×4 daily for 21 days. Symptoms should start to resolve within 1–2 weeks of commencing therapy. Patients should be advised to abstain from sex until completion of treatment. Sexual contacts should be notified, examined, tested and treated. Follow-up should continue until all symptoms and signs have resolved, which is usually by 3–6 weeks.

## Chancroid

Chancroid is caused by *Haemophilus ducreyi*. It used to be one of the most common causes of genital ulcers worldwide but its incidence has now decreased markedly. One of the drivers for its improved control and reduced incidence is its association with the acquisition of HIV infection. It is extremely rare in high-income countries.

### Clinical features

Chancroid has a short incubation period of 4–7 days. A tender papule develops at the site of inoculation, which breaks into a painful, ragged-edged ulcer with a necrotic base that bleeds easily. The usual sites of infection are the prepuce and glans penis in men and the labia minora and fourchette in women. There is often painful inguinal lymphadenopathy, which can develop
into large buboes that suppurate.

## Diagnosis and management

Detection of *H. ducreyi* DNA using PCR is the most sensitive diagnostic test but there are no commercial assays available for this. A ‘probable diagnosis’ may be made if the patient presents the appropriate clinical picture, without evidence of syphilis or HSV.

Testing for the other causes of genital ulcers should be undertaken (see **Box 12.5**) and should include an ulcer swab for HSV and TP PCR, an ulcer swab for *C. trachomatis* NAAT with genotyping for LGV if positive, and serology for syphilis, which should be repeated after the 3-month window period. A NAAT for *N. gonorrhoeae*, NAAT for *C. trachomatis* and serology for HIV should also be performed.

Single-dose regimens include azithromycin 1 g orally or ceftriaxone 250 mg i.m. Multiple-dose regimens are ciprofloxacin 500 mg ×2 daily for 3 days or erythromycin 500 mg ×4 daily for 7 days. Multiple-dose regimens should be used in HIV patients as treatment failures have been reported with single-dose therapy. Patients should be advised to abstain from sex for at least 7 days and be followed up at 3–7 days, when the ulcers should be healing. HIV-infected patients should be monitored closely, as healing may be slower. Sexual partners should be notified, examined and treated epidemiologically, as asymptomatic carriage has been reported.

## Donovonosis

Donovonosis (also known as granuloma inguinale) is exceedingly rare and is confined to a few countries in South-east Asia, South America and the Caribbean. It is caused by *Klebsiella granulomatis*.

## Clinical features

Nodules at the site of inoculation develop into friable, non-painful ulcers or hypertrophic lesions that increase in size. There is enlargement of the inguinal lymph nodes, which may ulcerate.

## Diagnosis and management

The diagnosis is made on the presence of Donovan bodies in scrapings or biopsies of the lesions. Donovan bodies are the encapsulated intracellular Gram-negative rods of *Klebsiella granulomatis* that are visible within histiocytes in the tissue samples. They appear deep purple when stained with Giemsa, Wright's or Leishman stains. Screening for all other STIs should be undertaken.

Antibiotic treatment should be given for a minimum of 3 weeks and until the lesions have healed. Regimens include azithromycin 1 g weekly or 500 mg daily, or ciprofloxacin 750 mg ×2 daily. Patients should be advised to abstain from sex for at least 3 weeks and be followed.
up until the lesions have fully resolved. Sexual partners should be notified, examined and treated if necessary.

### Pediculosis pubis

The pubic louse (*Phthirus pubis*) is able to attach tightly to the pubic and coarse body hair. It can also attach to eyelashes and eyebrows. It is host-specific and is transferred by close bodily contact. Although infestation may be asymptomatic, the most common complaint is of itch due to hypersensitivity to the louse bites.

### Diagnosis and management

Lice may be seen on the pubic and body hairs. They resemble small scabs or freckles but can be seen moving. The eggs (nits) are laid at the hair base and are strongly adherent to the hairs. Screening for other STIs should include NAAT for *N. gonorrhoeae*, NAAT for *C. trachomatis* and serology for syphilis and HIV.

Treatment should be applied to all areas of the body, including facial hair if present. Malathion 0.5% should be left on for at least 2 hours, and permethrin 1% left on for 10 minutes. A second application is usually advised after 3–7 days. Permethrin is safe in pregnancy. Sexual partners should be examined and treated if infected.

### Scabies

This is discussed on page 1347.

Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

Epidemiology and Pathogenesis

Epidemiology

Since the first description of AIDS in 1981 and the identification of the causative organism, HIV, in 1983, more than 78 million people are estimated to have been infected and 39 million people have died. At least 35 million people worldwide are living with HIV infection. Highly active anti-retroviral therapy (ART) has dramatically reduced mortality for those who are able to access care, transforming HIV from a universally fatal infection into a long-term manageable condition, with a consequent rise in global prevalence. Effective therapy since 2001 has also reduced infectiousness, and new infections globally have fallen by 38%, although there is considerable geographical diversity. Sub-Saharan Africa remains the most seriously affected, and in Eastern Europe and parts of central Asia, infection rates continue to rise. The human, societal and economic costs are huge. HIV is a major contributor to the global burden of disease, being the leading cause of disability-adjusted life-years for people aged 30–45 years. Demographics of the epidemic have varied greatly, influenced by social, behavioural, cultural and political factors. Current global estimates suggest that 38% of people living with HIV are on ART, but that, for each individual starting therapy, there are two new infections, highlighting the size of the problem and the global inequalities that exist in healthcare.

In the UK, falling death rates and sustained new infections mean that the total number of people living with HIV continues to rise. In 2013, 107 000 people were estimated to be living with HIV and 6000 were newly diagnosed. Individuals accessing care almost doubled in number from a decade earlier, and MSM and culturally diverse heterosexual populations from sub-Saharan Africa are the two largest groups of people living with HIV. Of those diagnosed with HIV in the UK, 30% are women. As mortality rates fall, the population living with HIV is becoming older, with 1 in 4 now aged 50 years and over.

Approximately one-quarter of those with HIV infection in the UK are undiagnosed and unaware of their infection, which contributes to late diagnosis, poorer clinical outcomes and onward transmission. Late diagnosis is now the most common cause of HIV-related morbidity and mortality in the UK. The proportion and number of people diagnosed late (with a CD4 count of <350 cells/mm$^3$ within 3 months of their diagnosis) declined from 57% in 2004 to 42% in 2013. Reducing late and undiagnosed HIV through wider testing, particularly in
patients presenting with clinical conditions that are associated with HIV and those in areas with high seroprevalence, is critical to both the individual and public health (Box 12.8).

### Box 12.8

**HIV testing**

**UK guidelines on where and who to test**

**Universal: clinical settings in which all patients should be offered HIV testing:**

- Genitourinary medicine/sexual health clinics
- Antenatal services
- Termination of pregnancy services
- Drug dependency programmes
- Healthcare services for tuberculosis, hepatitis B, hepatitis C and lymphoma
- High-prevalence areas where diagnosed HIV infection is ≥2 per 1000 resident population
- People in prison

**People in whom HIV testing is recommended**

- All patients diagnosed with a sexually transmitted infection
- Sexual partners of men and women known to be HIV-positive
- Men who have disclosed sexual contact with other men
- Female sexual contacts of men who have sex with men
- People reporting a history of injecting drug use
- Men and women known to be from a country of high HIV prevalence (>1%)
- Men and women who report sexual contact abroad or in the UK with individuals from countries of high HIV prevalence
- Patients presenting for healthcare where HIV enters the differential diagnosis (see Box 12.9)

**HIV-associated indicator conditions**

**Respiratory**

- Tuberculosis, pneumocystis\(^a\), bacterial pneumonia, aspergillosis

**Neurology**

- Cerebral toxoplasmosis\(^a\), primary cerebral lymphoma\(^a\), cryptococcal meningitis\(^a\), progressive multifocal leucoencephalopathy\(^a\), aseptic meningitis/encephalitis, cerebral abscess, space-occupying lesion of unknown cause, Guillain–Barré syndrome, transverse
myelitis, peripheral neuropathy, dementia

**Dermatology**
- Kaposi's sarcoma\(^a\), severe/recalcitrant seborrhoeic dermatitis, severe/recalcitrant psoriasis, multidermatomal/recurrent herpes zoster

**Gastroenterology**
- Persistent cryptosporidiosis\(^a\), oral candidiasis, oral hairy leukoplakia, chronic diarrhoea of unknown cause, weight loss of unknown cause, *Salmonella, Shigella, Campylobacter*, hepatitis B infection, hepatitis C infection

**Oncology**
- Non-Hodgkin's lymphoma\(^a\), anal cancer, anal intraepithelial dysplasia, lung cancer, seminoma, head and neck cancer, Hodgkin's lymphoma, Castleman's disease

**Gynaecology**
- Cervical cancer\(^a\), vaginal intraepithelial neoplasia, cervical intraepithelial neoplasia, grade 2 or above

**Haematology**
- Any unexplained blood dyscrasia, including thrombocytopenia, neutropenia and lymphopenia

**Ophthalmology**
- Cytomegalovirus retinitis, infective retinal diseases including herpesviruses and toxoplasma, any unexplained retinopathy

**ENT**
- Lymphadenopathy of unknown cause, chronic parotitis, lymphoepithelial parotid cysts

**Other**
- Mononucleosis-like syndrome (primary HIV infection), pyrexia of unknown origin, any lymphadenopathy of unknown cause, any sexually transmitted infection

\(^a\)AIDS-defining condition.

**Routes of acquisition**

Despite the fact that HIV can be isolated from a wide range of body fluids and tissues, the majority of infections are transmitted via semen, cervical secretions and blood. The most significant marker for transmission risk is the HIV viral load, which is highest in acute infection, and reduced by effective ART. HIV-associated stigma and discrimination, gender-based violence and, in some countries of the world, the legal position for those at especially
high risk can all impede access to appropriate services and increase the risks of transmission and acquisition of HIV.

**Sexual intercourse (vaginal and anal)**

Globally, heterosexual intercourse accounts for the vast majority of infections, and coexistent STIs, especially those causing genital ulceration, enhance transmission. Passage of HIV appears to be more efficient from men to women, and to the receptive partner in anal intercourse, than vice versa. In the UK, sex between men accounts for over half of the new diagnoses reported, but there is a consistent rate of heterosexual transmission. In Central and sub-Saharan Africa, the epidemic has always been heterosexual and more than half of infected adults in these regions are women. South-east Asia and the Indian subcontinent are experiencing an explosive epidemic, driven by heterosexual intercourse and a high incidence of other STIs.

**Mother-to-child transmission (transplacental, perinatal, breast-feeding)**

Vertical transmission is the most common route of HIV infection in children. European studies suggest that, without intervention, 15% of babies born to HIV-positive mothers are likely to be infected, although rates of up to 40% have been reported from Africa and the USA. Increased vertical transmission is associated with advanced disease in the mother, maternal viral load, prolonged and premature rupture of membranes, and chorioamnionitis. Transmission can occur in utero, although the majority of infections take place perinatally. Breast-feeding has been shown to double the risk of vertical transmission. In the developed world, interventions to reduce vertical transmission, including screening for infection in pregnancy, the use of anti-retroviral agents (ARVs) and the avoidance of breast-feeding, have led to a dramatic fall in the numbers of infected children. In the UK, the risk of vertically transmitted infection is 1 : 1000. The lack of access to these interventions in resource-poor countries in which 90% of infections occur is a major global issue.

**Contaminated blood, blood products and organ donations**

Screening of blood and blood products was introduced in 1985 in Europe and North America. Prior to this, HIV infection was associated with the use of clotting factors (for haemophilia) and with blood transfusions. In some parts of the world where blood products may not be screened and in areas where the rate of new HIV infections is very high, transfusion-associated transmission continues to occur.

**Contaminated needles (intravenous drug misuse, injections and needle-stick injuries)**

The practice of sharing needles and syringes for intravenous drug use continues to be a major route of transmission of HIV in parts of South-east Asia, Latin America and Eastern Europe. In some areas, including the UK, successful education and needle exchange schemes have reduced the rate of transmission by this route. Iatrogenic transmission from needles and
syringes used in developing countries is reported. Healthcare workers have a risk of approximately 0.3% following a single needle-stick injury with known HIV-positive blood. There is no evidence that HIV is spread by social or household contact or by blood-sucking insects such as mosquitoes and bed bugs.

Pathology

The virus

HIV belongs to the lentivirus group of the retrovirus family. There are two types, HIV-1 and HIV-2. HIV-1 is the most frequently occurring strain globally. HIV-2 is almost entirely confined to West Africa, although there is some spread to Europe, particularly France and Portugal. HIV-2 has only 40% structural homology with HIV-1 and, although it is associated with immunosuppression and AIDS, it appears to take a more indolent course than HIV-1. Many of the drugs that are used in HIV-1 are ineffective in HIV-2. The structure of HIV is shown in Figure 12.10.

Retroviruses are characterized by possession of the enzyme reverse transcriptase, which allows viral RNA to be transcribed into DNA and thence incorporated into the host cell genome. Reverse transcription is an error-prone process with a significant rate of mis-incorporation of bases. This, combined with a high rate of viral turnover, leads to considerable...
genetic variation and a diversity of viral subtypes or clades. On the basis of DNA sequencing, HIV-1 is divided into four distinct strains, which represent four independent cross-species transfers: three (M, N and O) based on the chimpanzee-related strains of simian immunodeficiency virus (SIV) and one (P) that may represent chimpanzee to gorilla to human transmission.

- **Group M (major) subtypes** (98% of infections worldwide) exhibit a high degree of diversity, with subtypes (or clades), denoted A–K. There is a predominance of subtype B in Europe, North America and Australia, but areas of Central and sub-Saharan Africa have multiple M subtypes, clade C being the most common. Recombination of viral material generates an array of circulating recombinant forms (CRFs), which increase the genetic diversity and are becoming more common.

- **Group N (new)** is mostly confined to parts of west Central Africa (e.g. Gabon).

- **Group O (outlier) subtypes** are highly divergent from group M and are largely confined to small numbers centred on Cameroon.

- **Group P**, related to gorilla strains of SIV, has been identified from a patient from Cameroon.

### Pathogenesis

The interrelationship between HIV and the host immune system is the basis of the pathogenesis of HIV disease. At the time of initial exposure, the virus is transported by dendritic cells from mucosal surfaces to regional lymph nodes, where permanent infection is established, usually by one ‘founder virus’. The host cellular receptor that is recognized by HIV surface glycoprotein gp120 is the CD4 molecule, which defines the cell populations that are susceptible to infection (*Fig. 12.11*). The interaction between CD4 and HIV gp120 surface glycoprotein, together with host chemokine CCR5 or CXCR4 co-receptors, is responsible for HIV entry into cells. Although CCR5 CD4 memory T lymphocytes within all body systems are susceptible to infection and depletion, those found in the gastrointestinal tract are heavily infected early in the process. These lymphocytes become rapidly depleted, leading to compromised mucosal immune function, and thus allowing microbial lipopolysaccharides to enter the circulation. HIV infection that is independent of CD4 receptors can occur in astrocytes and renal epithelial cells, leading to end-organ damage.
Studies of viral turnover have demonstrated a virus half-life in the circulation of about 6 hours. To maintain observed levels of plasma viraemia, $10^8$–$10^9$ virus particles need to be released and cleared daily. Virus production by infected cells lasts for about 2 days and is probably limited by the death of the cell, owing to direct HIV effects. This links HIV replication to the process of CD4 destruction and depletion. Progressive loss of activated CD4 T lymphocytes due to killing by CD8 cells is a key factor in the immunopathogenesis of HIV. Natural killer cells are involved in the host immune response, although escape mutations within the virus population compromise their antiviral effects. The production of neutralizing antibodies, which, in some people, can be against several viral subtypes, occurs at about 12 weeks after infection.

Resulting cell-mediated immunodeficiency leaves the host open to infections with intracellular pathogens, while coexisting antibody abnormalities predispose to infections with capsulated bacteria. HIV is associated with immune activation, a long-term inflammatory state,
which is a key driver of disease progression. T-cell activation is observed from the earliest stages of infection, which, in turn, leads to an increase in the numbers of susceptible CD4-bearing target cells that can become infected and destroyed. This inflammatory state is associated with HIV itself, with co-pathogens such as cytomegalovirus, and with the translocation of microbial products, in particular lipopolysaccharides, from the gut into the systemic circulation following HIV destruction of normal mucosal immunity. Raised levels of inflammatory cytokines and coagulation system activation occur. These inflammatory responses may remain, despite effective ART, and play a role in HIV-associated end-organ damage, as well as raising the risks of myocardial infarction and some malignancies.

**Further reading**

Clinical Approach to the Patient with HIV

Diagnosis and natural history

HIV is now a manageable chronic condition with a life expectancy that can match that of the general population, in those who start effective ART early enough. Starting treatment when disease is more advanced compromises clinical outcomes. In 2013, 24% of those living with HIV in the UK were unaware of their infection; 42% of people newly diagnosed in the UK in 2013 were ‘late presenters’ – that is, they had a CD4 count below the threshold to start therapy (<350 cells/mm³); and in 33%, the CD4 count was <200 cells/mm³, putting them at high risk of HIV-associated pathology (Fig. 12.12). Increasing the uptake of HIV testing is a major public health objective. Guidelines on HIV testing from the British HIV Association (BHIVA) and the National Institute for Health and Care Excellence (NICE) include clinical settings in which HIV testing should be universally offered, together with a list of clinical situations and diagnoses (indicator conditions) that are highly predictive of HIV infection and in which HIV testing should be recommended (Box 12.8). Testing should be recommended for all new registrants in primary care and patients admitted to acute medical care in areas of the UK where HIV seroprevalence is >2/1000 population.

Discussion about HIV testing and the consent required is straightforward and within the competencies of a wide range of healthcare professionals. Sensitive and specific point-of-care HIV antibody tests using either blood or oral fluids can give results within minutes and have extended the possibilities for diagnosis. Home sampling approaches, with specimens sent to a central laboratory and results given over the telephone, have been shown to increase testing
rates in some populations. Changes in legislation in the UK now allow for the sale of home testing kits for HIV, although ‘kite-marked’ kits are not yet available. It is crucial for all reactive point-of-care tests to be followed up with confirmatory serological assays and for appropriate arrangements to be made to ensure that patients receive their test results and those who are found to be HIV-positive have rapid routes into specialist care.

**Investigation of HIV**

HIV infection is diagnosed either by detection of virus-specific antibodies (anti-HIV) or by direct identification of viral material. The recommended UK first-line assay is one that tests for HIV antibody and p24 antigen simultaneously. These fourth-generation assays have the advantage of reducing the time between infection and an HIV-positive test result to 1 month, which is several weeks earlier than with sensitive third-generation (antibody-only detection) assays.

**Detection of IgG antibody to envelope components**

This is the most commonly used marker of infection. The routine tests used for screening are based on enzyme-linked immunosorbent assay (ELISA) techniques, which may be confirmed with Western blot assays. Up to 3 months (mean 6 weeks) may elapse from initial infection to antibody detection (serological latency, or window period). These antibodies to HIV have no protective function and persist for life. As with all IgG antibodies, anti-HIV will cross the placenta. All babies born to HIV-positive women will thus have the antibody at birth. In this situation, anti-HIV antibody is not a reliable marker of active infection, and in uninfected babies will be gradually lost over the first 18 months of life.

Simple and rapid HIV antibody assays are increasingly available, giving results within minutes. Assays that can utilize alternative body fluids to serum/plasma, such as oral fluid, whole blood and urine, are now available and home testing kits are being developed. These tests are extremely sensitive and may give false-positive results, making it necessary to perform a confirmatory test.

A serologic testing algorithm for recent HIV seroconversions (STARHS) can be used to identify recently acquired infection. A highly sensitive ELISA that is able to detect HIV antibodies 6–8 weeks after infection is used on blood in patients with a positive oral fluid test, in parallel with a less sensitive (detuned) test that identifies later HIV antibodies within 130 days. A positive result on the sensitive test and a negative ‘detuned’ test are indicative of recent infection, while positive results on both tests point to an infection that is more than 130 days old. The major application of this is in epidemiological surveillance and monitoring.

**Detection of IgG antibody to p24 (anti-p24)**

This can be detected from the earliest weeks of infection and through the asymptomatic phase. It is frequently lost as the disease progresses.

**Genome detection assays**
Nucleic acid-based assays that amplify and test for components of the HIV genome are available. These assays are used to aid the diagnosis of HIV in the babies of HIV-positive mothers or in situations where serological tests may be inadequate, such as in early infection when antibody may not be present, or in subtyping HIV variants for medico-legal reasons. (See the discussion of viral load monitoring on p. 339.)

**Detection of viral p24 antigen (p24ag)**
This is detectable shortly after infection but has usually disappeared by 8–10 weeks after exposure. It can be a useful marker in individuals who have been infected recently but have not had time to mount an antibody response.

**Isolation of virus in culture**
This is a specialized technique available in some laboratories as a diagnostic aid and a research tool.

**Clinical features of untreated HIV**
The spectrum of illnesses associated with HIV infection is broad and is the result of direct HIV effects, HIV-associated immune dysfunction, and the drugs used to treat the condition, as well as coexisting morbidity and co-infections. Since the introduction of effective therapy, the majority of people with HIV in resource-rich settings begin treatment whilst asymptomatic, before the onset of significant immunosuppression or progression to an AIDS-defining event.

Several classification systems exist, the most widely used being the 1993 Centers for Disease Control (CDC) classification (*Box 12.9*). This classification depends, to a large extent, on definitive diagnoses of infection, which makes it more difficult to apply in those areas of the world without sophisticated laboratory support.

---

**Box 12.9**

*Summary of the Centers for Disease Control (CDC) classification of HIV infection*
**Absolute CD4 count (mm$^3$)** | **A** | **B** | **C**
---|---|---|---
>500 | A1 | B1 | C1
200–499 | A2 | B2 | C2
<200 | A3 | B3 | C3

*Examples of category B conditions include: bacillary angiomatosis, candidiasis (oropharyngeal), constitutional symptoms, oral hairy leukoplakia, herpes zoster involving more than one dermatome, idiopathic thrombocytopenic purpura, listeriosis, pelvic inflammatory disease, especially if complicated by tubo-ovarian abscess, peripheral neuropathy.

As immunosuppression progresses, the patient is susceptible to an increasing range of opportunistic infections and tumours, certain of which meet the criteria for the diagnosis of AIDS (**Box 12.10**).

---

**Box 12.10**

**AIDS-defining conditions**

- Candidiasis of bronchi, trachea or lungs
- Candidiasis, oesophageal
- Cervical carcinoma, invasive
- Coccidioidomycosis, disseminated or extrapulmonary
- Cryptococcosis, extrapulmonary
- Cryptosporidiosis, chronic intestinal (1-month duration)
- Cytomegalovirus (CMV) disease (other than liver, spleen or nodes)
- CMV retinitis (with loss of vision)
- Encephalopathy, HIV-related
- Herpes simplex, chronic ulcers (1-month duration), or bronchitis, pneumonitis or oesophagitis
- Histoplasmosis, disseminated or extrapulmonary
- Isosporiasis, chronic intestinal (1-month duration)
- Kaposi's sarcoma
- Lymphoma, Burkitt's
- Lymphoma, immunoblastic (or equivalent term)
- Lymphoma (primary) of brain
- *Mycobacterium avium-intracellulare* complex or *M. kansasii*, disseminated or extrapulmonary
- *Mycobacterium tuberculosis*, any site
The definition of AIDS differs between the USA and Europe. The US definition includes individuals with CD4 counts of <200 cells/mm³, in addition to the clinical classification based on the presence of specific indicator diagnoses shown in Box 12.9. In Europe, the definition remains based on the diagnosis of specific clinical conditions with no inclusion of CD4 lymphocyte counts. Where ART is available and started before the development of severe immunosuppression, progression to AIDS is now uncommon.

**Incubation, seroconversion and primary illness**

Primary HIV infection (PHI) refers to the first 6-month period following HIV acquisition. This is a period of uncontrolled viral replication resulting in high levels of HIV circulating in the plasma and genital tract, and consequently of high infectiousness. At a population level, PHI is increasingly recognized as a contributor to onward transmission. In the UK, up to 20% of all newly diagnosed individuals are recently infected. The 2–4 weeks immediately following infection may be silent, both clinically and serologically. In a number of people, a self-limiting acute viral illness, which may be confused with glandular fever, occurs 3–6 weeks after exposure. This is a key point for making the diagnosis; however, HIV is frequently not considered in the differential. Symptoms include fever, arthralgia, myalgia, lethargy, lymphadenopathy, sore throat, mucosal ulcers and, occasionally, a transient, faint pink, maculopapular rash. Neurological symptoms are common, including headache, photophobia, myelopathy, neuropathy and, in rare cases, encephalopathy. The illness lasts up to 3 weeks and recovery is usually complete.

**Laboratory abnormalities** include lymphopenia with atypical reactive lymphocytes noted on the blood film, thrombocytopenia and raised liver transferases. CD4 lymphocytes may be markedly depleted and the CD4:CD8 ratio reversed. Antibodies to HIV may be absent during this early stage of infection, although the level of circulating viral RNA is high and p24 core protein may be detectable. NAAT assays of HIV RNA may be diagnostic 7 days before a p24 antigen test and 12 days before a sensitive HIV antibody test. If PHI is suspected but standard diagnostic tests are negative, then repeat testing in 7 days and referral for expert advice is recommended.

**Clinical latency**

The rate of clinical progression of untreated HIV is variable. The majority of people with HIV
infection are asymptomatic for a substantial but variable length of time. However, the virus continues to replicate and the person is infectious. Most people with HIV have a gradual decline in CD4 count over a period of approximately 10 years before progression to symptomatic disease or AIDS. Others progress much more rapidly, with continued high levels of viral RNA and a rapid decline in CD4 count over 2–5 years. Other long-term non-progressors may continue with a normal CD4 count over many years. Within this group, a small sub-population of elite controllers maintain a viral load <2000 copies/mL or even undetectable levels without therapy.

Older age is associated with more rapid progression. Gender and pregnancy per se do not appear to influence the rate of progression, although women may fare less well for a variety of reasons. A subgroup of patients with asymptomatic infection have persistent generalized lymphadenopathy (PGL), defined as lymphadenopathy (>1 cm) at two or more extra-inguinal sites for more than 3 months in the absence of causes other than HIV infection. The nodes are usually symmetrical, firm, mobile and non-tender. There may be associated splenomegaly. The architecture of the nodes shows hyperplasia of the follicles and proliferation of the capillary endothelium. Biopsy is rarely indicated. Similar disease progression has been noted in asymptomatic patients with or without PGL. Nodes may disappear with disease progression.

**Symptomatic HIV infection**

As HIV infection progresses, the viral load rises, the CD4 count falls and the patient develops an array of symptoms and signs. The clinical picture is the result of direct HIV effects and of the associated immunosuppression.

In an individual patient, the clinical consequences of HIV-related immune dysfunction will depend on at least three factors:

- **The microbial exposure of the patient throughout life.** Many clinical episodes represent reactivation of previously acquired infection, which has been latent. Geographical factors determine the microbial repertoire of an individual patient. Those organisms requiring intact cell-mediated immunity for their control are most likely to cause clinical problems.

- **The pathogenicity of organisms encountered.** High-grade pathogens, such as *Mycobacterium tuberculosis*, *Candida* and the herpesviruses, are clinically relevant, even when immunosuppression is mild, and will thus occur earlier in the course of the disease. Less virulent organisms occur at later stages of immunodeficiency.

- **The degree of immunosuppression of the host.** When patients are severely immunocompromised (CD4 count <100 cells/mm³), disseminated infections with organisms of very low virulence, such as *M. avium-intracellulare* (MAI) and *Cryptosporidium*, are able to establish themselves. These infections are very resistant to treatment, mainly because there is no functioning immune response to clear organisms. This hierarchy of infection allows for appropriate intervention with prophylactic drugs.

**End-organ effects of HIV**
Neurological disease

Infection of the nervous tissue occurs at an early stage but clinical neurological involvement increases as HIV advances. This includes **AIDS dementia complex (ADC)**, **sensory polyneuropathy** and **aseptic meningitis** (see p. 866). These conditions are much less common since the introduction of ART. The pathogenesis is thought to be due both to the release of neurotoxic products by HIV itself and to cytokine abnormalities secondary to immune dysregulation.

**ADC** has varying degrees of severity, ranging from mild memory impairment and poor concentration through to severe cognitive deficit, personality change and psychomotor slowing. Changes in affect are common and depressive or psychotic features may be present. The spinal cord may show vacuolar myelopathy histologically. In severe cases, computed tomography (CT) scanning of the brain shows atrophic change of varying degrees. Magnetic resonance imaging (MRI) changes consist of white matter lesions of increased density on T2-weighted sections. Electroencephalography (EEG) shows non-specific changes consistent with encephalopathy. The CSF is usually normal, although the protein concentration may be raised. Patients with mild neurological dysfunction may be unduly sensitive to the effects of other insults, such as fever, metabolic disturbance or psychotropic medication, any of which may lead to a marked deterioration in cognitive functioning.

**Sensory polyneuropathy** is seen in advanced HIV infection, mainly in the legs and feet, although hands may be affected. Severe forms cause intense pain, usually in the feet, which disrupts sleep, impairs mobility and generally reduces the quality of life.

**Autonomic neuropathy** may also occur with postural hypotension and diarrhoea. Autonomic nerve damage is found in the small bowel.

ARVs that penetrate the central nervous system (CNS) can lead to significant improvements in cognitive function in many patients with ADC. They may also have a neuroprotective role.

Eye disease

Eye pathology may occur in the later stages. The most serious condition is cytomegalovirus retinitis (see p. 258), which is sight-threatening. Retinal cotton wool spots due to HIV *per se* are rarely troublesome but they can be confused with cytomegalovirus retinitis. Anterior uveitis can present as acute red eye associated with rifabutin therapy for mycobacterial infections in HIV. Steroids used topically are usually effective but modification of the dose of rifabutin is required to prevent relapse. Pneumocystis, toxoplasmosis, syphilis and lymphoma can all affect the retina and the eye may be the site of first presentation.

Mucocutaneous manifestations

The skin is a common site for HIV-related pathology (*Box 12.11*), as the function of dendritic and Langerhans cells, both target cells for HIV, is disrupted. Delayed-type hypersensitivity, a good indicator of cell-mediated immunity, is frequently reduced or absent, even before clinical
signs of immunosuppression appear. Pruritus is a common complaint at all stages of HIV. Generalized dry, itchy, flaky skin is typical and the hair may become thin and dry. An intensely pruritic papular eruption favouring the extremities may be found, particularly in patients from African backgrounds. Eosinophilic folliculitis presents with urticarial lesions, particularly on the face, arms and legs.

### Box 12.11

**Some mucocutaneous manifestations of HIV infection**

#### Skin
- Dry skin and scalp
- Onychomycosis
- Seborrhoeic dermatitis
- Tinea: cruris, pedis
- Pityriasis: versicolor, rosea
- Folliculitis
- Acne
- Molluscum contagiosum
- Warts
- Herpes zoster: multi-dermatomal disseminated
- Papular pruritic eruption
- Scabies
- Ichthyosis
- Kaposi's sarcoma

#### Mucous membranes
- Candidiasis: oral, vulvovaginal
- Oral hairy leukoplakia
- Aphthous ulcers
- Herpes simplex: genital, oral, labial
- Periodontal disease
- Warts: oral, genital

*See also pages 1384–1385.*

Drug reactions with cutaneous manifestations are frequent, rashes developing notably to
sulphur-containing drugs, amongst others (see Fig. 31.52). Recurrent aphthous ulceration, which is severe and slow to heal, may impair the patient's ability to eat. Biopsy may be indicated to exclude other causes of ulceration. Topical steroids are useful and resistant cases may respond to thalidomide. In addition to the above, the skin is a common site of opportunistic infections (see pp. 1384–1385).

Haematological complications

These are common in advanced HIV infection.

- **Lymphopenia** progresses as the CD4 count falls.
- **Anaemia of chronic HIV infection** is usually mild, normochromic and normocytic.
- **Neutropenia** is common and usually mild.
- **Isolated thrombocytopenia** may occur early in infection and be the only manifestation of HIV for some time. Platelet counts are often moderately reduced but can fall dramatically to 10–20 × 10^9/L, producing easy bleeding and bruising. Circulating antiplatelet antibodies lead to peripheral destruction. Megakaryocytes are increased in the bone marrow but their function is impaired. Effective ART usually produces a rise in platelet count. Thrombocytopenic patients undergoing dental, medical or surgical procedures may need therapy with human immunoglobulin, which gives a transient rise in platelet count, or with platelet transfusion. Steroids are best avoided.
- **Pancytopenia** occurs because of underlying opportunistic infection or malignancies, in particular *M. avium-intracellulare*, disseminated cytomegalovirus and lymphoma.
- **Other complications** involve myelotoxic drugs, which include zidovudine (megaloblastic anaemia, red cell aplasia, neutropenia), lamivudine (anaemia, neutropenia), ganciclovir (neutropenia), systemic chemotherapy (pancytopenia) and co-trimoxazole (agranulocytosis).

Gastrointestinal effects

Weight loss and diarrhoea are common in people with advanced untreated HIV infection (see Box 13.19). Wasting is a common feature of advanced HIV infection, which, although originally attributed to direct HIV effects on metabolism, is usually a consequence of anorexia. There is a small increase in resting energy expenditure in all stages of HIV, but weight and lean body mass usually remain normal during periods of clinical latency when the patient is eating normally.

HIV enteropathy with varying degrees of villous atrophy has been described with chronic diarrhoea when no other pathogen has been found.

Hypochlorhydria is reported in patients with advanced HIV disease and may have consequences for drug absorption and bacterial overgrowth in the gut.

Rectal lymphoid tissue cells are the targets for HIV infection during penetrative anal sex and may be a reservoir for infection to spread through the body.
Renal complications

**HIV-associated nephropathy (HIVAN)**; see p. 737, although rare, can cause significant renal impairment, particularly in more advanced disease. It is most frequently seen in black male patients and can be exacerbated by heroin use.

**Nephrotic syndrome** subsequent to focal glomerulosclerosis is the usual pathology, which may be a consequence of HIV cytopathic effects on renal tubular epithelium. The course is usually relentlessly progressive and dialysis may be required.

Many **nephrotoxic drugs** are used in the management of HIV-associated pathology, particularly foscarnet, amphotericin B, pentamidine and sulfadiazine. Tenofovir is associated with Fanconi syndrome (see p. 1286).

Respiratory complications

The upper airway and lungs serve as a physical barrier to air-borne pathogens and any damage will decrease the efficiency of protection, leading to an increase in upper and lower respiratory tract infections. The sinus mucosa may also function abnormally in HIV infection and is frequently the site of chronic inflammation. Response to antibacterial therapy and topical steroids is usual but some patients require surgical intervention. A similar process is seen in the middle ear, which can lead to chronic otitis media.

**Lymphoid interstitial pneumonitis (LIP)** is well described in paediatric HIV infection but is uncommon in adults. There is an infiltration of lymphocytes, plasma cells and lymphoblasts in alveolar tissue. Epstein–Barr virus may be present. The patient presents with dyspnoea and a dry cough, which may be confused with pneumocystis infection (see p. 349). Reticular nodular shadowing is seen on chest X-ray. Therapy with steroids may produce clinical and histological benefit in some patients.

Endocrine complications

Various endocrine abnormalities have been reported, including reduced levels of testosterone and abnormal adrenal function. The latter assumes clinical significance in advanced disease when intercurrent infection superimposed on borderline adrenal function precipitates clear adrenal insufficiency, requiring replacement doses of glucocorticoid and mineralocorticoid. Cytomegalovirus is also implicated in adrenal-deficient states.

Cardiac complications

Cardiovascular pathology is increasingly recognized as a cause of morbidity in people with HIV. Although lipid dysregulation has been associated with ARV medication, the observation has been made that high-density lipoprotein (HDL) levels are lower in those with untreated HIV infection than in HIV-negative controls. In a large international study (SMART), ischaemic heart disease was more common in those who took intermittent ARV therapy than in those who
maintained viral suppression. Cardiomyopathy, although rare, is associated with HIV and may lead to congestive cardiac failure. Lymphocytic and necrotic myocarditis has been described. Ventricular biopsy should be performed to ensure that other treatable causes of myocarditis are excluded.

**Conditions associated with HIV immunodeficiency**

Immunodeficiency (see pp. 138–142) allows the development of opportunistic infections (Box 12.12 and see also Box 12.21). These are diseases caused by organisms that are not usually considered pathogenic, unusual presentations of known pathogens, and the occurrence of tumours that may have an oncogenic viral aetiology. Susceptibility increases as the patient becomes more immunosuppressed. CD4 T-lymphocyte numbers are used as markers to predict the risk of infection. Patients with CD4 counts of >200 cells/mm$^3$ are at low risk for the majority of AIDS-defining opportunistic infections. A hierarchy of thresholds for specific infectious risks can be constructed. Mechanisms include defective T-cell function against protozoa, fungi and viruses, impaired macrophage function against intracellular bacteria such as *Mycobacteria* and *Salmonella*, and defective B-cell immunity against capsulated bacteria such as *Streptococcus pneumoniae* and *Haemophilus*. Many of the organisms causing clinical disease are ubiquitous in the environment or are already carried by the patient.

---

**Box 12.12**

**Major HIV-associated pathogens**

**Protozoa**
- *Toxoplasma gondii*
- *Cryptosporidium parvum*
- *Microsporidia* spp.
- *Leishmania donovani*
- *Isospora belli*

**Viruses**
- *Cytomegalovirus*
- *Herpes simplex*
- *Varicella zoster*
- *Human papillomavirus*
- *JC polyomavirus*

**Fungi and yeasts**
- *Pneumocystis jiroveci*
• Cryptococcus neoformans
• Candida spp.
• Dermatophytes (Trichophyton)
• Aspergillus fumigatus
• Histoplasma capsulatum
• Coccidioides immitis

**Bacteria**

• Salmonella spp.
• Mycobacterium tuberculosis
• M. avium-intracellulare
• Streptococcus pneumoniae
• Staphylococcus aureus
• Haemophilus influenzae
• Moraxella catarrhalis
• Rhodococcus equi
• Bartonella quintana
• Nocardia

Diagnosis in an immunosuppressed patient may be complicated by a lack of typical signs, as the inflammatory response is impaired. Examples are lack of neck stiffness in cryptococcal meningitis or minimal clinical findings in early *Pneumocystis jiroveci* pneumonia. Multiple pathogens may coexist. Indirect serological tests are frequently unreliable. Specimens should be obtained from the appropriate site for examination and culture in order to make a diagnosis.

**Assessment and monitoring of HIV-positive patients**

**Initial assessment**

People are newly diagnosed with HIV in an increasingly wide range of settings and need to be transferred appropriately into effective care. All those with a new diagnosis of HIV should be reviewed by an HIV clinician within 2 weeks of diagnosis, or earlier if the patient is symptomatic or has other acute needs. A full medical history, physical examination and laboratory evaluation should be undertaken in all newly diagnosed patients to determine the stage of infection and the presence of co-morbidities and co-infections, and to assess overall physical, mental and sexual health. The initial assessment should also include details of the patient's socioeconomic situation, relationships, family and social support networks, and substance misuse, together with contact tracing and partner notification. Specialist advice should be sought if there are children who require testing. Baseline investigations will depend
on the clinical setting, but those appropriate for an asymptomatic person in the UK are shown in Box 12.13.

---

**Box 12.13**

Baseline assessment investigations for a newly diagnosed asymptomatic patient with HIV infection

**History of all other coexisting conditions, including sexual, psychiatric and reproductive health**

- Full drug history, including recreational substances
- Vaccination history
- Social circumstances to include relationships, disclosure, support

**Haematology**

- Full blood count, differential count and film

**Biochemistry**

- Serum, liver and renal function, including estimated glomerular filtration rate (eGFR)
- Fasting serum lipid profile, total cholesterol, high-density lipoprotein (HDL) cholesterol
- Fasting blood glucose
- Serum bone profile, including 25-OH-vitamin D
- Urinalysis
- Dipstick for blood, protein and glucose
- Urine protein:creatinine ratio

**Immunology**

- Lymphocyte subsets (repeat to confirm baseline within 1–3 months)
- HLA-B*5701 status

**Virology**

- HIV antibody (confirmatory)
- HIV viral load
- HIV genotype and subtype determination
- Hepatitis A IgG
- Hepatitis B surface antigen and full profile
- Hepatitis C antibody (followed by hepatitis C RNA testing if antibody-positive, and confirmation of antibody-positive status if RNA negative)
**Microbiology**
- Toxoplasmosis serology
- Syphilis serology
- Tuberculosis status
- Screen for other sexually transmitted infections

**Other**
- Cervical cytology
- Chest X-ray if indicated
- 10-year cardiovascular risk assessment
- Fracture risk assessment
- Body mass index (BMI)

**Monitoring**

Patients are regularly monitored, depending on infection and treatment stage.

For people who are not yet on therapy, monitoring should take place 2–4 times per year, with longer intervals for those with higher CD4 counts, to assess progression of the infection and the need for treatment. Decisions about appropriate intervention can be made.

For people starting therapy and those on established effective therapy, monitoring is described in on page 344.

**Immunological monitoring**

*CD4 lymphocytes.* The absolute CD4 count and its percentage of total lymphocytes fall as HIV progresses. These figures bear a relationship to the risk of occurrence of HIV-related pathology, and patients with counts <200 cells/mm$^3$ are at greatest risk. Rapidly falling CD4 counts and those at or below 350 are an indication for immediate initiation of ART. Factors other than HIV (e.g. smoking, exercise, intercurrent infections and diurnal variation) also affect CD4 numbers. CD4 counts are performed at approximately 4–6-monthly intervals unless values are approaching critical levels for intervention, in which case they are performed more frequently.

**Virological monitoring**

*Viral load (HIV RNA).* HIV replicates at a high rate throughout the course of infection, many billions of new virus particles being produced daily. The rate of viral clearance is relatively constant in any individual and thus the level of viraemia is a reflection of the rate of virus replication. This has both prognostic and therapeutic value.

The commonly used term ‘viral load’ encompasses viraemia and HIV RNA levels. Three *HIV RNA assays for viral load* are in current use:
- branched-chain DNA (bDNA)
• reverse transcription polymerase chain reaction (RT-PCR)
• nucleic acid sequence-based amplification (NASBA).

Results are given in copies of viral RNA/mL of plasma, or converted to a logarithmic scale, and there is good correlation between tests. The most sensitive test is able to detect as few as 20 copies of viral RNA/mL. Transient increases in viral load are seen following immunizations (e.g. for influenza and Pneumococcus) or during episodes of acute intercurrent infection (e.g. tuberculosis), and viral load measurements should not be carried out within a month of these events.

By about 6 months after seroconversion to HIV, the viral set-point for an individual is established and there is a correlation between HIV RNA levels and long-term prognosis, independent of the CD4 count. Those patients with a viral load consistently >100 000 copies/mL have a 10 times higher risk of progression to AIDS over the ensuing 5 years than those consistently <10 000 copies/mL.

HIV RNA is the standard marker of treatment efficacy (see below). Both duration and magnitude of virus suppression are pointers to clinical outcome. The aim of therapy is to secure long-term virological suppression, and a rising viral load in a patient whose adherence is assured indicates drug failure.

Baseline measurements are followed by repeat estimations at intervals of 4–6 months, ideally in conjunction with CD4 counts, to allow both pieces of evidence to be used together in decision-making. Following initiation of ART or changes in therapy, a reduction in viral load should be seen by 4 weeks, reaching a maximum at 10–12 weeks, when repeat viral load testing should be carried out (see Fig. 12.12).

Genotype determination
Clear genotype variations exist within HIV; not only are there variations between viral subtypes but also well-identified point mutations are associated with resistance to ARVs. New infections with drug-resistant variants of HIV may be seen. Viral genotype analysis is recommended for all newly diagnosed patients with HIV. The most appropriate sample is the one closest to the time of diagnosis and the results are used to guide the selection of ART agents.

Management of HIV-Positive Patients

Effective ART has transformed the clinical outcomes for people with HIV, extending life expectancy towards that of the general population, bringing down morbidity and cutting infectiousness to people who are HIV-negative. Current management strategies aim to maximize wellbeing with long-term, effective suppressive therapy within a chronic condition model, beginning before the patient is symptomatic (Box 12.14). The treatment of opportunistic conditions in immunosuppressed patients is most commonly seen either in situations where ART is not available or in previously undiagnosed patients presenting with advanced infection. With access and adherence to potent, tolerable ARVs within a managed clinical setting, life expectancy for people with HIV can approach that of the general population. Nevertheless, there is still no cure for HIV and patients live with a chronic, potentially infectious and unpredictable condition. Limitations on ART efficacy include the inability of existing drugs to clear HIV from certain intracellular pools, the occurrence of drug side-effects, adherence requirements, complex drug–drug interactions and the emergence of resistant viral strains. Even with complete viral suppression, ART does not fully restore health, and treated infection is associated with a variety of non-AIDS complications, including cardiovascular disease and some cancers.

Box 12.14

An approach to sick HIV-positive patients

Potential problems

- Adverse drug reactions
- Drug–drug interactions
- Presentation or complications of malignancy
- Immune reconstitution phenomenon
- Infection in an immunocompromised host
- Acute opportunistic infections
- Organic or functional brain disorders
- Non-HIV-related pathology

Full medical history

- Anti-retroviral drugs, recreational drugs, prophylaxis, travel, previous HIV-related pathology, potential source of infectious agents (food hygiene, pets, contacts with acute infections, contact with tuberculosis, sexually transmitted infections)
- Secure confidentiality; ask the patient who is aware of the HIV diagnosis

Full physical examination
• Signs of adverse drug reactions, e.g. skin rashes, oral ulceration
• Signs of disseminated sepsis
• Clinical evidence of immunosuppression, e.g. oral candida, oral hairy leukoplakia
• Focal neurological signs and/or meningism
• Evidence of altered mental state – organic or functional
• Examine:
  – Genitalia, e.g. herpes simplex, syphilis, gonorrhoea
  – Fundi, e.g. cytomegalovirus retinitis
  – Mouth
• Lymphadenopathy

**Immediate investigations**

• Full blood count and differential count
• Liver and renal function tests
• Plasma glucose
• Blood gases, including acid–base balance
• Blood cultures, including specimens for mycobacterial culture
• Microscopy and culture of available/appropriate specimens: stool, sputum, urine, cerebrospinal fluid
• Malaria screen in recent travellers from malaria areas
• Serological tests for cryptococcal antigen, toxoplasmosis; save serum for viral studies
• Chest X-ray
• CT/MRI scan of brain if there are focal neurological signs and *always* before lumbar puncture

---

*Lymphocyte subsets and HIV viral load assays may yield misleading results during intercurrent illness.*

---

**The aims of management** in HIV infection are to:

• maintain physical and mental health
• improve the quality of life
• increase survival rates
• restore and improve immune function
• avoid onward transmission of the virus
• provide appropriate clinical care as needed.

This requires long-term, maximal suppression of HIV activity using ARV medication and management adopting a multidisciplinary team approach. Regular assessment is needed to
obtain details of intercurrent medical problems, medications, vaccinations, any recreational drug use, sexual history, reproductive decision-making, cervical cytology, and social situation to include support networks, employment, benefits and accommodation. Depression and anxiety are common among people living with HIV and can have a deleterious impact on adherence to medication regimens, making it important for mood and cognitive function to be routinely and regularly assessed. Psychological support may be needed, not only for the patient but also for family, friends and carers. Regular reviews of sexual and reproductive health, together with advice on reducing the risk of HIV transmission, must be provided and future sexual practices discussed. Information is required to allow people to make informed choices about childbearing. The implications for sexual partners and existing family members should be considered and diagnostic testing offered as necessary. Regular monitoring of weight, body mass index, blood pressure and cardiovascular risk is required. Dietary assessment and advice should be freely accessible. General health promotion advice on smoking, alcohol, diet, drug misuse and exercise should be given, particularly in light of the cardiovascular, metabolic and hepatotoxicity risks associated with HIV and its treatment.

**Anti-retroviral drugs**

The treatment of HIV using anti-retroviral therapy (ART; Box 12.15) continues to evolve and improve. Increased potency, reduced toxicity, greater convenience of formulation, and availability of compounds with different mechanisms of action, coupled with an improved understanding of drug resistance, have combined to improve HIV clinical and virological outcomes consistently. An increase in the numbers of compounds, and the array of drug–drug interactions, for example, combine to make HIV treatment complex, and better clinical outcomes have been linked closely to physician expertise and the numbers of patients under direct care. With several of the older compounds now available as generics, some drug costs are likely to fall, and commissioners are increasingly focusing on the cost-effectiveness of the newer agents to justify their use. Regularly updated treatment guidelines are produced in the UK by the British HIV Association and in the USA by the Department of Health and Human Services. The most up-to-date versions can be found on their websites (see ‘Further reading’) and the current version must be used.

<tr>
<th>Drug class and nucleotide reverse transcriptase inhibitors (NRTIs)</th>
<th>Drugs</th>
<th>Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Tenofovir, abacavir; zidovudine, stavudine, lamivudine, emtricitabine</td>
<td>Tenofovir associated with renal dysfunction Abacavir associated with hypersensitivity reactions in at-risk individuals (HLA-B*5701) Zidovudine and stavudine (both now rarely used in the UK) are associated with fat redistribution (lipodystrophy) Abacavir plus lamivudine should only be used when baseline VL is &lt;100,000 copies/mL The combination of tenofovir plus emtricitabine is a preferred first-line regimen in most regions</td>
</tr>
<tr>
<td>Non-nucleoside reverse transcriptase inhibitors (NNRTIs)</td>
<td>Efavirenz, nevirapine, etravirine, rilpivirine</td>
<td>Efavirenz can cause central nervous system toxicity (usually time-limited) Nevirapine can cause severe hepatotoxicity in patients with higher CD4 cell counts (&gt;250 cells/mm³ for women and &gt;400 cells/mm³ for men) Rilpivirine should only be used when baseline VL is &lt;100,000 copies/mL Etravirine is given twice daily and has generally been used as a second-line regimen</td>
</tr>
<tr>
<td>Integrase inhibitors or integrase strand transfer inhibitors (INSTIs)</td>
<td>Raltegravir, dolutegravir, elvitegravir</td>
<td>Integrase inhibitors are generally well tolerated and have fewer adverse effects than other ARV classes Raltegravir is taken twice daily Elvitegravir requires boosting by cobicistat</td>
</tr>
<tr>
<td>Protease inhibitors</td>
<td>Fosamprenavir, atazanavir, darunavir, lopinavir, saquinavir (ritonavir)</td>
<td>Most protease inhibitors are extensively metabolized by the cytochrome P450 3A system; ritonavir is generally given at low doses (100–200 mg per day) to inhibit P450 and boost the co-administered protease inhibitors Most protease inhibitors are associated with hyperlipidaemia and other metabolic abnormalities such as insulin resistance Long-term protease inhibitor exposure has been associated with increased risk of cardiovascular disease</td>
</tr>
<tr>
<td>CCR5 inhibitors</td>
<td>Maraviroc</td>
<td>Maraviroc is only active in patients who do not have virions that use CXCR4 for cell entry. A specialized assay is therefore needed to screen for co-receptor tropism. By contrast with other ARVs, maraviroc binds to a host rather than a viral target</td>
</tr>
<tr>
<td>Fusion inhibitors</td>
<td>Enfuvirtide</td>
<td>Enfuvirtide must be given subcutaneously twice daily and is very expensive; generally used only in patients who have no other therapeutic options</td>
</tr>
</tbody>
</table>

Some drugs, such as zidovudine, stavudine and nevirapine, are generally used in resource-limited regions because of cost considerations. These are not recommended as preferred agents in resource-rich regions in view of their potential toxic effects. VL, viral load.

(Modified from: Volberding PA, Deeks SG. Antiretroviral therapy and management of HIV infection. Lancet 2010; 376(9734):49–62.)

The key practical principles of prescribing ARVs are given in **Box 12.16**.

**Box 12.16**

**Prescribing anti-retroviral drugs (ARVs): practice points**
<table>
<thead>
<tr>
<th>Characteristics of ARVs</th>
<th>Practice points</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Adherence for the long term is key to success</strong></td>
<td>Make treatment decisions in partnership with the patient. Check for any factors that may compromise accurate adherence. Ensure that the proposed drug regimen fits with lifestyles. Clarify that the patient is fully conversant with the requirements and understands the reasons for strict adherence. Check access to appropriate storage conditions for some agents.</td>
</tr>
<tr>
<td><strong>Should not be stopped suddenly</strong></td>
<td>Make sure that mechanisms are in place to ensure adequate drug supplies, e.g. regular clinic appointments, repeat prescriptions, home delivery of medications. Beware unexpected time away from home, e.g. holidays, intercurrent hospital admissions, immigration detention, police detention. If there is an urgent medical indication to stop, obtain advice from a specialist physician or pharmacist.</td>
</tr>
<tr>
<td><strong>Can be compromised by the introduction of other medications, including other ARVs and vice versa</strong></td>
<td>Take care with DDA therapies in hepatitis C (expert advice required). Be careful with enzyme inducers, e.g. rifampicin, rifabutin, warfarin, nevirapine, which will reduce the effective levels of some ARVs. Remember that methadone levels may be reduced by efavirenz. Note that some ARVs block the metabolism of other agents, which may reach toxic levels, e.g. steroids, statins. Always check potential interactions before adding new agents; see <a href="http://www.hiv-druginteractions.org">www.hiv-druginteractions.org</a>. Remember that therapeutic drug monitoring is necessary.</td>
</tr>
<tr>
<td><strong>Can interact adversely with some herbal, complementary and recreational agents</strong></td>
<td>Note that herbal remedies that induce cytochrome P450, e.g. St John's wort and Chinese herbal remedies, will reduce levels of some ARVs. Check potential interactions before adding new agents; see <a href="http://www.hiv-druginteractions.org">www.hiv-druginteractions.org</a>. Remember that therapeutic drug monitoring is necessary.</td>
</tr>
<tr>
<td><strong>May produce additive toxicities when given with other medications</strong></td>
<td>For example, note that corticosteroid (inhaled and systemic) levels may be elevated, statins, hepatotoxicity with anti-tuberculosis medication, myelosuppression with chemotherapy or high-dose co-trimoxazole.</td>
</tr>
<tr>
<td><strong>Are associated with a range of adverse drug reactions, which may be confused with other pathology</strong></td>
<td>For example, note that rash, fever, nausea, diarrhoea may all be caused by intercurrent pathology and/or ARVs.</td>
</tr>
<tr>
<td><strong>May exacerbate co-morbidities</strong></td>
<td>Remember immune reconstitution inflammatory syndrome (IRIS). Examples include hepatic dysfunction due to hepatitis B and C, cardiovascular risk, osteoporosis.</td>
</tr>
</tbody>
</table>

**Reverse transcriptase inhibitors**

**Nucleoside/nucleotide analogues**

Nucleoside reverse transcriptase inhibitors (NRTIs) inhibit the synthesis of DNA by reverse transcription and also act as DNA chain terminators. NRTIs need to be phosphorylated intracellularly for activity to occur. These were the first group of agents to be used against HIV. Usually, two drugs of this class are combined to provide the ‘backbone’ of an ART regimen. Several fixed-dose NRTI combinations are available, which helps reduce the pill burden. NRTIs have been associated with mitochondrial toxicity (see p. 346), a consequence of their effect on the human mitochondrial DNA polymerase. Lactic acidosis is a recognized complication of the older members this group of drugs. Nucleotide analogues (nucleotide reverse transcriptase inhibitors, NtRTIs) have a similar mechanism of action but require only two intracellular phosphorylation steps for activity (as opposed to the three steps for nucleoside analogues).
**Non-nucleoside analogues**

Non-nucleoside reverse transcriptase inhibitors (NNRTIs) interfere with reverse transcriptase by direct binding to the enzyme. They are generally small molecules that are widely disseminated throughout the body and have a long half-life. NNRTIs affect cytochrome P450. They are ineffective against HIV-2. The level of cross-resistance across the class is very high. All have been associated with rashes and elevation of liver enzymes. Second-generation NNRTIs, such as etravirine and rilpivirine, which have fewer adverse effects, have some activity against viruses resistant to other compounds of the NNRTI class.

**Protease inhibitors**

Protease inhibitors (PIs) act competitively on the HIV aspartyl protease enzyme, which is involved in the production of functional viral proteins and enzymes. As a consequence, viral maturation is impaired and immature dysfunctional viral particles are produced. Most of the PIs are active at very low concentrations and *in vitro* are found to have synergy with reverse transcriptase inhibitors. However, there are differences in toxicity, pharmacokinetics, resistance patterns and also cost, which influence prescribing. Cross-resistance can occur across the PI group. There appears to be no activity against human aspartyl proteases (e.g. renin), although there are clinically significant interactions with the cytochrome P450 system. This is used to therapeutic advantage, ‘boosting’ blood levels of PI by blocking drug breakdown with small doses of ritonavir or cobicistat. PIs have been linked with abnormalities of fat metabolism and control of blood sugar, and some have been linked with deterioration in clotting function in people with haemophilia. In general, PIs have a higher genetic barrier to resistance than other drug classes, and newer PIs such as darunavir have activity against viruses resistant to the older drugs in the class.

**Integrase inhibitors**

These drugs act as a selective inhibitor of HIV integrase, which blocks viral replication by preventing insertion of HIV DNA into the human DNA genome. Three compounds are in clinical use and are effective in treatment of both drug-experienced and drug-naive patients, with tolerability and safety profiles that are superior to those of NNRTIs and PIs. For these reasons, dolutegravir, a second-generation integrase inhibitor, has been shown to be superior to both efavirenz and darunavir, and also has a high genetic barrier to resistance.

**Co-receptor blockers**

Maraviroc is a chemokine receptor antagonist that blocks the cellular CCR5 receptor entry by CCR5 tropic strains of HIV. These strains are found in earlier HIV infection and, with time adaptations (against which maraviroc is ineffective), allow the CXCR4 receptor to become the more dominant form. The drug is metabolized by cytochrome P450 (3A), giving the potential for drug–drug interactions. Tropism assays to establish that the patient is carrying a CCR5 tropic virus are required before treatment is used.
Fusion inhibitors

Enfuvitide is the only licensed compound in this class of agents. It is an injectable peptide derived from HIV gp41 that inhibits gp41-mediated fusion of HIV with the target cell. It is synergistic with NRTIs and PIs. Although resistance to enfuvitide has been described, there is no evidence of cross-resistance with other drug classes. Because it has an extracellular mode of action there are few drug–drug interactions. Side-effects relate to the subcutaneous route of administration in the form of injection site reactions.

Starting therapy

Although the benefits of ART in HIV infection are indisputable, treatment regimens require a long-term commitment to high levels of adherence. Risks of therapy include short- and longer-term side-effects, drug–drug interactions and the potential for development of resistant viral strains, although, with newer agents and improved formulations, the difficulties associated with treatment have diminished. The full involvement of patients in therapeutic decision-making is essential for success. Various national guidelines and treatment frameworks exist (e.g. guidelines from BHIVA, guidelines from the US Department of Health and Human Services (DHHS), recommendations from the International Antiviral Society (IAS)). Laboratory marker data, including viral load, genotype and CD4 counts, together with individual circumstances, underpin therapeutic decision-making. The current UK recommendations are shown in Box 12.17. In situations where therapy is recommended but the patient elects not to start, then more intensive clinical and laboratory monitoring is advisable.

Box 12.17

When to start anti-retroviral therapy (ART)

Primary HIV infection

• Treatment is recommended if any one of the following criteria is met:
  – There is neurological involvement
  – The CD4 count is <350 cells/mm$^3$
  – Any AIDS-defining illness is present (see Box 12.10)

Established HIV infection

• CD4 <250 cells/mm$^3$
  – Treat
• CD4 251–350 cells/mm$^3$
  – Treat as soon as patient is ready
• CD4 >350 cells/mm$^3$
  – Consider enrolment into a ‘when to start’ trial
• Treatment to prevent onward transmission
– The evidence that treatment with ART lowers the risk of transmission should be discussed with all patients, and an assessment of the current risk of transmission to others made at the time of this discussion. If, following discussion, a patient with a CD4 cell count $>350 \text{ cells/mm}^3$ wishes to start ART to reduce the risk of transmission to partners, ART should be initiated

**AIDS diagnosis/CDC stage C**

– Treat (except for tuberculosis when CD4 is $>350 \text{ cells/mm}^3$)

CDC, Centers for Disease Control.

Questions still remain about the best time to start therapy. Unequivocal clinical benefit has been demonstrated with the use of ARVs in advanced HIV disease. In all patients with symptomatic HIV disease, HIV-related co-morbidity, AIDS or a CD4 count that is consistently $<200 \text{ cells/mm}^3$, treatment should be initiated as soon as possible. In such situations, there is a significant risk of serious HIV-associated morbidity and mortality, and the longer-term prognosis for patients initiating therapy $<200 \text{ cells/mm}^3$ is not as good as for those who start at higher counts.

In asymptomatic patients, the absolute CD4 count is the key investigation used to guide treatment decisions. The UK recommendation is that therapy should be started at or around a CD4 count of 350 cells/mm$^3$. Treatment should not be delayed if the CD4 count is close to this threshold.

Debate persists around starting therapy at higher CD4 counts. The risk of disease progression for individuals with a count $>350 \text{ cells/mm}^3$ is low and has to be balanced against ARV therapy toxicity and the development of resistance. However, there is growing appreciation of the long-term inflammatory effects of HIV that predispose to non-AIDS illnesses, which, together with the reduction in infectiousness for those on effective therapy, is shifting opinion towards starting sooner. Earlier intervention at higher CD4 counts may be considered in those with a higher risk of disease progression: for example, with high viral loads ($>60,000 \text{ copies/mL}$) or rapidly falling CD4 count (losing more than 80 cells/year). Co-infection with hepatitis B and C virus may be an indication for earlier intervention (see p. 351). Patients with primary HIV infection and neurological involvement, an AIDS-defining illness or a CD4 count $<350 \text{ cells/mm}^3$ should start therapy, which should be continued indefinitely. Special situations (seroconversion, pregnancy, post-exposure prophylaxis) in which ARV agents may be used are described on pages 346–347.

The evidence that treatment reduces infectiousness should be discussed with all patients with HIV; those who wish to start treatment to reduce the risk of transmission to others should do so, irrespective of CD4 count.
Choice of drugs

The drug regimen used for starting therapy must be individualized to suit each patient's needs. As differences in drug efficacy become less marked, tailoring treatment to the patient's needs and lifestyle is key to success. Treatment is initiated with three drugs: two NRTIs in combination, with a third agent – either an NNRTI, a boosted PI or an integrase inhibitor (Boxes 12.15 and 12.18). The development of fixed-dose co-formulations reduces pill burden, increases convenience and facilitates adherence.

Box 12.18

Initial ART regimens: choice of initial therapy and preferred regimens

Therapy-naive patients should start with a regimen that contains two nucleoside reverse transcriptase inhibitors and a third agent, either a ritonavir-boosted protease inhibitor, a non-nucleoside reverse transcriptase inhibitor or an integrase inhibitor

<sup>a</sup>Drugs listed in alphabetical order.

<sup>b</sup>Co-formulated as Truvada.

<sup>c</sup>Co-formulated as Kivexa.

<sup>d</sup>Abacavir is contraindicated if patient is HLA-B*5701-positive.

<sup>e</sup>Use recommended only if baseline viral load is <100,000 copies/mL.

<sup>f</sup>Nevirapine is contraindicated if baseline CD4 is >250 cells/mm<sup>3</sup> in women or >400 cells/mm<sup>3</sup> in men.

Nucleoside reverse transcriptase inhibitor

The choice of two NRTIs to form the backbone of therapy is influenced by efficacy, toxicity and ease of administration. The availability of once-daily, one-tablet, fixed-dose combinations, Truvada (tenofovir/emtricitabine) and Kivexa (abacavir/lamivudine), has led to the prescription of one of these as the two-NRTI backbone for the majority of patients who are naive to medication. Kivexa should be used only in those who are HLA-B*5701-negative. Data comparing Truvada and Kivexa in naive patients have demonstrated the non-inferiority of
Kivexa at viral levels <100 000 copies/mL. In patients with high viral levels, Kivexa should be reserved for use when Truvada is contraindicated.

**Non-nucleoside reverse transcriptase inhibitor**

The decision about whether to use an NNRTI, a boosted PI or an integrase inhibitor will depend on the particular circumstances of each patient. In the UK, however, an NNRTI-based regimen is still the most commonly prescribed for patients starting treatment.

*Efavirenz* is the recommended option in the UK, having demonstrated good durability over time, and potency at low CD4 counts and in high viral loads. It is associated with CNS side-effects, such as dysphoria and insomnia. Rilpivirine has fewer side-effects and is better tolerated than efavirenz, but is less effective when the viral load is >100 000 copies/mL, making it an alternative rather than a preferred first-line drug. Single-tablet, fixed-dose preparation of efavirenz co-formulated with Truvada (Atripla) and rilpivirine with Truvada (Eviplera) allows for a ‘one pill once a day’ regimen.

*Nevirapine* is of equivalent potency to efavirenz but has a higher incidence of hepatotoxicity and rash. Toxicity is greater in women and in those with higher CD4 counts. It is contraindicated in women with CD4 counts >250 cells/mm$^3$ and in men with counts >400 cells/mm$^3$. It can be a useful alternative to efavirenz if CNS side-effects are troublesome, and in women with lower CD4 counts who wish to conceive.

*Etravirine* is a second-generation NNRTI with some activity against drug-resistant strains, and is useful in the treatment of experienced patients.

**Protease inhibitors**

This class of drugs has demonstrated excellent efficacy in clinical practice. PIs are usually combined with a low dose of ritonavir (a ‘boosting’ PI), which provides a pharmacokinetic advantage by blocking cytochrome P450 metabolism. If this approach is used, the half-life of the active drug is increased, allowing greater drug exposure, fewer pills, enhanced potency and a minimized risk of resistance. The disadvantages include a greater pill burden and increased risk of greater lipid abnormalities, particularly raised fasting triglycerides. Cobicistat, a novel cytochrome P450 inhibitor with no intrinsic anti-HIV activity, is an alternative.

Atazanavir, darunavir and lopinavir, boosted with ritonavir, are most commonly used as first-line therapy. All three can cause gastrointestinal disturbance and lipid abnormalities. Atazanavir increases unconjugated bilirubin levels and may produce icterus. All have interactions with cytochrome P450.

**Integrase inhibitors**

The potency of this class of drug, coupled with the relatively favourable side-effect profile in comparison to efavirenz and fewer drug interactions in comparison to PIs, makes it an increasingly popular third agent.

Raltegravir, the first licensed compound in this drug class, has high anti-HIV activity for
both treatment-naive and treatment-experienced patients, with a favourable side-effect profile and few drug interactions. The genetic barrier for resistance is relatively low, twice daily dosing is required and there are no single-tablet co-formulations available.

Elvitegravir is metabolized via the cytochrome P450 pathway, requiring co-administration of a cytochrome-P450 blocker to secure adequate plasma concentrations, thus increasing the drug–drug interaction potential. Single-tablet co-formulations exist with tenofovir, emtricitabine and cobicistat (Stribild). Dolutegravir, a second-generation integrase inhibitor with a good side-effect profile, has a higher genetic barrier to resistance than raltegravir and can be dosed once daily. A fixed-dose tablet of dolutegravir co-formulated with abacavir and lamivudine has recently been approved.

**Monitoring therapy**

Success rates for initial therapy using modern ARVs, as judged by virological response, are very high. By 4 weeks of therapy, the viral load should have dropped by at least 1 log10 copies/mL and by 12–24 weeks should be below 50 copies/mL. A suboptimal response at either time point demands a full assessment and possible change in therapy. Once stable on therapy, the viral load should be routinely measured every 3–6 months. CD4 count should be repeated at 1 and 3 months after starting ART and then every 3–4 months. Once the viral load is <50 copies/mL and the CD4 count has been <350 cells/mm$^3$ for at least 12 months, monitoring frequency may fall to 6-monthly or even longer (*Box 12.19*). Impaired immunological recovery is associated with treatment initiation in advanced infection (a low CD4 count and late presentation) and with older age.

---

**Box 12.19**

**Monitoring patients on ART**

**Clinical history**

- Assessment of adherence to medication
- Evidence of ART toxicity
- Documentation of any new clinical conditions occurring since last assessment
- Drug history, including all co-medications (prescribed, recreational, over-the-counter, complementary and herbal)

**Physical examination**

- Blood pressure
- Weight
- HIV viral load
- Lymphocyte subsets
- Full blood count
• Urinalysis if tenofovir is being used
• Liver and renal function
• Fasting lipid profile
• Fasting blood glucose

Additional investigations (depending on the clinical picture)
• HIV genotype if there is evidence of virological failure
• Therapeutic drug level monitoring

Regular clinical assessment should include review of adherence to, and tolerability of, the regimen, weight, blood pressure and urinalysis. Patients should be monitored for drug toxicity, including full blood count, liver and renal function, and fasting lipids and glucose levels.

Drug resistance
Resistance to ARVs (Box 12.20) results from mutations in the protease reverse transcriptase and integrase genes of the virus. HIV has a rapid turnover, with $10^8$ replications occurring per day. The error rate is high, resulting in genetic diversity within the population of virus in an individual, which will include drug-resistant mutants. When drugs only partially inhibit virus replication, there will be a selection pressure for the emergence of drug-resistant strains. The rate at which resistance develops depends on the frequency of pre-existing variants and the number of mutations required. Resistance to most NRTIs and PIs occurs with an accumulation of mutations, whilst a single-point mutation will confer high-level resistance to NNRTIs. There is evidence for the transmission of HIV strains that are resistant to all or some classes of drugs. Studies of primary HIV infection have shown prevalence rates of between 2% and 20%. Prevalence of primary mutations associated with drug resistance in chronically infected patients not on treatment ranges from 3% to 10% in various studies.

Box 12.20
Mechanisms and implications of HIV drug resistance
1. HIV replicates rapidly and inaccurately. Replication in the presence of anti-retroviral (ARV) drugs leads to a selection pressure for those mutations that can survive, i.e. selects for drug resistance
2. Specific point mutations in the viral reverse transcriptase, protease and integrase genes correlate with reduced drug sensitivity and can be identified by genotyping the virus
3. Inadequate ARV drug levels both fail to suppress viral replication/viral load and precipitate drug resistance
4. Inadequate drug levels can result from poor adherence, altered gastrointestinal tract absorption, increased drug breakdown and drug–drug interactions
5. Some ARVs, especially NNRTIs and integrase inhibitors, have a low genetic barrier,
i.e. a small number of mutations that occur rapidly can quickly result in high levels of resistance

6. Stopping drugs with a long half-life can leave a sub-therapeutic drug tail for long enough for resistant strains to develop

7. In patients on stable ARV therapy, the introduction of new drugs that have an impact on cytochrome P450 pathways can lead to dangerous alterations in ARV drug levels

8. Therapeutic drug monitoring (TDM) may be a useful investigation for some drugs in some circumstances

9. Without drug selection pressure, wild-type virus reasserts itself; resistant variants no longer make up the major circulating viral strains and may not be found on investigation. This means that genotyping should, if possible, be carried out on specimens obtained whilst the patient is on therapy

10. Resistant variants survive and are archived. They reappear if the drug selection pressure is re-introduced. This means that all previous genotypes need to be considered when assessing virological failure and planning new therapy

HIV anti-retroviral drug resistance testing has become routine clinical management in patients at diagnosis/before starting therapy and for whom therapy is failing. The tests are based on PCR amplification of virus and give an indirect measure of drug susceptibility in the predominant variants. Such assays are limited by both the starting concentration of virus and their ability to detect minority strains.

For results to be useful in situations where therapy is failing, samples must be analysed when the patient is on therapy, as once the selection pressure of therapy is withdrawn, wild-type virus becomes the predominant strain and resistance mutations present earlier may no longer be detectable.

Databases containing nearly all published HIV (amongst others) and protease sequences and associated resistance patterns are maintained in real time by Stanford University (see ‘Further reading’).

Phenotypic assays provide a more direct measure of susceptibility but the complexity of the assays limits availability.

Drug interactions

Drug therapy in HIV is complex and the potential for clinically relevant drug interactions is substantial. Both PIs and NNRTIs are able to inhibit and induce cytochrome P450 variably, influencing both their own metabolic rates and those of other drugs. Both inducers and inhibitors of cytochrome P450 are sometimes prescribed simultaneously. Induction of metabolism may result in sub-therapeutic ARV levels with the risk of treatment failure and development of viral resistance, whilst inhibition can raise drug levels to toxic values and precipitate adverse reactions.

Conventional (e.g. rifamycins) and complementary therapies (e.g. St John's wort) affect cytochrome P450 activity and may precipitate substantial drug interactions. Therapeutic drug
monitoring (TDM), indicating peak and trough plasma levels, may be useful in certain settings.

Potential interactions can be checked using the online tool maintained by Liverpool University (see ‘Further reading’).

**Adherence**

Patients’ beliefs about their personal need for medicines and their concerns about treatment affect how and whether they take them. Adherence to treatment is pivotal to success. Levels of adherence below 95% have been associated with poor virological and immunological responses, although some of the newer ARVs are more forgiving. Poor absorption and low bioavailability mean that, for some compounds, trough levels are barely adequate to suppress viral replication, and missing even a single dose will result in plasma drug levels falling dangerously low. Patchy adherence facilitates the emergence of drug-resistant variants, which, in time, will lead to virological treatment failure.

Factors implicated in poor adherence may be associated with the medication, with the patient or with the provider. The former include side-effects linked with medications, the degree of complexity and pill burden, and inconvenience of the regimen. Patient factors include the level of motivation and commitment to the therapy, psychological wellbeing, the level of available family and social support, and health beliefs. Supporting adherence is a key part of clinical care and specific guidelines are available (BHIVA 2004). Education of patients about their condition and treatment is a fundamental requirement for good adherence, as is education of clinicians in adherence support techniques. The acceptability and tolerability of the regimen, together with an assessment of adherence, should be documented at each visit. Provision of acute and ongoing multidisciplinary support for adherence within clinical settings should be universal. Medication-alert devices may be useful for some patients.

**Treatment failure**

Failure of ART – that is, persistent viral replication causing immunological deterioration and eventual clinical evidence of disease progression – is caused by a variety of factors, such as poor adherence, limited drug potency, and food or other medication that may compromise drug absorption. There may be drug interactions or limited penetration of drug into sanctuary sites such as the CNS, permitting viral replication. Side-effects and other patient-related elements contribute to poor adherence.

**Changing therapy**

A rise in viral load, a falling CD4 count or new clinical events that imply progression of HIV disease are all reasons to review therapy. Reasons for treatment failure include the emergence of resistant viral strains, poor patient adherence and intolerance/adverse drug reactions. Virological failure – that is, two consecutive viral loads of >400 copies/mL in a previously fully suppressed patient – requires investigation. Viral genotyping should be used to help select future therapy, choosing at least two new agents to which the virus is fully sensitive. If a new suitable treatment option is available, it should be started as soon as possible.
Treatment failure in highly treatment-experienced patients poses considerable challenges but new classes of ARVs, with activity against drug-resistant strains of HIV, make long-term virological suppression a realistic objective, even in heavily pre-treated patients. However, in some situations, it may be better to hold back a new drug and await development of another new agent to give the maximum chance of success.

If the patient has a viral load below the limit of detection and a change needs to be made because of intolerance of a particular drug, then a switch should be made to another sensitive drug within the same class. Simplification of complex regimens may be considered if adherence is problematic.

**Stopping therapy**

ARVs may have to be stopped in, for example, cumulative toxicity, or when there are potential drug interactions with medications needed to deal with another more pressing problem. If adherence is poor, stopping completely may be preferable to continuing with inadequate dosing, in order to reduce the development of viral resistance. Poor quality of life and the view of the patient should be discussed.

The NRTIs efavirenz and nevirapine have long half-lives and, depending on the other components of the regimen, may need be stopped before the other drugs in the mixture to reduce the risk of drug resistance. If this is not possible, a boosted PI may be used, either as a substitute for the NNRTI or as monotherapy, for several weeks to cover the period of sub-therapeutic levels.

**Complications of anti-retroviral therapy**

Side-effects are a common problem in ART (see Box 12.15). Some are acute and associated with initiation of medication, whilst others emerge after longer-term exposure to drugs.

**Allergic reactions**

Allergic reactions occur with greater frequency in HIV infection and have been documented with all the ARVs. Abacavir is associated with a potentially fatal hypersensitivity reaction, strongly associated with the presence of HLA-B*5701, usually within the first 6 weeks of treatment. There may be a discrete rash and often a fever, coupled with general malaise and gastrointestinal and respiratory symptoms. The diagnosis is clinical and symptoms resolve when abacavir is withdrawn. Re-challenge with abacavir can be fatal and is contraindicated. In the UK, routine screening for the HLA-B*5701 allele has reduced the incidence of abacavir hypersensitivity. Allergies to NNRTIs (often in the second or third week of treatment) usually present with a widespread maculopapular pruritic rash, often with a fever and disordered liver biochemical tests. Reactions can resolve, even with continuing therapy, but drugs should be stopped immediately in any patient with mucous membrane involvement or severe hepatic dysfunction.

**Lipodystrophy and metabolic syndrome**
A syndrome of lipodystrophy occurs in patients with HIV on ART, comprising characteristic morphological changes and metabolic abnormalities. The main characteristics include a loss of subcutaneous fat in the arms, legs and face (lipoatrophy), deposition of visceral, breast and local fat, raised total cholesterol, HDL cholesterol and triglycerides, and insulin resistance with hyperglycaemia. The syndrome is potentially associated with increased cardiovascular morbidity. The highest incidence occurs in those taking combinations of NRTIs and PIs. The older drugs, stavudine and zidovudine, are associated with the lipoatrophy component of the process. Dietary advice and increase in exercise may improve some of the metabolic problems and help body shape. Statins and fibrates are recommended to reduce circulating lipids. Simvastatin is contraindicated, as it has high levels of drug interactions with PIs.

**Mitochondrial toxicity and lactic acidosis**

Mitochondrial toxicity, mostly involving the older drugs, stavudine and didanosine, in the nucleoside analogue class, leads to raised lactate and lactic acidosis, which has, in some cases, been fatal. NRTIs inhibit gamma-DNA polymerase and other enzymes that are necessary for normal mitochondrial function. Symptoms are often vague and insidious, and include anorexia, nausea, abdominal pain and general malaise. Venous lactate is raised and the anion gap is typically widened. This is a serious condition, requiring immediate cessation of ART and provision of appropriate supportive measures until normal biochemistry is restored. All patients should be alerted to the possible symptoms and encouraged to attend hospital promptly.

**Bone metabolism**

A variety of bone disorders have been reported in HIV: in particular, osteopenia, osteoporosis and avascular necrosis. The prevalence of these conditions has varied widely in different studies. ARVs, particularly PIs, have been implicated in the aetiology, although untreated HIV is believed to have a direct impact on bone metabolism.

**IRIS**

Paradoxical inflammatory reactions (immune reconstitution inflammatory syndrome, IRIS) may occur on initiating ART. This occurs usually in people who have been profoundly immunosuppressed and begin therapy. As their immune system recovers, they are able to mount an inflammatory response to a range of pathogens, which can include exacerbation of symptoms with new or worsening clinical signs. Examples include unusual mass lesions or lymphadenopathy associated with mycobacteria, including deteriorating radiological appearances associated with tuberculosis infection. Inflammatory retinal lesions in association with cytomegalovirus, deterioration in liver function in chronic hepatitis B carriers, and vigorous vesicular eruptions with herpes zoster have also been described. To avoid this situation, certain pathogens, in particular *Mycobacterium tuberculosis* and *Cryptococcus*, should be treated for several weeks to reduce the microbiological burden before ARVs are initiated.
Specific therapeutic situations

**Acute seroconversion**

ART in patients presenting with an acute seroconversion illness is controversial. This stage of disease may represent a unique opportunity for therapy, as there is less viral diversity and the host immune capacity is still intact. There is evidence to show that the viral load can be reduced substantially by aggressive therapy at this stage, although it rises when treatment is withdrawn. The longer-term clinical sequelae of treatment at this stage remain uncertain. People with severe symptoms during primary HIV infection may gain a clinical improvement on ARVs. If treatment is contemplated in this situation, then it should be assumed that it will be continued for the long term.

**Pregnancy**

In the UK, the mother-to-child HIV transmission rate is 1% for all women diagnosed prior to delivery and 0.1% for women on ART with a viral load of <50 copies/mL. Management of HIV-positive pregnant women requires close collaboration between obstetric, medical and paediatric teams. The management aim is to deliver a healthy, uninfected baby to a healthy mother without prejudicing the future treatment options of the mother. Although considerations of pregnancy must be factored into clinical decision-making, pregnancy *per se* should not be a contraindication to providing optimum HIV-related care for the woman. HIV-positive women are advised against breast-feeding, which doubles the risk of vertical transmission. Delivery by caesarean section reduced the risk of vertical transmission in the pre-highly active anti-retroviral therapy (HAART) era, but if the woman is on effective ART and the labour is uncomplicated, vaginal delivery carries no additional risk. Women conceiving on an effective ART regimen should continue on their medication. For women naive to therapy who require treatment of their own HIV, whether pregnant or not, triple therapy is the regimen of choice. Risk of vertical transmission increases with viral load. Although the fetus will be exposed to more drugs, the chances of reducing the viral load, and hence preventing infection, are greatest with a potent triple therapy regimen in the mother. In this situation, *treatment* should start as soon as possible and continue during delivery. The baby should receive zidovudine for 4 weeks postpartum and the mother should remain on ARVs with appropriate monitoring and support.

Women who do not need treatment for themselves should be prescribed a short course of ART, initiated at the beginning of the second trimester if the baseline viral load is >30 000 HIV RNA copies/mL. Consideration should be given to starting earlier if the viral load is >100 000 HIV RNA copies/mL.

**Post-exposure prophylaxis**

The time taken for HIV infection to become established after exposure offers an opportunity for prevention. Animal models provide support for the use of triple ARVs for post-exposure prophylaxis (PEP) but there are no prospective trials to inform the best approach and each
situation should be evaluated on a case-by-case basis to estimate the potential risk of infection and potential treatment benefit.

Healthcare workers may be treated following occupational exposure to HIV, as may those exposed sexually. The risk of acquisition of HIV following exposure is dependent on the risk that the source is HIV-positive (if this is unknown in a sexual exposure) and the risk of transmission of the particular exposure. PEP may be useful up to 72 hours after possible exposure. In the UK, the standard regimen is Truvada plus raltegravir, although this may be varied depending on what is known about the source. When the source patient is known to have an undetectable HIV viral load (<200 copies HIV RNA/mL), PEP is not recommended.

Treatment is given for 4 weeks and the recipient should be monitored for toxicity. The at-risk patient should be tested for established HIV infection before PEP is dispensed. Rapid point-of-care tests are particularly useful in this setting. PEP following sexual exposure should not be seen as a substitute for other methods of prevention. Pre-exposure prophylaxis is discussed on page 355.

Towards cure

Current therapy, although effective, is life-long, expensive and complex. There is increasing interest in the possibilities of a cure for HIV: either a ‘functional’ cure, which would mean long-term control of the virus without the use of drugs, or a ‘sterilizing’ cure, which would require all HIV-containing cells to be eliminated. Several reports of successful interventions exist. These include a patient with HIV infection who underwent bone marrow transplantation for acute myeloid leukaemia (the ‘Berlin Patient’), interventions very early in the course of the infection, which may allow immune function to be preserved. Ways are being explored in which latently infected T cells could be purged. The possibilities are being studied of making cells resistant to new HIV infection, using gene manipulation to alter the CCR5 receptor that mediates viral entry into the cell. Despite some early encouraging results, it is clear that there is still a very long way to go and that, at least for the moment, there is no realistic alternative to life-long ART.

Opportunistic infections in the ART era

Although effective ART has resulted in a remarkable decline in opportunistic infections in patients with HIV, not all those at risk may be either on or adhering to effective treatment. In 2009, 19% of those newly diagnosed with HIV in the UK had a CD4 count of <200 cells/mm³ at presentation, and over 25% of those living with HIV remain undiagnosed, making late presentation and opportunistic infections more likely. In parallel, the types of infection seen in the context of HIV have altered, with fewer episodes of the ‘classic’ opportunistic infections, such as Pneumocystis pneumonia and cytomegalovirus, but an increase in community-acquired infections such as Strep. pneumoniae and Haemophilus influenzae (Box 12.21).

*See Box 24.33. COPD, chronic obstructive pulmonary disease; CT, computed tomography.

Immune reconstitution with ART may produce unusual responses to opportunistic pathogens and confuse the clinical picture. Thus, prevention and treatment of opportunistic infections remains an integral part of the management of HIV infection.

**Prevention of opportunistic infection in patients with HIV**

**Avoidance of infection**

Exposure to certain organisms can be avoided in those known to be HIV-positive and immunosuppressed. Attention to food hygiene will reduce exposure to *Salmonella*, toxoplasmosis and *Cryptosporidium*, and protected sexual intercourse will reduce exposure to herpes simplex virus (HSV), hepatitis B and C viruses, and papillomaviruses. Cytomegalovirus-negative patients should be given cytomegalovirus-negative blood products. Travel-related infection can be minimized with appropriate advice.

**Immunization strategies**

Guidance on the appropriate use of vaccines in HIV (*Box 12.22*) is available from BHIVA (see ‘Further reading’). Immunization may not be as effective in HIV-positive individuals.

**Box 12.22**

**Use of vaccines in HIV-infected adults**

**Vaccines for use in all HIV-infected adults (all inactivated)**

- Anthrax
- Cholera – WC/rBS
- *Haemophilus influenzae* b (Hib)
- Hepatitis A
- Hepatitis B
- Influenza – parenteral
- Japanese encephalitis
- Meningococcus – MenC
- Meningococcus – ACWY
- Pneumococcus – PPV23
• Poliomyelitis – parenteral (IPV)
• Rabies
• Tetanus–diphtheria (Td)
• Tick-borne encephalitis
• Typhoid – ViCPS

**Vaccines contraindicated in all HIV-infected adults**

• Cholera – CVD103-HgR (live)
• Influenza – intranasal (live)
• Poliomyelitis – oral (OPV) (live)
• Smallpox (vaccinia) (live)
• Tuberculosis (BCG) (live)
• Typhoid – Ty21a (live)

**Vaccines for use only in asymptomatic HIV-infected adults with a current CD4 count >200 cells/mm³**

• Measles, mumps, rubella (MMR)
• Varicella
• Yellow fever

*(Based on BHIVA Guidelines 2006: www.bhiva.org.)*

---

Hepatitis A and B vaccines should be given to those without natural immunity who are at risk, particularly if there is coexisting liver pathology, such as hepatitis C.

**Chemoprophylaxis**

In the absence of a normal immune response, many opportunistic infections are hard to eradicate using antimicrobials and the recurrence rate is high. Primary and secondary chemoprophylaxis has reduced the incidence of many opportunistic infections. Advantages must be balanced against the potential for toxicity, drug interactions and cost, with each medication added to what are often complex drug regimens.

• Primary prophylaxis is effective in reducing the risk of *Pneumocystis jiroveci*, toxoplasmosis and *Mycobacterium avium-intracellulare*.

• Primary prophylaxis is **not** normally recommended against cytomegalovirus, herpesviruses or fungi.

  With the introduction of ART and immune reconstitution, ongoing chemoprophylaxis can be discontinued in those patients with CD4 counts that remain consistently >200 cells/mm³. In areas where effective ART may not be available, long-term secondary prophylaxis still has a role. Other less severe but recurrent infections may also warrant prophylaxis (e.g. herpes

**Specific Conditions Associated with HIV Infection**

**Fungal infections**
Pneumocystis jiroveci infection

*Pneumocystis jiroveci* most commonly causes pneumonia (PCP; see p. 1106) but can cause disseminated infection. It is not usually seen until patients are severely immunocompromised with a CD4 count <200 cells/mm$^3$. The introduction of effective ART and primary prophylaxis in patients with CD4 counts of <200 cells/mm$^3$ has significantly reduced the incidence in the UK. The organism damages alveolar epithelium, which impedes gas exchange and reduces lung compliance.

The onset is often insidious over a period of weeks, with a prolonged period of increasing shortness of breath (usually on exertion), non-productive cough, fever and malaise. **Clinical features** on examination include tachypnoea, tachycardia, cyanosis and signs of hypoxia. Fine crackles are heard on auscultation, although in mild cases there may be no auscultatory abnormality. In early infection, the chest X-ray is normal but the typical appearances are of bilateral perihilar interstitial infiltrates, which can progress to confluent alveolar shadows throughout the lungs. High-resolution CT scans of the chest demonstrate a characteristic ground-glass appearance, even when there is little to see on the chest X-ray. The patient is usually hypoxic and desaturates on exercise. Definitive diagnosis rests on demonstrating the organisms in the lungs via bronchoalveolar lavage or by PCR amplification of the fungal DNA from a peripheral blood sample. As the organism cannot be cultured *in vitro*, it must be directly observed either with silver staining or with immunofluorescent techniques.

**Treatment** should be instituted as early as possible. First-line therapy is with intravenous co-trimoxazole (120 mg/kg daily in divided doses) for 21 days. Up to 40% of patients receiving this regimen will develop some adverse drug reaction, including a typical allergic rash. If the patient is sensitive to co-trimoxazole, intravenous pentamidine (4 mg/kg per day) or dapsone and trimethoprim is given for the same duration. Atovaquone or a combination of clindamycin and primaquine is also used. In severe cases ($P_aO_2 < 9.5$ kPa), systemic corticosteroids reduce mortality and should be added. Continuous positive airways pressure (CPAP) or mechanical ventilation (see pp. 1165–1166) is required if the patient remains severely hypoxic or becomes too tired. Pneumothorax may complicate the clinical course in an already severely hypoxic patient. If not already on ART, this should be initiated early in the course of infection.

**Secondary prophylaxis** is required in patients whose CD4 count remains <200 cells/mm$^3$, to prevent relapse, the usual regimen being co-trimoxazole 960 mg three times a week. Patients sensitive to sulphonamide are given dapsone, pyrimethamine or nebulized pentamidine. The last protects only the lungs and does not penetrate the upper lobes particularly efficiently; hence, if relapses occur on this regimen, they may be either atypical or extrapulmonary.

Cryptococcosis

The most common presentation of cryptococcal infection (see p. 296) in the context of HIV is meningitis, although pulmonary and disseminated infections can also occur. The organism, *C.*
*C. neoformans*, is widely distributed, often in bird droppings, and is usually acquired by inhalation. The onset may be insidious with non-specific fever, nausea and headache. As the infection progresses, the conscious level is impaired and changes in affect may be noted. Fits or focal neurological presentations are uncommon. Neck stiffness and photophobia may be absent, as these signs depend on the inflammatory response of the host, which, in this setting, is abnormal.

**Diagnosis** is made on examination of the CSF (perform a CT scan before lumbar puncture to exclude space-occupying pathology). Indian ink staining shows the organisms directly and CSF cryptococcal antigen is positive at variable titre. It is unusual for the cryptococcal antigen to become negative after treatment, although the levels should fall substantially. Cryptococci can also be cultured from CSF and/or blood.

Factors associated with a poor prognosis include a high organism count in the CSF, a low white cell count in the CSF, and an impaired consciousness level at presentation.

Initial **treatment** is usually with intravenous liposomal amphotericin B (4.0 mg/kg per day) with or without flucytosine as induction, although intravenous fluconazole (400 mg daily) is useful if renal function is impaired or if amphotericin side-effects are troublesome.

Patients diagnosed with cryptococcal disease should receive ART, starting at approximately 2 weeks after commencement of cryptococcal treatment, to minimize the risk of IRIS.

## Candidiasis

Mucosal infection, particularly oral, with *Candida* (see p. 295) is common in immunosuppressed HIV-positive patients. *C. albicans* is the usual organism, although *C. krusei* and *C. glabrata* occur. Pseudomembranous candidiasis, consisting of creamy plaques in the mouth and pharynx, is easily recognized but erythematous *Candida* appears as reddened areas on the hard palate or as atypical areas on the tongue. Angular cheilitis can occur in association with either form. Vulvovaginal *Candida* may be difficult to treat.

Oesophageal *Candida* infection produces odynophagia (see p. 366). Fluconazole or itraconazole is the agent of choice for **treatment**. Disseminated *Candida* is uncommon in the context of HIV infection, but if present, fluconazole is the preferred drug; amphotericin, voriconazole or caspofungin is also used. *C. krusei* may colonize patients who have been treated with fluconazole, as it is fluconazole-resistant. Amphotericin is useful in the treatment of this infection, and an attempt to type *Candida* from clinically azole-resistant patients should be made. The most successful strategy for managing HIV-positive patients with candidiasis is effective ART.

## Aspergillosis

Infection with *Aspergillus fumigatus* (see pp. 295–296) is rare in HIV, unless there are coexisting factors, such as lung pathology, neutropenia, transplantation or glucocorticoid use. Spores are air-borne and ubiquitous. Following inhalation, lung infection proceeds to haematogenous spread to other organs. Sinus infection occurs.
Voriconazole is the preferred treatment, with liposomal amphotericin B (3 mg/kg i.v. daily) as an alternative. Caspofungin is also effective.

### Histoplasmosis, blastomycosis, coccidioidomycosis and *Penicillium marneffei* infection

These fungal infections are geographically restricted but should be considered in HIV-positive patients who have travelled to areas of high risk. The most common manifestation is with pneumonia, which may be confused with *Pneumocystis jiroveci* in its presentation (see above), although systemic infection is reported, particularly with *Penicillium*, which can also produce papular skin lesions. Treatment is with amphotericin B.

### Protozoal infections

#### Toxoplasmosis

*Toxoplasma gondii* (see p. 305) most commonly causes encephalitis and cerebral abscess in the context of HIV, usually as a result of reactivation of previously acquired infection. The incidence depends on the rate of seropositivity to toxoplasmosis in the particular population. High antibody levels are found in France (90% of the adult population). About 25% of the adult UK population is seropositive to *Toxoplasma*. Clinical features include a focal neurological lesion and convulsions, fever, headache and possible confusion. Examination reveals focal neurological signs in more than 50% of cases. Eye involvement with chorioretinitis may also be present. In most, but not all, cases of *Toxoplasma*, serology is positive. Typically, contrast-enhanced CT scan of the brain shows multiple ring-enhancing lesions. A single lesion on CT may be found to be one of several on MRI. A solitary lesion on MRI, however, makes a diagnosis of toxoplasmosis unlikely.

**Diagnosis** is by characteristic radiological findings on CT and MRI. Single photon emission computed tomography (SPECT) may also be helpful differentiating toxoplasmosis from primary CNS lymphoma. In most cases, an empirical trial of anti-toxoplasmosis therapy is instituted; if this leads to radiological improvement within 3 weeks, this is considered diagnostic. The differential diagnosis includes cerebral lymphoma, tuberculoma or focal cryptococcal infection.

**Treatment** is with pyrimethamine for at least 6 weeks (loading dose 200 mg, then 50 mg daily), combined with sulfadiazine and folic acid. Clindamycin and pyrimethamine may be used in patients allergic to sulphonamide.

ART should be initiated as soon as the patient is clinically stable, approximately 2 weeks after acute treatment has begun to minimize the risk of IRIS.

#### Cryptosporidiosis

*Cryptosporidium parvum* (see p. 307) can cause a self-limiting acute diarrhoea in an
immunocompetent individual. In HIV infection, it can cause severe and progressive watery diarrhea, which may be associated with anorexia, abdominal pain, and nausea and vomiting. In the era of ART, the infection is rare. Cysts attach to the epithelium of the small bowel wall, causing secretion of fluid into the gut lumen and failure of fluid absorption. It is also associated with sclerosing cholangitis (see pp. 476–477). The cysts are seen on stool specimen microscopy using Kinyoun acid-fast stain and are readily identified in small bowel biopsy specimens. ART is associated with complete resolution of infection following restoration of immune function; otherwise, treatment is largely supportive. Nitazoxanide may have some effect.

### Microsporidiosis

Enterocytozoon bieneusi and Septata intestinalis are causes of diarrhoea. Spores can be detected in stools using a trichrome or fluorescent stain that attaches to the chitin of the spore surface. ART and immune restoration constitute the treatment of choice and can have a dramatic effect.

### Leishmaniasis

Leishmaniasis (see pp. 303–305) occurs in immunosuppressed HIV-positive individuals who have been in endemic areas, which include South America, tropical Africa and much of the Mediterranean. Symptoms are frequently non-specific, with fever, malaise, diarrhoea and weight loss. Splenomegaly, anaemia and thrombocytopenia are significant findings. Amastigotes may be seen on bone marrow biopsy or from splenic aspirates. Serological tests exist for Leishmania but they are not reliable in this setting.

**Treatment** is with liposomal amphotericin, the drug of choice, and ART once the patient is stable. Relapse is common without ART, in which case long-term secondary prophylaxis may be given.

### Viral infections

#### Hepatitis B and C virus co-infection with HIV

Because of the comparable routes of transmission of hepatitis viruses (see pp. 454–455 and 459) and HIV, co-infection is common, particularly in MSM, drug users and those infected by blood products. A higher prevalence of hepatitis viruses is found in those with HIV infection than in the general population. Globally, estimates suggest that 5–15% of people with HIV have chronic hepatitis B virus (HBV) infection and about one-third have hepatitis C virus (HCV) infection. In the UK, 6.9% of adults with HIV are also estimated to be HBsAg-positive. A global epidemic of acute hepatitis C has been observed over the past decade amongst HIV-positive MSM.

As treatment advances have improved HIV prognosis, hepatitis virus co-infection has
become an increasingly significant cause of morbidity and mortality, making the management of HIV and hepatitis co-infection a necessary aspect of clinical care.

All those with newly diagnosed HIV should be screened for hepatitis A, B and C; for those without evidence of immunity, hepatitis A and B vaccines should be provided.

Patients with HIV and hepatitis co-infection are more likely to have rapid liver disease progression than people with mono-infection. In all patients with chronic HCV/HIV and HBV/HIV infections, liver disease should be staged (see p. 452) For those who are likely to have cirrhosis, appropriate monitoring for complications of portal hypertension and HCV screening should be performed. Patients with HIV and liver disease should be jointly managed by clinicians from HIV and hepatitis backgrounds. For people with end-stage liver disease, care should be based in specialist centres, ideally with link to a transplant unit.

In co-infected patients, the hepatotoxicity associated with certain ARVs may be potentiated. Advice on alcohol use and safer sexual practices should be given to all co-infected patients.

**Hepatitis B infection**

Hepatitis B infection (see pp. 454–457) does not appear to influence the natural history of HIV or responses to anti-HIV treatment; however, in HIV co-infected patients, there is a significantly reduced rate of hepatitis B e antigen (HBeAg) clearance, the HBV viral load is higher, and the risk of developing chronic infection is increased. In those with resolved or controlled hepatitis B infection, disease may reactivate. Liver disease occurs most commonly in those with high HBV DNA levels indicative of continuing replication. In HBV infection, detection and quantification of HBV DNA act as a marker of viral activity and are predictive of response to treatment. Baseline HBV resistance testing may guide interventions in those previously exposed to antiviral drugs.

Decisions about whether HBV and/or HIV require treatment must be based on assessment of both viruses. All treatments for HBV that include agents with concomitant anti-HIV activity, including tenofovir and emtricitabine, must be used within an effective anti-HIV regimen. UK guidelines recommend that ART inclusive of anti-HBV-active agents should be initiated in all co-infected patients with a CD4 count of <500 cells/mm³, or with evidence of fibrotic liver damage or with active HBV replication. Patients with a CD4 of ≥500 cells/mm³, an HBV DNA of <2000 IU/mL, and minimal or no evidence of fibrosis can be given the option to commence treatment or to be monitored not less than 6-monthly with HBV DNA and measurement of alanine aminotransferase (ALT), and at least yearly for evidence of fibrosis. Initiation of ART may result in a flare of HBV resulting from the improved immune function. If ART is not indicated for HIV and the CD4 count is ≥500 cells/mm³, the approach to HBV treatment may include the use of HBV-exclusive agents pegylated interferon and adefovir to avoid inducement of HIV resistance.

**Hepatitis C infection**

Hepatitis C is associated with more rapid progression of HIV infection and the CD4 responses to ART in co-infected patients may be blunted. Hepatitis C progression is both more likely and
more rapid in the presence of HIV infection, and the hepatitis C viral load tends to be elevated. The drug-related hepatotoxicity may be worse in those with HCV co-infection. Assessment of co-infected patients requires full clinical and laboratory evaluation and staging of both infections. For HCV, both viral load and genotype will influence therapeutic decision-making.

*Treatment* is a rapidly changing and complex field with increasing availability of direct-acting antivirals (DAAs) for the treatment of hepatitis C.

All HIV/HCV co-infected patients should be given the option to commence ART. For those with CD4 cell counts of <500 cells/mL, irrespective of whether HCV treatment is planned or not, ART should be initiated. If HCV therapy is planned, then for those with CD4 cell counts between 350 and 500 cells/mL, ART should be started first. Patients with a CD4 cell count of >500 cells/mL, including those who defer hepatitis C therapy, should be given the option to commence ART. If they opt to defer, they should be monitored closely for HIV or hepatitis C disease progression, including at least an annual assessment of liver fibrosis.

All patients with HCV/HIV infection should be assessed for suitability for treatment of hepatitis C. The drug options for HCV in individuals with co-infection are similar to the choices for those infected with HCV alone (see pp. 460–461), depending on the stage of disease, HCV genotype and co-administered ART. The introduction of DAAs for HCV has changed the treatment landscape. The latest HCV agents (see pp. 460–461) are given for 12 weeks with response rates of more than 90%.

When DAAs are chosen, some restriction on first-line ARV choice exists due to drug–drug interactions. The ritonavir-boosted AbbVie regimen may interact with commonly used HIV medications and there are reports of an interaction between tenofovir and sofosbuvir. Careful selection of the most effective combination of antivirals is required and expert opinion should be sought. Online information resources (see ‘Further reading’) provide data on possible interactions.

All those with HIV/HCV co-infection who defer treatment should undergo hepatic elastography (see p. 446) or an alternative non-invasive form of monitoring at least annually.

*Acute hepatitis C* has increased in people with HIV, particularly MSM, and recognized epidemics have been reported in a number of countries, including the UK. UK guidelines recommend that patients without a decrease of 2log10 in HCV RNA at week 4 post diagnosis of acute infection, or with a positive HCV RNA at week 12 post diagnosis of acute infection, be offered therapy for 24 weeks with pegylated interferon and ribavirin. Immune responses to HCV do not protect against re-infection, and high rates have been reported following both therapeutic and spontaneous clearance. Patients who initially clear HCV but have evidence of re-emergent virus should be assessed for relapse or re-infection; relapse is treated as for chronic HCV and re-infection is managed as for acute hepatitis C. The benefits and cost-effectiveness of the new all-oral HCV regimens in patients with acute hepatitis C have not yet been assessed but the drugs are likely to be effective, although very costly.

---

**Cytomegalovirus infection**
Cytomegalovirus (CMV; see pp. 258–259) has been the cause of considerable morbidity in HIV-positive individuals, especially in the later stages of disease when the CD4 count is consistently <100 cells/mm³. The availability of ART has dramatically altered the epidemiology, as a majority of patients start ARVs before they are at risk for CMV disease. The major problems encountered are retinitis, colitis, oesophageal ulceration, encephalitis and pneumonitis. CMV infection is associated with an arteritis, which may be the major pathogenic mechanism. CMV also causes polyradiculopathy and adrenalitis.

**CMV retinitis**

This occurs once the CD4 count is <50 cells/mm³. Although usually unilateral to begin with, the infection may progress to involve both eyes. Presenting features depend on the area of retina involved (loss of vision being most common with macular involvement) and include floaters, loss of visual acuity, field loss and scotomata, orbital pain and headache.

Examination of the fundus ([Fig. 12.13](#)) reveals haemorrhages and exudates, which follow the vasculature of the retina (so-called ‘pizza pie’ appearances). The features are highly characteristic and the diagnosis is made clinically. Retinal detachment and papillitis may occasionally occur. If untreated, retinitis spreads within the eye, destroying the retina within its path. Routine fundoscopy should be carried out on all HIV-positive patients to look for evidence of early infection. Any patient with symptoms of visual disturbance should have a thorough examination with pupils dilated; if no evident pathology is seen, a specialist ophthalmological opinion should be sought.

![FIGURE 12.13 Untreated cytomegalovirus retinitis.](#)

*Treatment* for CMV should be started as soon as possible, with either oral valganciclovir (900 mg twice daily), i.v. ganciclovir (5 mg/kg twice daily), or foscarnet (90 mg/kg twice daily) given intravenously for at least 3 weeks or until retinitis is quiescent. If immunosuppression is not reversed, reactivation is common, leading to blindness. The major
side-effect of ganciclovir is myelosuppression, and foscarnet is nephrotoxic. Maintenance therapy may be required until ART is instituted and has improved immune competence. Valganciclovir, an oral prodrug of ganciclovir, has some long-term benefit when used as maintenance therapy, but a lower efficacy than intravenous ganciclovir. Ganciclovir can be given directly into the vitreous cavity but regular injections are required. A sustained-release implant of ganciclovir can be surgically inserted into the affected eye. Cidofovir is available for use when the above drugs are contraindicated. It has renal toxicity.

**CMV gastrointestinal conditions**

*CMV colitis* usually presents with abdominal pain, often generalized or in the left iliac fossa, diarrhoea that may be bloody, generalized abdominal tenderness and a low-grade fever. Dilated large bowel may be seen on abdominal X-ray. Sigmoidoscopy shows a friable or ulcerated mucosa; histology shows the characteristic ‘owl’s eye’ cytoplasmic inclusion bodies (see *Fig. 11.21*).

*Treatment* is with i.v. ganciclovir (5 mg/kg twice daily) for 14–28 days; when stable, optimization of ART improves symptoms and the histological changes are reversed. Restoration of immune competence with ART removes the need for maintenance therapy.

*Other sites* along the gastrointestinal tract are also prone to CMV infection: for example, ulceration of the oesophagus, usually in the lower third, causes odynophagia. CMV can also cause hepatitis.

**CMV neurological conditions**

*CMV encephalopathy* has clinical similarities to that caused by HIV itself, although it tends to be more aggressive in its course. *CMV polyradiculopathy* can affect the lumbosacral roots, leading to muscle weakness and sphincter disturbance. The CSF has an increase in white cells, which, surprisingly, are almost all neutrophils. Although progression may be arrested by anti-CMV medication, functional recovery may not occur. Diagnosis may be based on MRI and CSF PCR. *Treatment* is with ganciclovir. ART should be started after anti-CMV treatment.

### Herpesvirus infection

**Herpes simplex primary infection** (see pp. 247–249) occurs with greater frequency and severity, presenting in an ulcerative rather than vesicle form in profoundly immunosuppressed individuals. Genital, oral and occasionally disseminated infection is seen. Viral shedding may be prolonged in comparison with immunocompetent patients.

### Varicella zoster virus infection

Varicella zoster can occur at any stage of HIV but tends to be more aggressive and longer-lasting in the more immunosuppressed patient. Multidermatomal zoster may occur.

*Treatment* with aciclovir is usually effective. Frequent recurrences need suppressive therapy. Aciclovir-resistant strains (usually due to thymidine kinase-deficient mutants) in HIV-
positive patients have become more common. Such strains may respond to foscarnet.

*Herpesvirus 8 (HHV-8)* is the causative agent of Kaposi’s sarcoma (see p. 265).

### Epstein–Barr virus infection

Patients with HIV have been shown to have high levels of Epstein–Barr virus (EBV) colonization (see p. 258). There are increased EBV titres in oropharyngeal secretions and high levels of EBV-infected B cells. The normal T-cell response to EBV is depressed in HIV. EBV is strongly associated with primary cerebral lymphoma and non-Hodgkin's lymphoma (see below). Oral hairy leukoplakia caused by EBV is a sign of immunosuppression first noted in HIV but now also recognized in other conditions. It appears intermittently on the lateral borders of the tongue or the buccal mucosa as a pale, ridged lesion. Although it is usually asymptomatic, patients may find it unsightly and occasionally painful. The virus can be identified histologically and on electron microscopy. There is a variable response to *treatment* with aciclovir.

### Human papillomavirus infection

Human papillomavirus (HPV; see p. 326) produces genital, plantar and occasionally oral warts, which may be slow to respond to therapy and recur repeatedly. HPV is associated with the more rapid development of cervical and anal intraepithelial neoplasia, which in time may progress to squamous cell carcinoma of the cervix or rectum in HIV-positive individuals. HPV vaccination is now available (see p. 326).

### Polyomavirus infection

JC virus, a member of the papovavirus family, which infects oligodendrocytes, causes progressive multifocal leucoencephalopathy (PML; see p. 263). This leads to demyelination, particularly within the white matter of the brain. The features are of progressive neurological and/or intellectual impairment, often including hemiparesis or aphasia. The course is usually inexorably progressive but a stuttering course may be seen. Radiologically, the lesions are usually multiple and confined to the white matter. They do not enhance with contrast and do not produce a mass effect. MRI *(Fig. 12.14)* is more sensitive than CT and reveals enhanced signal on T2-weighted images of the lesions. MRI appearances and JC virus detection by PCR in a CSF sample are usually sufficient for diagnosis and avoid the need for a tissue diagnosis requiring brain biopsy. There is no specific *treatment*. Effective ART is the only intervention that has been shown to deliver both clinical and radiological remission.
Bacterial infections

Bacterial infection in HIV is common. Cell-mediated immune responses normally control infection against intracellular bacteria, e.g. mycobacteria. The abnormalities of B-cell function associated with HIV lead to infections with encapsulated bacteria, as reduced production of IgG2 cannot protect against the polysaccharide coat of such organisms. These functional abnormalities may be present well before there is a significant decline in CD4 numbers and so bacterial sepsis may be seen at early stages of HIV infection. *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Moraxella catarrhalis* infections are examples. Bacterial infection is often disseminated and, although usually amenable to standard antibiotic therapy, may reoccur. Long-term prophylaxis is required if recurrent infection is frequent.

*Mycobacterium tuberculosis* infection

Many parts of the world, such as Africa, that have a high prevalence of tuberculosis (TB; see p. 290) also have high rates of HIV infection, both of which are increasing. The respiratory transmission of TB means both HIV-positive and HIV-negative people are being infected. TB can cause disease when there is only minimal immunosuppression and thus often appears early in the course of HIV infection. HIV-related TB frequently represents reactivation of latent TB, but there is also clear evidence of newly acquired infection and hospital-acquired spread in HIV-positive populations.

The pattern of disease differs with immunosuppression:

- Patients with relatively well-preserved CD4 counts have a clinical picture similar to that seen in HIV-negative patients with pulmonary infection.
- In more advanced HIV disease, atypical pulmonary presentations occur without cavitation and prominent hilar lymphadenopathy, or extrapulmonary TB affecting lymph nodes, bone marrow or liver. Bacteraemia may be present.

**Diagnosis** depends on demonstrating the organisms in appropriate tissue specimens. The response to tuberculin testing is blunted in HIV-positive individuals and is unreliable. Sputum
microscopy may be negative, even in pulmonary infection, and culture techniques are the best diagnostic tool.

*M. tuberculosis* infection usually responds well to standard *treatment* regimens, although the duration of therapy may be extended, especially in extrapulmonary infection. Multidrug resistant and extensive drug-resistant TB (see p. 290) is becoming a problem, particularly in the USA, where it is developing into a health danger. Cases from HIV units in the UK have been reported. Compliance with anti-tuberculous therapy needs to be emphasized. Treatment of TB (see below) is not curative and long-term isoniazid prophylaxis may be given. In patients from TB-endemic areas, primary prophylaxis may prevent the emergence of infection.

**Drug–drug interactions** between anti-retroviral and anti-tuberculous medications are complex and are a consequence of enzyme induction or inhibition. Rifampicin is a potent inducer of cytochrome P450, which is also the route for metabolism of HIV PIs. Using both drugs together results in a reduction in circulating PI with reduced efficacy and increased potential for drug resistance. Some PIs themselves block cytochrome P450, which leads to potentially toxic levels of rifampicin and problems such as uveitis and hepatotoxicity. The NNRTI class also interacts variably with rifamycins, requiring dose alterations. Additionally, there are overlapping toxicities between ART regimens and anti-tuberculous drugs, in particular hepatotoxicity, peripheral neuropathy and gastrointestinal side-effects. Rifabutin has a weaker effect on cytochrome P450 and may be substituted for rifampicin. Dose adjustments must be made for drugs used in this situation to take account of these interactions.

**Paradoxical inflammatory reactions** (IRIS), which can include exacerbation of symptoms, new or worsening clinical signs, and deteriorating radiological appearances, have been associated with the improvement of immune function seen in HIV-positive patients starting ART in the face of *M. tuberculosis* infection. They are most commonly seen in the first few weeks after initiation of ART in patients recovering from TB and can last several weeks or months. The syndrome does not reflect inadequate TB therapy and is not confined to any particular combination of ARVs. It is vital to exclude new pathology in this situation. However, delaying ART increases the risks of further opportunistic events. Allowing at least 2 weeks of anti-tuberculous therapy before commencing ART allows some reduction in the burden of mycobacteria. If the CD4 count is <100 cells/mm³, then ARVs should be started at about 2 weeks of anti-tuberculous medication. If the CD4 count is >200 cells/mm³, then initiation of ART may be delayed for at least 6 weeks after the start of anti-tuberculous therapy.

**Mycobacterium avium-intracellulare infection**

Atypical mycobacteria, particularly *M. avium-intracellulare* (MAI), generally appear only in the very late stages of HIV infection when patients are profoundly immunosuppressed. MAI is a saprophytic organism of low pathogenicity that is ubiquitous in soil and water. Entry may be via the gastrointestinal tract or lungs with dissemination via infected macrophages.

The major **clinical features** are fevers, malaise, weight loss, anorexia and sweats. Dissemination to the bone marrow causes anaemia. Gastrointestinal symptoms may be
prominent with diarrhoea and malabsorption. At this stage of disease, patients frequently have other concurrent infections, so differentiating MAI is difficult on clinical grounds. Direct examination and culture of blood, lymph node, bone marrow or liver give the diagnosis most reliably.

MAI is typically resistant to standard anti-tuberculous treatments, although ethambutol may be useful. Drugs such as rifabutin in combination with clarithromycin or azithromycin reduce the burden of organisms and, in some, ameliorate symptoms. A common combination is ethambutol, rifabutin and clarithromycin. Addition of amikacin to a drug regimen may produce a good symptomatic response. Primary prophylaxis with rifabutin or azithromycin may delay the appearance of MAI, but no corresponding increase in survival has been shown.

Infections due to other organisms

Influenza virus A (IVA) is no more frequent in HIV-positive people, but has been associated with an increased severity and complication rate in those with HIV, in particular when CD4 counts are low. Oseltamivir oral 75 mg twice daily for 5 days should be used as treatment. People with HIV should be vaccinated annually against IVA. Prophylaxis with oseltamivir is used in unvaccinated individuals with a CD4 count <200 cells/mm³.

Salmonellae (non-typhoidal; see p. 275) are much less frequent pathogens in HIV infection if effective ART is being used. Salmonellae are able to survive within macrophages, this being a major factor in their pathogenicity. Organisms are usually acquired orally and frequently result in disseminated infection. Gastrointestinal disturbance may be disproportionate to the degree of dissemination, and once the pathogen is in the bloodstream, any organ may be infected. Salmonella osteomyelitis and cystitis have been reported. Diagnosis is from blood and stool cultures. Despite increasing reports of resistance, a majority of isolates are sensitive to oral ciprofloxacin 500 mg twice daily for 5 days. Education on food hygiene should be provided.

Skin conditions, such as folliculitis, abscesses and cellulitis, are common and are usually caused by Staph. aureus. Periodontal disease, which may be necrotizing, causes pain and damage to the gums. It is more common in smokers but no specific causative agent has been identified. Therapy is with local debridement and systemic antibiotics.

Strongyloides (see pp. 311–312), a nematode found in tropical areas, may produce a hyper-infection syndrome in HIV-positive patients. Larvae are produced, which invade through the bowel wall and migrate to the lung and occasionally to the brain. Albendazole or ivermectin may be used to control infection. Gram-negative septicaemia can develop (see p. 311).

Scabies (see p. 1347) may be much more severe in HIV infection. It may be widely disseminated over the body and appear as atypical, crusted papular lesions known as ‘Norwegian scabies’, from which mites are readily demonstrated. Superadded staphylococcal infection may occur. Treatment with conventional agents, such as lindane, may fail and ivermectin has been used to good effect in some patients.

Neoplasms
HIV infection is associated with an increased risk of cancer, the most tightly linked being Kaposi's sarcoma, non-Hodgkin's lymphoma and cervical cancer, which are AIDS-defining. Other cancers that have an association with infectious agents, such as liver and anal cancer and Hodgkin's lymphoma, although not AIDS-defining, are significantly more common in HIV-positive patients. Patterns are changing and there has been a marked reduction in AIDS-defining malignancy in association with effective ART. The increased longevity for people with HIV increases the risks for development of cancers that are associated with older age. Some data suggest that ART may provide some prevention benefits for non-AIDS-defining malignancies.

### Kaposi's sarcoma

Kaposi's sarcoma (KS; see pp. 1374–1375) in association with HIV (epidemic KS) behaves more aggressively than that associated with HIV-negative populations (endemic KS). The incidence has fallen significantly since the introduction of ART. Human herpesvirus 8 (HHV-8) is involved in the pathogenesis. KS skin lesions are characteristically pigmented and well circumscribed, occurring in multiple sites. KS is a multicentric tumour consisting of spindle cells and vascular endothelial cells, which together form slit-like spaces in which red blood cells become trapped. This process is responsible for the characteristic purple hue of the tumour. In addition to the skin lesions, KS affects lymphatics and lymph nodes, the lung and gastrointestinal tract, giving rise to a wide range of symptoms and signs. Most patients with visceral involvement also have skin or mucous membrane lesions. Visceral KS carries a worse prognosis than disease confined to the skin. KS is seen around the eye (Fig. 12.15), particularly in the conjunctivae, which can lead to periorbital oedema.

![Figure 12.15 Kaposi's sarcoma of the eyelid.](image)

ART leads to regression of lesions. Local radiotherapy gives good results in skin lesions
and is helpful in lymph node disease. In aggressive disease, systemic chemotherapy is indicated.

### Lymphoma

A significant proportion of patients with HIV develop lymphoma, mostly of the non-Hodgkin's, large B-cell type. These are frequently extranodal, often affecting the brain, lung and gastrointestinal tract. Many of these tumours are strongly associated with Epstein–Barr virus, with evidence of expression of latent gene nuclear antigens such as EBNA 1–6, some of which are involved in the immortalization of B cells and drive a neoplastic pathway.

HIV-associated lymphomas are frequently very aggressive. Patients often present with systemic ‘B’ syndromes and progress rapidly, despite chemotherapy. Primary cerebral lymphoma is variably responsive to radiotherapy but overall carries a poor prognosis. Lymphomas occurring early in the course of HIV infection tend to respond better to therapy and carry a better prognosis, occasionally going into complete remission.

### Cervical carcinoma

Women with HIV are at increased risk of cervical cancer caused by oncogenic subtypes of human papillomavirus. Annual cervical cytology is indicated to monitor for pre-malignant changes.

### Further reading

Prevention and Control of HIV Infection

HIV is a completely preventable infection, yet rates of new HIV infection continue and prevention measures remain fundamental to the control of the epidemic. Combinations of behavioural, biomedical and structural approaches with interventions appropriate for the particular population at risk are required. Models of the epidemic in the UK suggest that a majority of new infections are transmitted from people who are unaware of their HIV status. Reducing the high rates of undiagnosed infection through scaling-up of testing and treatment is therefore central to an effective prevention response. For those at high risk of acquisition, there needs to be an additional emphasis on the need for repeat testing, as those with early infection and a high viral load are particularly infectious. Vaccine development has been hampered by the genetic variability of the virus and the complex immune response that is required from the host, with disappointing results from trials of candidate agents.

Consistent condom use and education for behaviour change have been key strategies. Provision of clean injecting equipment has been successful in those countries where it has been implemented.

Medically performed circumcision has been shown in African studies of HIV-negative heterosexual men to reduce the female-to-male transmission of HIV by at least 50%. A more modest reduction in HIV incidence in HIV-negative women following circumcision of HIV-positive male partners has been demonstrated but only at 2 years after the procedure.

The role of ART in the prevention of infection has grown enormously in the past few years. Initiation of ART by people with HIV substantially reduces onward transmission. A 96% reduction in risk of HIV transmission from HIV-positive people to their HIV-uninfected heterosexual sexual partners has been demonstrated. Vertical transmission can be reduced to negligible levels by the use of effective ART in pregnant women.

Post-exposure prophylaxis (PEP) following sexual or occupational exposure can reduce the risk of infection if implemented promptly. The use of ARVs by people who are HIV-negative prior to potential exposure (pre-exposure prophylaxis, PrEP), to prevent acquisition of infection, has been shown to be successful in a number of clinical trial settings in MSM, although the results from similar studies amongst heterosexual women have been less successful. Daily Truvada (see p. 344) demonstrated an 86% decrease in the risk of HIV infection amongst MSM in the UK PROUD study, and a similar rate of protection when taken intermittently in the French IPERGAY trial. On the basis of these results, work is required that will allow the scaling-up of access to PrEP in the UK.

Partner notification schemes are helpful but are sensitive and controversial. Availability and
accessibility of confidential HIV testing provide an opportunity for individual health education and risk reduction to be discussed.

Understanding and changing behaviour is crucial but notoriously difficult, especially in areas that carry as many taboos as sex, HIV and AIDS. Stigma, poverty, punitive legislation, social unrest and war all contribute to the spread of HIV. Political will, not always readily available, is required if progress in these areas is to be seen.

Introduction

The gastrointestinal tract has many functions, such as digestion, absorption and excretion, as well as the synthesis of hormones, growth factors and cytokines. In addition, a complex enteric
nervous system controls its function and communicates with the central and peripheral nervous systems. Finally, as the gastrointestinal tract contains the largest source of foreign antigens, it has very well-developed arms of both the innate and the acquired immune systems. The intestinal microbiota exerts a range of beneficial functions aiding nutrition, absorption and the development of a mature immune system. Disruption of the composition and diversity of the microbiota is associated with the development of gastrointestinal and systemic disease.

In developed countries, gastrointestinal symptoms are a common reason for attendance at primary care clinics and at hospital outpatient departments. Approximately 75% of these consultations are for non-organic symptoms. The clinician's main task is therefore to recognize when organic disease must be sought or excluded, remembering that 20% of all cancers occur in the gastrointestinal tract (Fig. 13.1). In developing countries, malnutrition and poor hygiene make infection a more probable diagnosis. The clinician needs to recognize and treat these infections promptly and also help with prevention.

![Relative contribution of gastrointestinal sites to all cancers.](image)

---

**Clinical Approach to the Patient with Gastrointestinal Disease**

**Clinical features of gastrointestinal disease**

**Stomatitis and halitosis**

*Stomatitis* is inflammation in the mouth from any cause. Angular stomatitis is inflammation of the corners of the mouth.

*Halitosis* (bad breath) is a common symptom and is due to poor oral hygiene, anxiety (often when halitosis is more apparent to the patient than real) or rarer causes, such as oesophageal stricture and pulmonary sepsis.
Dyspepsia and indigestion

‘Indigestion’ is common: 80% of the population will suffer from this symptom at some time. Dyspepsia is an inexact term used to describe a number of upper abdominal symptoms such as heartburn, acidity, pain or discomfort, nausea, wind, fullness or belching. Patients who use the term ‘indigestion’ may also be describing lower gastrointestinal symptoms such as constipation or the presence of undigested vegetable material in the stool, so obtaining a precise history is necessary.

Features of dyspepsia that are suggestive of serious diseases such as cancer are known as ‘alarm’ symptoms. They include:

• dysphagia
• weight loss
• vomiting
• anorexia
• haematemesis or melaena.

Patients aged ≥55 years who demonstrate these features have a higher possibility of significant gastrointestinal pathology and should be investigated on an urgent basis.

Dysphagia and odynophagia

These symptoms are described on pages 365–366.

Vomiting

Many gastrointestinal (and non-gastrointestinal) conditions are associated with vomiting (Box 13.1).

Box 13.1

Causes of vomiting: some examples

• Any gastrointestinal disease
• Infections:
  – Viral (influenza, norovirus)
  – Bacterial (pertussis, urinary infection)
• Central nervous system disease:
  – Raised intracranial pressure
  – Vestibular disturbance, e.g. motion sickness
  – Migraine
• Metabolic:
  – Uraemia
  – Hypercalcaemia
**Vomiting** is regulated by a complex reflex involving central neural control centres, located in the lateral reticular formation of the medulla, which are stimulated by the chemoreceptor trigger zones (CTZs) in the floor of the fourth ventricle, and also by vagal afferents from the gut. The central zones are directly stimulated by toxins, drugs, motion sickness and metabolic disturbances. Raised intracranial pressure has a direct effect on the vomiting centre, leading to vomiting. Luminal toxins, inflammation and mechanical obstruction are local gastrointestinal causes of vomiting.

**Nausea** is a feeling of wanting to vomit, often associated with autonomic effects, including salivation, pallor and sweating. It frequently precedes actual vomiting. Retching is a strong, involuntary, unproductive effort to vomit, associated with abdominal muscle contraction but without expulsion of gastric contents through the mouth.

**Faeculent vomiting** suggests low intestinal obstruction or the presence of a gastrocolic fistula.

**Haematemesis** is vomiting of fresh or altered blood (‘coffee-grounds’) (see pp. 384–387).

**Early morning nausea and vomiting** are seen in pregnancy, alcohol dependence and some metabolic disorders (e.g. uraemia).

**Persistent nausea** alone is often stress-related and is not due to gastrointestinal disease.

**Flatulence**
This term describes excessive wind. It is used to indicate belching, abdominal distension, gurgling and the passage of flatus per rectum. Swallowing air (aerophagia) is described on page 430. Some of the swallowed air passes into the intestine, where most of it is absorbed, but some remains to be passed rectally. Colonic bacterial breakdown of non-absorbed carbohydrate also produces gas. Rectal flatus thus consists of nitrogen, carbon dioxide, hydrogen and methane. It is normal to pass rectal flatus up to 20 times/day. Causes of increased gas production and intake include a high-fibre diet and carbonated drinks.

**Diarrhoea and constipation**
These are common complaints and in the community are not usually due to serious disease. They are described in detail on pages 425–428 and 415–417, respectively. Some general rules concerning the aetiology and investigation of diarrhoea are shown in **Box 13.2**.

---

**Box 13.2**

**Simple rules in diarrhoea**

- A single episode of diarrhoea is commonly due to dietary indiscretion or anxiety.
- Large-volume, watery stools always have an organic cause.
- Bloody diarrhoea implies colonic and/or rectal disease.
- Acute diarrhoea lasting 2–3 days is most often due to an infective cause.
- Inflammatory bowel disease should be considered for severe or prolonged symptoms.
• Stool cultures should be taken to exclude an infective cause.

Patients often consider themselves constipated if their bowels are not open on most days, though normal stool frequency is very variable, from 3 times daily to 3 times a week. The difficult passage of hard stool is also regarded as constipation, irrespective of stool frequency. Constipation with hard stools is rarely due to organic colonic disease.

**Abdominal pain**

Organic abdominal pain is stimulated mainly by the stretching of smooth muscle or organ capsules. Severe acute abdominal pain can be caused by a large number of gastrointestinal conditions, and normally presents as an emergency (see pp. 432–435). An apparent ‘acute abdomen’ can occasionally be due to referred pain from the chest, as in pneumonia, or to metabolic causes, such as diabetic ketoacidosis or porphyria.

Check:
• site *(Fig. 13.2)*, intensity, character, duration and frequency of the pain

**FIGURE 13.2** The abdominal quadrants.

• aggravating and relieving factors
• associated symptoms, including non-gastrointestinal symptoms.

**Upper abdominal pain**

**Epigastric pain** is very common and is often related to food intake. Although functional dyspepsia is the most common diagnosis, the symptoms of peptic ulcer disease can be identical. **Heartburn** (a burning pain behind the sternum) is a common symptom of gastro-oesophageal reflux.
**Right hypochondrial pain** may originate from the gall bladder or biliary tract. Biliary pain can also be epigastric. **Biliary pain** is typically intermittent and severe, lasts a few hours and remits spontaneously, to recur weeks or months later. Hepatic congestion (e.g. in hepatitis or cardiac failure) and sometimes peptic ulcer disease can present with pain in the right hypochondrium. Chronic, persistent or constant pain in the right (or left) hypochondrium in a well-looking patient is a frequent functional symptom; this chronic pain is not due to gall bladder disease (see pp. 491–492).

**Lower abdominal pain**

**Pain in the left iliac fossa** may be colonic in origin (e.g. acute diverticulitis) but chronic pain is most commonly associated with functional bowel disorders.

**Lower abdominal pain in women** occurs in a number of gynaecological disorders and the differentiation from gastrointestinal disease may be difficult.

**Pain in the right iliac fossa** may be due to acute appendicitis or ileocaecal disease, but may also commonly be functional.

**Proctalgia fugax** is a severe pain deep in the rectum that comes on suddenly but lasts only for a short time. It is not due to organic disease.

**Abdominal wall pain**

Persistent abdominal pain with localized tenderness, which is not relieved by tensing the abdominal muscles, is probably from the abdominal wall itself. Causes are thought to include nerve entrapment, external hernias, and entrapment of internal viscera (commonly omentum) within traumatic or surgical alterations of abdominal wall musculature.

**Anorexia and weight loss**

Anorexia describes reduced appetite. It is common in systemic disease and may be seen in psychiatric disorders. Anorexia often accompanies cancer but is usually a late symptom and not of diagnostic help. Weight loss is almost always due to reduced food intake and is a frequent accompaniment of gastrointestinal diseases. Weight loss in malabsorption disorders is primarily due to anorexia. Weight loss with a normal or increased dietary intake only occurs with hyperthyroidism and other catabolic states. Weight loss should always be assessed objectively, as patients' impressions are unreliable.

**Examination of the gastrointestinal system**

**Examination of the abdomen**

**Inspection**

Look for abdominal distension. Common causes (‘the five Fs’) are: flatus, fat, fetus, fluid and faeces. Intermittent distension is most commonly a feature of functional bowel disorders.
Palpation
Feel for palpable masses or abdominal tenderness. All abdominal quadrants should be palpated in turn, followed by deeper palpations; remember to watch the patient's face for signs of pain or discomfort. Evaluate any palpable mass and note its size, shape and consistency and whether it moves with respiration, to decide which organ is involved. Some abdominal organs may be just palpable normally, usually in thin people (Fig. 13.3). Riedel's lobe is an anatomical variant consisting of a palpable enlargement of the lateral portion of the right lobe of the liver. The hernial orifices should be examined if intestinal obstruction is suspected.

![Image](image.png)

**FIGURE 13.3** The organs that are sometimes palpable in thin subjects.

Percussion
Abdominal percussion detects the areas of dullness caused by the liver and spleen, those due to ascites or those over masses. It can also detect a full bladder. Ascites is a term for excess fluid in the peritoneal cavity. It is detected clinically by central abdominal resonance caused by gas within small bowel loops, with dullness in the flanks that shifts when the patient lies on their side. This ‘shifting dullness’ is a reliable physical sign, if 1–2 L of fluid are present.

Auscultation
Auscultation is not of great value in abdominal disease, except for evaluation of bowel sounds in the acute abdomen (see p. 433). Abdominal bruits are often present in normal subjects and are rarely clinically significant.

A succussion splash suggests gastric outlet obstruction if the patient has not drunk for 2–3 hours. The splash of fluid in the stomach can be heard with a stethoscope laid on the abdomen when the patient is moved.

Examination of the rectum and sigmoid colon
A digital examination of the rectum should be performed in all patients with a change in bowel habit or rectal bleeding, and prior to endoscopic examination of the rectum.

- **Proctoscopy (Box 13.3)** is performed in all patients with a history of bright red rectal
bleeding to look for anorectal pathology such as haemorrhoids; a rigid sigmoidoscope is too narrow and long to enable adequate examination of the anal canal.

**Box 13.3**

**Proctoscopy**

- The proctoscope is passed into the anus and the obturator is removed.
- The patient strains down as the proctoscope is removed.
- Haemorrhoids are seen as purplish veins in the left lateral, right posterior or right anterior position.
- Fissures may also be seen, but pain often prevents the procedure from being performed.

**Sigmoidoscopy**, either flexible or rigid, is part of the routine hospital examination in cases of diarrhoea and in patients with lower abdominal symptoms such as a change in bowel habit or rectal bleeding. **Rigid sigmoidoscopy** can visualize the distal 20–25 cm of large bowel, whereas **flexible sigmoidoscopy (FS)** can reach up to the splenic flexure (60 cm), and is typically performed in the endoscopy unit after evacuation of the distal colon using an enema or suppository. Rigid sigmoidoscopy is more mobile and is easily performed on the ward or in the outpatient department. Most rectal bleeding is due to benign anorectal disease (haemorrhoids or fissure in ano) and an otherwise normal FS can be reassuring and avoids over-investigation. Up to 60% of colonic neoplasms occur within the range of FS and FS is therefore used as screening test for colorectal cancer in asymptomatic average-risk individuals.

**Stool examination**

It is useful to confirm a patient's account (e.g. passing of blood or steatorrhoea). The shape and size may be helpful (e.g. ‘rabbit dropping’ or ribbon-like stools in irritable bowel syndrome). Stool charts for recording consistency and frequency of defecation are useful in inpatients to follow the progress of diarrhoea, particularly in the management of severe colitis. The Bristol Stool Chart is commonly used in the UK (*Fig. 13.4*).
Investigation of gastrointestinal disease

Routine haematology and biochemistry, followed by endoscopy and radiology, are the principal investigations. The investigation of small bowel disease is discussed in more detail on pages 394–395. Manometry is mainly used in oesophageal disease (see p. 366) and anorectal disorders (see pp. 419–420).

Endoscopy

Video endoscopes relay colour images to a high-definition television monitor. The tip of the endoscope can be angulated in all directions, and channels in the instrument are used for air insufflation, water injection, suction, and the passage of accessories such as biopsy forceps or brushes for obtaining tissue, snares for polypectomy and needles for injection therapies. Permanent photographic or video records of the procedure are obtained.

• **Oesophagogastroduodenoscopy (OGD, ‘gastroscopy’)** is the investigation of choice for upper gastrointestinal disorders with the possibility of therapy and mucosal biopsy. Findings include reflux oesophagitis, gastritis, ulcers and cancer. Therapeutic OGD is used to treat...
upper gastrointestinal haemorrhage and both benign and malignant obstruction. The mortality for diagnostic endoscopy is 0.001% with significant complications in 1 : 10 000, usually when performed as an emergency (e.g. gastrointestinal haemorrhage).

• **Colonoscopy** allows good visualization of the whole colon and terminal ileum. Biopsies can be obtained and polyps removed. Benign strictures can be dilated and malignant strictures stented. The success rate for reaching the caecum should be at least 90% after training. Cancer, polyps and diverticular disease are the most common significant findings. Perforation occurs in 1 : 1000 examinations but this is higher (up to 2%) after polypectomy and endoscopic mucosal resection (*Box 13.4*).

---

**Box 13.4**

**Gastroscopy and colonoscopy**

- Explain the procedure to the patient, including benefits and risks.
- Discuss the need for sedation.
- Obtain written informed consent.

**Gastroscopy**

- The patient should be fasted for at least 4 h.
- Give oxygen and monitor oxygen saturation with an oximeter.
- Give lidocaine throat spray or sedation (midazolam ± opiate if required).
- Pass the gastroscope to the duodenum under direct vision.
- Examine during insertion and withdrawal.
- Gastroscopy takes 5–15 min, depending on the indication and findings.
- Withhold fluid and food until local anaesthetic/sedation wears off.
- Complications are rare but beware of over-sedation, perforation and aspiration.
- The patient must be accompanied home if sedation has been given.

**Colonoscopy**

- Stop oral iron a week before the procedure.
- Restrict the diet to low-residue foods for 48 h; clear fluids only for 24 h.
- Use a local bowel-cleansing regime, usually starting 24 h beforehand (e.g. two sachets of sodium picosulfate with magnesium citrate and 2–4 bisacodyl tablets, or macrogols 2–4 L, or local alternative; more if constipated).
- Give oxygen and monitor O₂ levels.
- Give sedation (midazolam ± opiate) if required by the patient.
- Pass the colonoscope to the caecum or ileum under direct vision.
- Examine in detail during withdrawal.
Colonoscopy takes 15–30 min, depending on the colon anatomy, indication and findings.

- Withhold fluid and food until sedation wears off.
- Observe the patient for at least an hour after sedation has been given.
- Complications are rare but beware of over-sedation, perforation and aspiration.
- The patient must be accompanied home if sedation has been given.

- **Endoscopic retrograde cannulation of biliary and pancreatic duct (ERCP)** combines endoscopy and fluoroscopy to visualize the pancreaticobiliary tree. It is not used diagnostically but is employed for interventions such as gall stone extraction and stenting of benign and malignant strictures in the common bile duct. Complications include perforation, pancreatitis and sepsis.

- **Endoscopic ultrasound (EUS)** is performed with a gastroscope incorporating an ultrasound probe at the tip. It is used diagnostically for lesions in the oesophageal or gastric wall, including the detailed TNM staging (see pp. 375–376) of oesophageal/gastric cancer, and for the detection and biopsy of pancreatic tumours and cysts.

- **Endoanal and endorectal ultrasonography** are performed to define the anatomy of the anal sphincters (see p. 418), to detect perianal disease and to stage superficial rectal tumours.

- **Balloon enteroscopy**, either double- or single-balloon, can examine the small bowel from the duodenum to the ileum, adopting both cranial and caudal approaches, and using specialized enteroscopes in expert centres.

- **Capsule endoscopy** is used for the evaluation of obscure gastrointestinal bleeding (after negative gastroscopy and colonoscopy) and for the detection of small bowel tumours and occult inflammatory bowel disease. It should be avoided if strictures are suspected.

**Imaging**

Full clinical information must be provided before the examination, and ideally, the images obtained should be reviewed with the radiologist to aid interpretation. The optimal technique to be used will depend on local expertise.

**Plain X-rays**

Plain X-rays of the chest and abdomen are chiefly used in the investigation of an acute abdomen. Interpretation depends on analysis of gas shadows inside and outside the bowel. Plain films are particularly useful where obstruction or perforation is suspected, to exclude toxic megacolon in colitis, and to assess faecal loading in constipation. Calcification may be
seen with gall-bladder stones and in chronic pancreatitis, though computed tomography is more sensitive for both.

**Ultrasound**

Ultrasonography involves no radiation and is the first-line investigation for abdominal distension: for example, in ascites, a mass or suspected inflammatory conditions. It can show dilated, fluid-filled loops of bowel in obstruction, and thickening of the bowel wall. It can be used to guide biopsies or percutaneous drainage. In an acute abdomen, ultrasound can diagnose cholecystitis, appendicitis, enlarged mesenteric glands and other inflammatory conditions.

**Computed tomography**

Computed tomography (CT) involves a significant dose of radiation (approximately 10 millisieverts). Modern multislice fast scanners and techniques, involving intraluminal and intravenous contrast, enhance diagnostic capability. Intraluminal contrast may be positive (Gastrografin or Omnipaque) or negative (usually water). The bowel wall and mesentery are well seen after intravenous contrast, especially with negative intraluminal contrast. Clinically unsuspected diseases of other abdominal organs are quite often also revealed *(Fig. 13.5A)*.
FIGURE 13.5 Computed tomography in gastrointestinal disease. A. CT scan of the normal abdomen at the level of T12. (1) Aorta; (2) spine; (3) top of right kidney; (4) liver; (5) gall bladder; (6) stomach (containing air); (7) pancreas; (8) spleen. B. CT cross-sectional (two-dimensional) image of a colonic polyp on a long stalk. The colon has been emptied as for visual colonoscopy. The pedunculated polyp and its stalk show enhancement after intravenous contrast. C. Three-dimensional reconstruction of part of the colon (false colour) generated by a computer program from multiple axial CT images. A sessile polypoid lesion is shown. (B and C: Courtesy of Dr Paul Jenkins.)

CT is widely used as a first-line investigation for the acute abdomen. It is sensitive for small volumes of gas from a perforated viscus, as well as leakage of contrast from the gut lumen.

Inflammatory conditions, such as abscesses, appendicitis, diverticulitis, Crohn's disease and its complications, are well demonstrated. In high-grade bowel obstruction, CT is usually diagnostic of both the presence and the cause of the obstruction.

CT is widely used in cancer staging and as guidance for biopsy of tumour or lymph nodes.
**CT pneumocolon/CT colonography** (virtual colonoscopy) after CO$_2$ insufflation into a previously cleansed colon provides an alternative to colonoscopy for diagnosis of colonic mass lesions *(Fig. 13.5B)*. It is being evaluated as a screening test for colon pathology with sensitivities of over 90% for >10 mm polyps.

**Unprepared CT** is a good test for colon cancer in the frail (often elderly) patient who would have problems with bowel preparation.

**Magnetic resonance imaging**

Magnetic resonance imaging (MRI) uses no radiation and is particularly useful in the evaluation of rectal cancers and of abscesses and fistulae in the perianal region. It is also useful in small bowel disease (MR enteroclysis) and in hepatobiliary and pancreatic disease.

**Positron emission tomography**

Positron emission tomography (PET) relies on detection of the metabolism of fluorodeoxyglucose. It is used for staging oesophageal, gastric and colorectal cancer and in detecting metastatic and recurrent disease. PET/CT adds additional anatomical information.

**Contrast studies**

- **Barium swallow** examines the oesophagus and proximal stomach. Its main use is for investigating dysphagia.

- **Double-contrast barium meal** examines the oesophagus, stomach and duodenum. Barium is given to produce mucosal coating, and effervescent granules producing carbon dioxide in the stomach create a double contrast between gas and barium. This test has high accuracy for the detection of significant pathology, such as ulcers and cancer, but requires good technique. Gastroscopy is a more sensitive test and enables biopsy of suspicious areas.

- **Small bowel meal or follow-through** specifically examines the small bowel. Ingested barium passes through the small bowel into the right colon. The fold pattern and calibre of the small bowel are assessed. Specific views of the terminal ileum can be obtained and are used to identify early changes in patients with suspected Crohn's disease. MRI is being used more frequently, as it does not involve radiation.

- **Absorbable water-soluble (Gastrografin or Omnipaque) contrast agents** should be used in preference to barium when perforation is suspected anywhere in the gut.

**Radioisotopes**

Radionuclides are used to a varying degree, depending on availability and expertise. Some of the more common indications and techniques are as follows:

- Detection of the urease activity of *Helicobacter pylori* – $^{13}$C urea breath test (see p. 379).

- Measurement of the *rate of gastric emptying* – sequential gamma camera scans after oral [$^{99m}$Tc]technetium-sulphur colloid or indium-labelled diethylene triamine penta-acetic acid ($^{111}$In-DTPA).
• Demonstration of a *Meckel's diverticulum* – gamma camera scan after intravenous $[^{99m}\text{Tc}]$pertechnetate, which has affinity for gastric mucosa.

• Assessment of the extent of *inflammation* and presence of inflammatory collections in inflammatory bowel disease – gamma camera scan after intravenous injection of white cells labelled with $[^{99m}\text{Tc}]$-hexamethylpropyleneamine oxime (HMPAO).

• Evaluation of *neuroendocrine tumours* and their metastases – gamma camera scan after intravenous radiolabelled octreotide or meta-iodobenzylguanidine (MIBG).

• Assessment of *obscure gastrointestinal bleeding* – gamma camera abdominal scan after intravenous injection of red cells labelled with $[^{99m}\text{Tc}]$ (only useful if the bleeding is $>2$ mL/min).

• Measurement of *albumin loss* in the stools (in *protein-losing enteropathy*) – following albumin labelled *in vivo* with intravenous $^{51}\text{CrCl}_3$. This test has largely been replaced by the measurement of the intestinal clearance of $\alpha_1$-antitrypsin.

• Assessment of *bile salt malabsorption* (in patients with unexplained diarrhoea) – gamma camera scan to measure both isotope retention and faecal loss of orally administered $^{75}\text{Selenium-homocholic acid taurine (SeHCAT)}$ (see p. 427).

• Detection of *bacterial overgrowth* in the small bowel – measurement of $^{14}\text{CO}_2$ in breath following oral $^{14}\text{C glycocholic acid}$.

**The Mouth**

The oral cavity extends from the lips to the pharynx and contains the tongue, teeth and gums. Its primary functions are mastication, swallowing and speech. Problems in the mouth are extremely common and, although they may be trivial, they can produce severe symptoms. Poor dental hygiene is often a factor.

**Recurrent aphthous ulceration**

Idiopathic aphthous ulceration is common and affects up to 25% of the population. Recurrent painful round or ovoid mouth ulcers are seen with inflammatory halos. They are more common in females and non-smokers, usually appear first in childhood, and tend to reduce in number and frequency before the age of 40. Other family members may be affected. There is no sign of systemic disease.

• *Minor aphthous ulcers* are the most common; they are $<10$ mm diameter, have a grey/white centre with a thin erythematous halo, and heal within 14 days without scarring. They rarely affect the dorsum of the tongue or hard palate.

• *Major aphthous ulcers* ($>10$ mm diameter) often persist for weeks or months and heal with scarring.

The cause is not known. Deficiencies of iron, folic acid or vitamin $\text{B}_{12}$ (with or without
gastrointestinal disorders) are sometimes found but are not causally linked. Secondary causes, such as Crohn's disease, should be excluded (Box 13.5).

---

**Box 13.5**

**Causes of mouth ulcers**

- Idiopathic aphthous ulceration (most common)
- Gastrointestinal disease:
  - Inflammatory bowel disease
  - Coeliac disease
- Infection:
  - Viral – herpes simplex virus (HSV), human immunodeficiency virus (HIV), Coxsackie
  - Fungal – candidiasis
  - Bacterial – syphilis, tuberculosis
- Systemic disease:
  - Reactive arthritis (see p. 686)
  - Behçet syndrome
  - Systemic lupus erythematosus
- Trauma:
  - e.g. Dentures
- Neoplasia:
  - e.g. Squamous cell carcinoma
- Drugs:
  - In erythema multiforme major, toxic epidermal necrolysis
  - Chemotherapy, antimalarials
- Skin disease:
  - Pemphigoid
  - Pemphigus
  - Lichen planus

---

There are no specific effective therapies. Sufferers should avoid oral trauma, and acidic foods or drinks that cause pain. Topical (1% triamcinolone) or systemic corticosteroids may lessen the duration and severity of the attacks. Chlorhexidine gluconate or tetracycline mouthwash, dapsone, colchicine, thalidomide and azathioprine have all been used with variable effect.

**Neoplasia (squamous cell carcinoma)**

Malignant tumours of the mouth account for 1% of all malignant tumours in the UK. The
majority develop on the floor of the mouth or lateral borders of the tongue. Early lesions may be painless, but advanced tumours are easily recognizable as hard, indurated ulcers with raised and rolled edges. Aetiological agents include tobacco, heavy alcohol consumption and the areca nut. Human papillomavirus 16 causes some oral cancers. Pre-malignant lesions include leucoplakia (single adherent white patch), lichen planus, submucous fibrosis and erythroplakia (a red patch).

Management

Treatment is by surgical excision, which may require extensive neck dissection to remove involved lymph nodes and/or radiotherapy. Ablative treatment with photodynamic therapy is being pioneered for early lesions.

Pigmented neoplastic lesions

These include melanotic naevi on the hard palate and buccal mucosa. These are rarer in the mouth than on the skin. Malignant melanomas are rare, but more common in males, and occur mainly on the upper jaw. The 5-year survival is only 5%.

Non-neoplastic lesions

Oral white patches

Transient white patches either are due to Candida infection or are very occasionally found in systemic lupus erythematosus. Local causes include mechanical, irritative or chemical trauma from drugs (e.g. ill-fitting dentures or aspirin). Oral candidiasis in adults is seen following therapy with broad-spectrum antibiotics or inhaled steroids, and in people with diabetes, patients who are seriously ill or those who are immunocompromised.

Persistent white patches can be due to leucoplakia, which is associated with alcohol and (particularly) smoking; it is pre-malignant. A biopsy should always be taken; histology shows alteration in the keratinization and dysplasia of the epithelium. Treatment is unsatisfactory. Isotretinoin possibly reduces disease progression. Oral lichen planus presents as white striae, which can rarely extend into the oesophagus.

Oral pigmented lesions

Racial pigmentation is scattered and symmetrically distributed. Amalgam tattoo is the most common form of localized oral pigmentation and consists of blue–black macules involving the gingivae; it results from dental amalgam sequestering into the tissues. Diseases causing pigmentation include Peutz–Jeghers syndrome and Addison's disease. Heavy metals (e.g. lead, bismuth and mercury) and drugs (e.g. phenothiazines and antimalarials) all cause pigmentation of the gums.
The tongue

The tongue may be affected by inflammatory or malignant processes, with similar lesions to those described above.

Glossitis

Glossitis is a red, smooth, sore tongue associated with vitamin $B_{12}$, folate, iron, riboflavin and nicotinic acid deficiency. It is also seen in infections due to *Candida*.

Black hairy tongue

A black hairy tongue is due to a proliferation of chromogenic microorganisms causing brown staining of elongated filiform papillae. The causes are unknown, but heavy smoking and the use of antiseptic mouthwashes have been implicated.

Geographic tongue

A geographic tongue is an idiopathic condition occurring in 1–2% of the population and may be familial. There are erythematous areas surrounded by well-defined, slightly raised irregular margins. The lesions are usually painless and the patient should be reassured.

The gums

The gums (gingivae) are the mucous membranes covering the alveolar processes of the mandible and the maxilla. Diseases of the gum are shown in *Box 13.6*.

The teeth

Dental caries occur as a result of bacterial damage to tooth structures leading to tooth decay and ‘cavities’. The main cause in humans is *Streptococcus mutans*, which is cariogenic only in the presence of dietary sugar. Dental caries can progress to pulpitis and pulp necrosis, and spreading infection can cause dentoalveolar abscesses. If there is soft tissue swelling, antibiotics (e.g. amoxicillin or metronidazole) should be prescribed prior to dental intervention.

Erosion of the teeth can result from exposure to acid (e.g. in bulimia nervosa) or, very occasionally, from severe gastro-oesophageal reflux disease.

Oral manifestations of human immunodeficiency virus infection

Patients infected with human immunodeficiency virus (HIV) often have characteristic oral lesions. Lesions strongly associated with HIV infection include candidiasis (with erythema and/or white exudates), erythematous candidiasis, oral hairy leucoplakia, Kaposi's sarcoma, non-Hodgkin's lymphoma, necrotizing ulcerative gingivitis and necrotizing ulcerative periodontitis; these are described elsewhere.

All oral lesions are much less common since the introduction of anti-retroviral therapy (ART; see pp. 341–346).

The Salivary Glands

Diseases of the salivary glands are shown in *Box 13.7*.

---

**Box 13.7**

**Diseases of the salivary glands**

- Dry mouth (xerostomia):
  - Sjögren syndrome
  - Drugs (e.g. antimuscarinic, anti-parkinsonian, lithium, tricyclics, monoamine oxidase inhibitors (MAOIs))
  - Radiotherapy
  - Psychogenic
  - Dehydration
- Acute sialadenitis:
  - Viral (e.g. mumps)
  - Bacterial (e.g. *Staphylococcus*, *Streptococcus*)
- Salivary duct obstruction:
The Pharynx and Oesophagus

Anatomy and physiology

The **pharynx** consists of the nasal, oral and laryngeal sections. The latter is the part of the throat that connects to the oesophagus.

The **oesophagus** is a muscular tube approximately 20 cm long that connects the pharynx to the stomach just below the diaphragm. Its only function is to transport food from the mouth to the stomach. In the upper portion of the oesophagus, both the outer longitudinal layer and inner circular muscle layers are striated. In the lower two-thirds of the oesophagus, including the thoracic and abdominal parts containing the lower oesophageal sphincter, both layers are composed of smooth muscle.

The oesophagus is lined by stratified squamous epithelium, which extends distally to the squamocolumnar junction where the oesophagus joins the stomach, recognized endoscopically by a zigzag (‘Z’) line, just above the most proximal gastric folds.

The oesophagus is separated from the pharynx by the **upper oesophageal sphincter** (UOS), which is normally closed due to tonic activity of the nerves supplying the cricopharyngeus. The **lower oesophageal sphincter** (LOS) consists of a 2–4 cm zone in the distal end of the oesophagus that has a high resting tone and, assisted by the diaphragmatic sphincter, is largely responsible for the prevention of gastric reflux.

Swallowing

During swallowing, the bolus of food is voluntarily moved from the mouth to the pharynx. This process is mediated by a complex reflex involving a swallowing centre in the dorsal motor nucleus of the vagus in the brainstem. Once activated, the swallowing centre neurones send pre-programmed discharges of inhibition followed by excitation to the motor nuclei of the cranial nerves. This results in initial relaxation, followed by distally progressive activation of neurones to the oesophageal smooth muscle and LOS. Pharyngeal and oesophageal peristalsis mediated by this swallowing reflex causes **primary peristalsis. Secondary peristalsis** arises as a result of stimulation by a food bolus in the lumen, mediated by a local intra-oesophageal reflex. **Tertiary contractions** indicate pathological non-propulsive contractions resulting from aberrant activation of local reflexes within the myenteric plexus.

The smooth muscle of the thoracic oesophagus and LOS is supplied by vagal autonomic motor nerves consisting of extrinsic preganglionic fibres and intramural postganglionic
neurones in the myenteric plexus (*Fig. 13.6*). There are parallel excitatory and inhibitory pathways.

**FIGURE 13.6** Innervation of the oesophagus. The excitatory pathway consists of vagal preganglionic neurones releasing acetylcholine (ACh), connecting to postganglionic neurones that release ACh and substance P (SP). The inhibitory pathway consists of vagal preganglionic neurones releasing ACh, connecting to postganglionic neurones that release nitric oxide (NO), vasoactive intestinal peptide (VIP), adenosine triphosphate (ATP) and SP.

---

**Clinical features of oesophageal disorders**

**Symptoms**

Major oesophageal symptoms are:

- **Dysphagia.** Difficulty in swallowing is defined as a sensation of obstruction during the
passage of liquid or solid through the pharynx or oesophagus: that is, within 15 s of food leaving the mouth. The characteristics of the progression of dysphagia to solids can be helpful. For example, intermittent slow progression with a history of heartburn suggests a benign peptic stricture; relentless progression over a few weeks suggests a malignant stricture. The slow onset of dysphagia for solids and liquids at the same time suggests a motility disorder, such as achalasia (see pp. 371–372). The causes are shown in Box 13.8.

---

**Box 13.8**

**Causes of dysphagia**

**Disease of mouth and tongue**
- e.g. Candidiasis

**Neuromuscular disorders**
- Pharyngeal disorders
- Bulbar palsy (e.g. motor neurone disease, stroke)
- Myasthenia gravis

**Oesophageal motility disorders**
- Achalasia
- Scleroderma
- Diffuse oesophageal spasm
- Presbyoesophagus
- Diabetes mellitus
- Chagas' disease

**Extrinsic pressure**
- Mediastinal glands
- Goitre
- Enlarged left atrium

**Intrinsic lesion**
- Foreign body
- Stricture:
  - Benign – peptic, corrosive
  - Malignant – carcinoma
- Lower oesophageal ring
- Oesophageal web
• **Pharyngeal pouch**

• **Odynophagia.** This term describes pain during the act of swallowing and is suggestive of oesophagitis. Causes include reflux, infection, chemical oesophagitis due to drugs such as bisphosphonates or slow-release potassium, or oesophageal stenosis.

• **Substernal discomfort/heartburn.** This is a common symptom of reflux of gastric contents into the oesophagus. It is usually a retrosternal burning pain that can spread to the neck, across the chest; when severe, it can be difficult to distinguish from the pain of ischaemic heart disease. It is often worst lying down at night, when gravity promotes reflux, or on bending or stooping.

• **Regurgitation.** This is the effortless reflux of oesophageal contents into the mouth and pharynx. Uncommon in normal subjects, it occurs frequently in patients with gastro-oesophageal reflux disease or organic stenosis.

**Signs**

The main sign of oesophageal disease is weight loss due to reduced food intake. Cervical lymphadenopathy with cancer is uncommon. Very rarely, a pharyngeal pouch may be seen to swell the neck during drinking.

**Investigation of oesophageal disorders**

• **Barium swallow and meal.** A radiological contrast study of the oesophagus can give both anatomical and functional information, but on the whole has been superseded by gastroscopy as the initial investigation of choice.

• **Gastroscopy.** This is the usual first-line investigation for suspected oesophageal disorders.

• **Manometry (Fig. 13.7).** This is performed by passing a catheter through the nose into the oesophagus and measuring the pressures generated within the oesophagus. It is used to assess oesophageal motor activity and measure pressures within the sphincters. It is not a primary investigation and should be performed only when the diagnosis has not been achieved by history, radiological imaging or endoscopy. It is the gold standard investigation for motility disorders of the oesophagus such as achalasia. Recordings are usually made over a short time period or, much more rarely, for up to 72 h. High-resolution manometry has superseded conventional manometry and the greater concentration of pressure sensors enables the identification of a wider range of abnormalities of oesophageal function with a greater diagnostic accuracy.
Ambulatory pH monitoring. A pH-sensitive probe is positioned in the lower oesophagus and is used to identify acid reflux episodes (pH <4). Catheter and implantable sensors are available, with devices in place for 24 h, up to 96 h; both are insensitive to alkali. Although only 5–10% of recorded acid reflux episodes are perceived by the patient, pH is a valuable means of correlating episodes of acid reflux with patient's symptoms.

Impedance. A catheter is used to measure the resistance to flow of ‘alternating current’ in the contents of the oesophagus. Combined with measurement of pH, it allows assessment of acid, weakly acid, alkaline and gaseous reflux, which is helpful in understanding the symptoms that are produced by a non-acid reflux, particularly in those patients who continue to have symptoms while on proton pump inhibition. Treatment is, however, difficult in these conditions and usually involves either alginites or pro-motility agents, or a combination of the two.

Gastro-oesophageal reflux disease (GORD)

Pathophysiology

The reflux of gastric acid, pepsin, bile and duodenal contents back into the oesophagus can be influenced by many factors that overcome the innate defence mechanisms, primarily the lower oesophageal sphincter. Between swallows, the muscles of the oesophagus are relaxed, except for those of the two sphincters. The LOS in the distal oesophagus remains closed because of the unique property of the muscle, and relaxes when swallowing is initiated (see p. 365). Transient lower (o)esophageal sphincter relaxations (TLESRs) are part of normal physiology, but occur more frequently in patients with gastro-oesophageal reflux disease (GORD), allowing gastric acid to flow back into the oesophagus (Fig. 13.8). Increased abdominal pressure (pregnancy) and low LOS pressure also predispose to GORD.
**Other anti-reflux mechanisms** involve the intra-abdominal segment of the oesophagus, which acts as a flap valve. In addition, the mucosal rosette, formed by folds of the gastric mucosa, and the crural diaphragm at the LOS, which contracts and acts like a pinchcock, prevent acid reflux. A hiatus hernia can impair this mechanism (Box 13.9). Normally, the oesophagus is also ‘cleared’ rapidly of refluxate by secondary peristalsis, gravity and salivary bicarbonate.

### Box 13.9

**Hiatus hernia**

**Sliding hiatus hernia**
The oesophageal–gastric junction and part of the stomach ‘slide’ through the hiatus so that it lies above the diaphragm.
- Present in 30% of people over 50 years
- Produces no symptoms – any symptoms are due to reflux

**Rolling or para-oesophageal hernia**
Part of the fundus of the stomach prolapses through the hiatus alongside the oesophagus.
- The lower oesophageal sphincter remains below the diaphragm and remains competent
- Occasionally, severe pain occurs due to volvulus or strangulation

The clinical features of reflux occur when the anti-reflux mechanisms fail, allowing acidic gastric contents to make prolonged contact with the lower oesophageal mucosa. The sphincter relaxes transiently, independently of a swallow, after meals, and this is the cause of almost all reflux in normals and about two-thirds of GORD patients.

The role of the *acid pocket* in GORD has gained more credence in the last 5 years. Food and fluid generally increase the gastric pH, but the acid pocket is an area of unbuffered gastric acid that accumulates postprandially in the proximal stomach. It serves as a reservoir for acid
reflux, particularly in individuals with a hiatus hernia where the distal oesophagus is supradiaphragmatic, especially on lying flat. This can be specifically targeted with an antacid–alginate combination.

Oesophageal mucosal defence mechanisms

- **Surface.** Mucus and the unstirred water layer trap bicarbonate. This mechanism is a weak buffering mechanism compared to that in the stomach and duodenum.

- **Epithelium.** The apical cell membranes and the junctional complexes between cells act to limit diffusion of \( \text{H}^+ \) into the cells. In oesophagitis, the junctional complexes are damaged, leading to increased \( \text{H}^+ \) diffusion and cellular damage.

- **Postepithelium.** Bicarbonate normally buffers acid in the cells and intracellular spaces. Hydrogen ions impair the growth and replication of damaged cells.

- **Sensory mechanisms.** Acid stimulates primary sensory neurones in the oesophagus by activating the vanilloid receptor-1 (VR1). This can initiate inflammation and release of pro-inflammatory substances from the tissue and produce pain. Pain can also be due to contraction of longitudinal oesophageal muscle.

**Clinical features**

*Heartburn* is the major feature. The burning chest pain is aggravated by bending, stooping and lying down, which promote acid exposure, and may be relieved by oral antacids and alginates. The patient typically complains of pain on drinking hot liquids or alcohol.

Factors associated with GORD are shown in *Box 13.10.*

**Box 13.10**

**Factors associated with gastro-oesophageal reflux**

- Pregnancy or obesity
- Fat, chocolate, coffee or alcohol ingestion
- Large meals
- Cigarette smoking
- Drugs – antimuscarinic, calcium-channel blockers, nitrates
- Systemic sclerosis
- Treatment for achalasia
- Hiatus hernia

The correlation between heartburn and oesophagitis is poor. Some patients have mild oesophagitis but severe heartburn, while others have severe oesophagitis in the absence of symptoms, and can present with haematemesis or iron deficiency anaemia from chronic blood
loss. Psychosocial factors are often determinants of symptom severity, with heartburn increased during times of stress.

Differentiation of cardiac and oesophageal pain can be difficult; 20% of cases seen in emergency departments have GORD (Box 13.11). A trial of antacid therapy is often useful, resolving reflux-induced pain, before progressing to 24-hour pH studies only if symptoms persist.

### Box 13.11

**Classic features of the pain of gastro-oesophageal reflux and cardiac ischaemia**

**Reflux pain:** burning, worse on bending, stooping or lying down
- Seldom radiates to the arms
- Worse with hot drinks or alcohol
- Relieved by antacids

**Cardiac ischaemic pain**
- Gripping or crushing
- Radiates to neck or left arm
- Worse with exercise
- Accompanied by dyspnoea

**Regurgitation** of food and acid into the mouth occurs, particularly on bending or lying flat. Aspiration pneumonia is unusual without an accompanying obstruction, but cough and asthma can occur and respond slowly (1–4 months) to a proton pump inhibitor (PPI).

**Laryngopharyngeal reflux disease (LPRD)** is the transport of gastric contents into the larynx and pharynx, usually, although not exclusively, in the context of GORD. Heartburn may be one of the associated symptoms but cough, hoarse voice, postnasal drip and asthma are more frequently seen, but are not common.

### Diagnosis and investigations

The clinical diagnosis can usually be made without investigation. Unless there are alarm signs, especially dysphagia (see p. 365–366), patients under the age of 45 years can safely be treated initially without investigations. If investigation is required, there are two aims:

- **Assess oesophagitis and hiatal hernia by endoscopy.** If there is oesophagitis (Fig. 13.9) or Barrett's oesophagus (see pp. 370–371), reflux is confirmed.
\textbf{Document reflux by intraluminal monitoring (Fig. 13.10).} Twenty-four-hour intraluminal pH monitoring or impedance combined with manometry is helpful if there is no response to PPIs and should always be performed to confirm reflux before surgery. A DeMeester score is calculated, each reflux episode being defined as an oesophageal pH of <4; a score of >14.72 indicates reflux. There should also be a good correlation between reflux (pH <4.0) and symptoms. It is also helpful to assess oesophageal dysmotility as a potential cause of the symptoms, leading to impaired oesophageal clearance.
Management

Approximately half of patients with reflux symptoms in primary care can be treated successfully with simple antacids, loss of weight and raising the head of the bed at night. Precipitating factors should be avoided, with dietary measures, reduction in alcohol and caffeine consumption, and cessation of smoking. These measures are simple to say but difficult to carry out, though they are useful in mild disease in compliant patients.

Drugs

Alginate-containing antacids

Alginate-containing antacids (10 mL three times daily) are the most frequently used ‘over-the-counter’ agents for GORD. They form a gel or ‘foam raft’ with gastric contents to reduce reflux. Magnesium-containing antacids tend to cause diarrhoea while aluminium-containing compounds may cause constipation.

Dopamine antagonist prokinetic agents

The dopamine antagonist prokinetic agents metoclopramide and domperidone are occasionally helpful, as they enhance peristalsis and speed gastric emptying, but there are few data to substantiate this. The role of domperidone has been limited still further following reports of serious cardiac side-effects.

H₂-receptor antagonists

H₂-receptor antagonists (e.g. cimetidine, ranitidine, famotidine and nizatidine) are frequently used for acid suppression if antacids fail, as they can easily be obtained.

Proton pump inhibitors

Proton pump inhibitors (PPIs; omeprazole, rabeprazole, lansoprazole, pantoprazole, esomeprazole) inhibit gastric hydrogen/potassium-adenosine triphosphatase. PPIs reduce
gastric acid secretion by up to 90% and are the drugs of choice for all but mild cases. Most patients with GORD will respond well, with approximately 60% symptom-free after 4 weeks of a once-daily PPI. Patients with severe symptoms may need twice-daily PPIs and prolonged treatment, often for years. Once oesophageal sensitivity has normalized, a lower dose, e.g. omeprazole 10 mg, may be sufficient for maintenance. Long-term PPI prescription is not uncommon, and although some recent data have suggested side-effects such as osteoporosis, and an increase in gastrointestinal infections such as Clostridium difficile, these are uncommon and tend to occur in at-risk patients.

Patients who do not respond to a PPI and have continuing symptoms with a normal endoscopy are described as having non-erosive reflux disease (NERD) (Fig. 13.11). These patients are usually female and often the symptoms are functional, although a small group have a ‘hypersensitive’ oesophagus, giving discomfort with only slight changes in pH. Isomers of some of the original PPIs (e.g. dexlansoprazole) have the benefit of more effective gastric acid inhibition over a longer time period, as their metabolism of the active metabolite is slower.
Endoluminal gastroplication

In this endoscopic procedure, multiple plications or pleats are made below the gastro-oesophageal junction. Randomized controlled trials have shown benefit with reduction in heartburn, acid reflux episodes and PPI usage, but not sustained improvements in the oesophageal pH measurements.

Surgery

Surgery should never be performed for a hiatus hernia alone. The best predictors of a good surgical result are typical reflux symptoms with documented acid reflux, which correlates with symptoms and response to a PPI. With such highly selected cases in experienced hands, the laparoscopic Nissen fundoplication has a satisfaction rate of over 90% at 5 years, and available 10-year data show satisfaction rates remain high at 88%. Current surgical techniques return the oesophagogastric junction to the abdominal cavity, mobilize the gastric fundus, close
the diaphragmatic crura snugly and involve a short, tension-free fundoplication.

The *Linx reflux management system* consists of a row of magnets that increase LOS closure pressure, allowing food passage during swallowing; it is inserted laparoscopically. Improvement in quality of life with no PPI therapy has been shown but further studies are necessary. Patients cannot have an MRI study with the device *in situ*.

**Indications for operation** are not clear-cut but include intolerance to medication, the desire for freedom from medication, the expense of therapy and concern about long-term side-effects.

The most common cause of mechanical fundoplication failure is recurrent hiatus hernia.

Patients with oesophageal dysmotility unrelated to acid reflux, those with no response to PPIs and those with underlying functional bowel disease should rarely have surgery.

### Complications of gastro-oesophageal reflux disease

#### Peptic stricture

Since the advent of PPIs, peptic strictures have become far less common. They usually occur in patients over the age of 60 and present with intermittent dysphagia for solids, which worsens gradually over a long period. Mild cases may respond to PPIs alone. More severe cases need endoscopic dilatation and long-term PPI therapy. Surgery is required if medical treatment fails.

#### Barrett's oesophagus

Barrett's oesophagus (*Fig. 13.12*) is a condition in which part of the normal oesophageal squamous epithelium is replaced by metaplastic columnar mucosa to form a segment of ‘columnar-lined oesophagus’ (CLO). It is a complication of GORD and there is almost always a hiatus hernia present.
**Diagnosis and classification**

The diagnosis is made if endoscopy shows proximal displacement of the squamocolumnar mucosal junction and biopsy demonstrates columnar lining above the proximal gastric folds (>1 cm); intestinal metaplasia is no longer a requirement of the British Society of Gastroenterology definition but is central to the American College of Gastroenterology guidelines. Barrett's oesophagus may be seen as a continual circumferential sheet, as finger-like projections extending upwards from the squamocolumnar junction or as islands of columnar mucosa interspersed with areas of squamous mucosa. The Prague classification (**Fig. 13.13**) is used for recording the endoscopic distribution, stating both the length of circumferential CLO (C measurement) and the maximum length (M measurement), the distance from the top of the gastric folds to the most proximal tongue of the columnar mucosa.
Central obesity increases the risk of Barrett's by 4.3 times. Long-segment (>3 cm) and short-segment (<3 cm) Barrett's is found, respectively, in 5% and 15% of patients undergoing endoscopy for reflux symptoms. Barrett's is also often found incidentally in endoscoped patients without reflux symptoms. It is most common in middle-aged obese men. The major concern is that approximately 0.12–0.5% of Barrett's patients develop oesophageal adenocarcinoma per year, the majority, probably, through a gradual transformation from intestinal metaplasia to low-grade then high-grade dysplasia, before invasive adenocarcinoma. Barrett's increases the chance of developing oesophageal adenocarcinoma 30- to 50-fold in early studies but recent studies have shown the risk to be much lower and closer to a 1% lifetime risk in the typical patient.

Because of the poor correlation between Barrett's oesophagus and symptoms, screening is not recommended; however, in the absence of high-quality trial evidence, endoscopic surveillance is recommended by some. This involves inspection of the oesophageal mucosa with a high-definition gastroscope, and the taking of targeted biopsies of any focally abnormal tissue in addition to random biopsies from all four quadrants (every 1–2 cm) of the CLO. The interval between endoscopies is determined by the length of the CLO and the degree of cellular disturbance within it. High-grade dysplasia (HGD) is usually associated with endoscopically
visible nodules or ulceration, optimally visualized with a high-definition endoscope. Chromoendoscopy (the topical application of stains or pigments via the endoscope), narrow band and autofluorescence imaging may aid the diagnosis of dysplasia and carcinoma. Endoscopic technology has improved the detection of pre-malignant lesions, enabling their removal by either endoscopic mucosal resection (EMR) or endoscopic submucosal dissection, therefore preventing surgical oesophagectomy.

If **low-grade dysplasia** is found on endoscopic surveillance, a repeat endoscopy with quadrant biopsies every 1 cm is usually performed within 6 months, while on high-dose proton pump inhibition. Long-term surveillance and more aggressive endoscopic treatment of this group are the subjects of ongoing research.

If **high-grade dysplasia** is found, it is usually in the context of an endoscopically visible lesion, which, if nodular, is removed by endoscopic mucosal resection for more accurate histological staging. If high-grade dysplasia is detected in the absence of any endoscopically visible lesion, high-dose proton pump inhibition is started and repeat biopsies taken within 3 months. Endoscopic ultrasound is frequently used to stage this patient group more accurately, in order to exclude cancer and associated significant lymphadenopathy.

**Radiofrequency ablation (RFA)** has superseded photodynamic therapy as the technique of choice for endoscopic treatment of dysplasia within Barrett's segments following removal of any nodular lesions, returning the oesophagus to squamous lining. The benefit of RFA in low-grade dysplasia is currently under evaluation.

## Motility disorders

### Achalasia

Achalasia is characterized by oesophageal aperistalsis and impaired relaxation of the lower oesophageal sphincter. The lower oesophageal pressure is elevated in more than half of patients.

#### Clinical features

The incidence of achalasia is 1 : 100 000 and is equal in males and females. It occurs at all ages but is rare in childhood. Patients usually have a long history of intermittent dysphagia, characteristically for both liquids and solids from the onset. Regurgitation of food from the dilated oesophagus occurs, particularly at night, and aspiration pneumonia is a complication. Spontaneous chest pain occurs and is said to be due to oesophageal ‘spasm’; it may be misdiagnosed as cardiac pain. Dysphagia may be mild and accepted by the patient as normal; weight loss is usually minimal.

#### Pathogenesis

The aetiology of achalasia is unknown, with autoimmune, neurodegenerative and viral
aetiologies all being postulated. A similar clinical picture is seen in chronic Chagas’ disease (American trypanosomiasis; see pp. 302–303), where there is damage to the neural plexus of the gut.

Histopathology shows inflammation of the myenteric plexus of the oesophagus with reduction of ganglion cell numbers. Cholinergic innervation appears to be preserved. Reduction in nitric oxide synthase-containing neurones has been shown by immunohistochemical staining. Pharmacological studies in patients with achalasia support the selective loss of inhibitory, nitrergic neurones.

Differential diagnosis
The differential diagnosis of achalasia worldwide includes genetic syndromes, infectious diseases, neoplasms and chronic inflammatory conditions.

Investigations
• **Chest X-ray** shows a dilated oesophagus, sometimes with a fluid level seen behind the heart. The fundal gas shadow is absent.
• **Barium swallow** shows lack of peristalsis and often synchronous contractions in the body of the oesophagus, sometimes with dilatation. The lower end shows a ‘bird’s beak’ due to failure of the sphincter to relax (*Fig. 13.14*).
FIGURE 13.14 Barium swallow showing achalasia. There is an atonic body of the oesophagus and a narrowed distal end (arrowed). Note the food residue in the dilated oesophagus.

• **Oesophagoscopy** is performed to exclude a carcinoma at the lower end of the oesophagus, as this can produce a similar X-ray appearance. When there is marked dilatation, a 24-h liquid-only diet and a washout, prior to endoscopy, are useful to remove food debris. In true achalasia, the endoscope passes through the LOS with little resistance.

• **CT scan** excludes distal oesophageal cancer.

• **Manometry** shows aperistalsis of the oesophagus and failure of relaxation of the LOS (see **Fig. 13.7**).

### Management

All current forms of treatment for achalasia are *palliative*. Drug therapy rarely produces satisfactory or durable relief; nifedipine (20 mg sublingually), nitrates or sildenafil can be tried initially.

Endoscopic and surgical therapies are equally effective. Endoscopic dilatation of the LOS, using a pneumatic balloon under X-ray control, weakens the sphincter and is initially successful in 80% of cases. About 50% of patients require a second or third dilatation in the first 5 years. There is a low but significant risk of perforation. Intrasphincteric injection of
botulinum toxin A produces satisfactory initial results but the effects wear off within months. Further injections can be given. It is safer and simpler than dilatation, so may be valuable in patients at risk of death if a perforation occurs. Neither pneumatic dilatation nor botulinum toxin works as well in younger patients.

Surgical division of the LOS, Heller's operation, usually performed laparoscopically, is the surgical treatment of choice. Per oral endoscopic myotomy (POEM) is a novel technique, which is a division of the LOS using a gastroscope. The early results show great promise.

Reflux oesophagitis complicates all procedures and aperistalsis of the oesophagus remains.

### Complications

There is a slight increase in the incidence of squamous carcinoma of the oesophagus in both treated and untreated cases (7% after 25 years).

### Systemic sclerosis

The oesophagus is involved in almost all patients with this disease. Diminished peristalsis and oesophageal clearance, detected manometrically (see Fig. 13.7) or by barium swallow, is due to replacement of the smooth muscle by fibrous tissue. LOS pressure is decreased, allowing reflux with consequent mucosal damage. Strictures may develop. Initially, there are no symptoms, but dysphagia and heartburn occur as the oesophagus becomes more severely involved. Similar motility abnormalities may be found in other autoimmune rheumatic disorders, particularly if Raynaud's phenomenon is present. Treatment is as for reflux disease (see pp. 369–370) and benign stricture.

### Diffuse oesophageal spasm

This is a severe form of oesophageal dysmotility that can sometimes produce retrosternal chest pain and dysphagia. It can accompany GORD. Swallowing is accompanied by bizarre and marked contractions of the oesophagus without normal peristalsis (see Fig. 13.7). On barium swallow, the appearance may be that of a ‘corkscrew’ oesophagus. However, asymptomatic oesophageal ‘dysmotility’ is not infrequent, particularly in patients over the age of 60 years.

A variant of diffuse oesophageal spasm is the ‘nutcracker’ oesophagus, which is characterized by very high-amplitude peristalsis (pressures >200 mmHg) within the oesophagus. Chest pain is more common than dysphagia.

### Management

True oesophageal spasm producing severe symptoms is uncommon and treatment is often difficult. PPIs may be successful if reflux is a factor. Antispasmodics, nitrates, calcium-channel blockers and γ-aminobutyric acid (GABA) receptor agonists (e.g. baclofen) are used. Occasionally, balloon dilatation or even longitudinal oesophageal myotomy is necessary.
**Miscellaneous motility disorders**

Abnormalities of motility that occasionally produce dysphagia are found in the elderly, and in diabetes mellitus, myotonic dystrophy, oculopharyngeal muscular dystrophy and myasthenia gravis, as well as neurological disorders involving the brainstem.

**Other oesophageal disorders**

**Oesophageal diverticulum**

Diverticula occur:

- immediately *above* the upper oesophageal sphincter (pharyngeal pouch – Zenker's diverticulum; see p. 1322).
- near the *middle* of the oesophagus (traction diverticulum due to inflammation, or associated with diffuse oesophageal spasm or mediastinal fibrosis)
- just above the *lower* oesophageal sphincter (epiphrenic diverticulum – associated with achalasia).

Usually detected incidentally on a barium swallow performed for other reasons, these are often asymptomatic. Dysphagia and regurgitation can occur with a pharyngeal pouch, becoming more problematic as the diverticula increase in size (see p. 1322). These can be treated surgically and endoscopically.

**Rings and webs**

An oesophageal web is a thin, membranous tissue flap covered with squamous epithelium. Most acquired webs are located anteriorly in the postcricoid region of the cervical oesophagus and are well seen on barium swallow. They may produce dysphagia. In the *Plummer–Vinson syndrome* (or *Paterson–Brown–Kelly syndrome*), a web is associated with chronic iron deficiency anaemia, glossitis and angular stomatitis. This rare syndrome affects mainly women and its aetiology is not understood. The web may be difficult to see at endoscopy and is often ruptured unintentionally by the passage of the endoscope. Dilatation of the web is rarely necessary. Iron is given for the iron deficiency.

**Lower oesophageal rings**

Lower oesophageal rings are of two types:

1. *Mucosal (Schatzki’s ring, also called B ring)* is located at the squamocolumnar mucosal junction and is common (*Fig. 13.15*). It is associated with a characteristic history of intermittent bolus obstruction.
2. **Muscular (A ring)** is located proximal to the mucosal ring and is uncommon. It is covered by squamous epithelium and may cause dysphagia.

**Management** for these rings is usually with reassurance and dietary advice, but dilatation is occasionally necessary. After a single dilatation, 68% of patients with Schatzki's rings are symptom-free at 1 year and 35% remain symptom-free after 2 years, but only 11% are symptom-free at 3 years. Many also respond to oral PPI, either alone or with dilatation.

### Benign oesophageal stricture

Peptic stricture (**Fig. 13.16**) secondary to reflux is the most common cause of benign strictures (for treatment, see p. 370). They also occur after the ingestion of corrosives, radiotherapy, sclerotherapy of varices and prolonged nasogastric intubation. Dysphagia is usually treated by endoscopic dilatation. Surgery is sometimes required.

### Oesophageal infections

Infection is a cause of painful swallowing and is seen particularly in immunosuppressed (e.g.
on chemotherapy) and debilitated patients, and in those with acquired immunodeficiency syndrome (AIDS). Infection can occur with:

- *Candida*
- herpes simplex
- cytomegalovirus
- *Mycobacterium tuberculosis*.

It is occasionally difficult to distinguish between these disorders on oesophagoscopy, as only widespread ulceration is seen. In candidiasis, the characteristic white plaques are frequently found; oral candidiasis is not always present. The diagnosis of *Candida* infection can be confirmed by examining a direct smear taken at endoscopy, but often infections are mixed and cultures and biopsies must be performed. Tuberculosis causes deep ulceration with associated mediastinal lymphadenopathy.

### Management

Most patients on large doses of immunosuppressive agents are treated prophylactically for candidiasis with nystatin, fluconazole or amphotericin. Antifungal or antiviral treatment is prescribed appropriately for other infections.

### Mallory–Weiss syndrome

This is described on page 387.

### Eosinophilic oesophagitis

Eosinophils can be seen in the oesophageal mucosa (which is usually devoid of eosinophils microscopically) due to a variety of causes, such as eosinophilic (or allergic) oesophagitis and GORD.

Eosinophilic oesophagitis (*Fig. 13.17*) is increasingly recognized but its pathogenesis is unknown. There may be a personal or family history of allergic disorders, such as food allergy, eczema or asthma.
Patients present with a long history of dysphagia, food impaction, ‘heartburn’ and oesophageal pain caused by the eosinophil-induced oesophageal inflammation. Usually, the patient is male and white, and has an average age at diagnosis of 35, but eosinophilic oesophagitis is becoming more common in children.

Typical endoscopic abnormalities include mucosal furrowing, loss of vascular pattern due to a thickened mucosa, plaques of eosinophilic surface exudate and prominent circular folds, but the oesophagus may appear macroscopically normal. Reflux oesophagitis and Schatzki's rings may coexist. Endoscopic forceps biopsies should be taken throughout the oesophagus for histology and eosinophil numbers calculated.

The eosinophilic infiltration of the oesophagus due to reflux disease tends to have a different microscopic appearance and fewer eosinophils.

### Management

First-line treatment is with topical steroids, such as swallowing fluticasone spray or budesonide syrup. If this is not effective, systemic steroids or empirical elimination diets may also be used (dietary treatment is more beneficial in children). A cohort of patients respond to PPIs in the absence of GORD. Dilatation is sometimes necessary, with a risk of perforation of 2%.

### Oesophageal perforation

Oesophageal perforation most commonly occurs at the time of endoscopic dilatation and, rarely, following insertion of a nasogastric tube, gastroscope or transoesophageal echoprobe. Patients with malignant, corrosive or post-radiotherapy strictures are more likely to perforate than those with a benign peptic stricture.

### Management

This normally involves placement of an expanding covered oesophageal stent (see p. 376),
which usually seals the hole. A water-soluble contrast X-ray is performed after 2–3 days to check the perforation has sealed.

**Oesophageal rupture**

*Spontaneous* oesophageal rupture occurs with violent vomiting (Boerhaave syndrome), producing severe chest pain and collapse in typical cases. Diagnosis can be difficult because classic symptoms are absent in about one-third of cases, and delays in presentation for medical care are common. Rupture may follow alcohol ingestion. A chest X-ray shows a hydropneumothorax. The diagnosis is made with a water-soluble contrast swallow or on CT. The mortality rate is approximately 35%, making it the most lethal perforation of the gastrointestinal tract. The best outcomes are associated with early diagnosis and definitive surgical management within 12 hours of rupture. If intervention is delayed longer than 24 hours, the mortality rate (even after surgery) rises to above 50%, and to nearly 90% after 48 hours.

**Oesophageal tumours**

**Cancer of the oesophagus**

This is the sixth most common cancer worldwide. Squamous cancers occurring in the middle third account for 40% of tumours, and for 15% in the upper third. Adenocarcinomas occur in the lower third of the oesophagus and at the cardia, and represent approximately 45% of tumours. Primary small cell cancer of the oesophagus is extremely rare.

**Epidemiology and aetiology**

**Squamous cell carcinoma**

The geographic variation in incidence is greater than for any other carcinoma – often in regions very close to one another. Squamous cell carcinoma (SCC) is common in Ethiopia, China, South and East Africa, and the Caspian regions of Iran. By contrast, North, Central and West Africa have low rates.

In the UK, the incidence is 5–10 per 100 000 and SCC represents 2.2% of all malignant disease. The incidence is decreasing, in contrast to that of adenocarcinoma. SCC of the oesophagus is more common in men (2 : 1). Risk factors are shown in *Box 13.12*.

**Box 13.12**

**Risk factors for cancer of the oesophagus**

**Squamous cell carcinoma**
High levels of alcohol consumption increase the risk of squamous cell cancer of the oesophagus, while tobacco use is associated with an increased incidence of both squamous cell and adenocarcinomas of the oesophagus. Smoking, obesity and low fruit and vegetable consumption are implicated in approximately 9 in 10 squamous cell cancers of the oesophagus.

Diet rich in fibre, carotenoids, folate, vitamin C and non-starchy vegetables probably decrease the risk of oesophageal cancer, whereas diets high in saturated fat, cholesterol and refined cereals have been associated with an increased risk. Red and processed meat intake has been associated with an increased risk of both oesophageal SCC and adenocarcinoma. Conversely, fish and white meat consumption have been inversely associated with risk of oesophageal SCC in case–control studies from Italy, Switzerland and Uruguay.

**Adenocarcinoma**

These tumours primarily arise in columnar-lined epithelium in the lower oesophagus (see *Barrett's oesophagus*, pp. 370–371). The incidence of this tumour is increasing in western industrialized countries. It currently accounts for more than 70% of all new oesophageal cancer diagnoses. Extension of an adenocarcinoma of the gastric cardia into the oesophagus can present with the same symptoms. Previous reflux symptoms increase the risk up to eight-fold and the risk is proportional to their severity.
Clinical features

Carcinoma of the oesophagus occurs mainly in those aged 60–70 years. Dysphagia is progressive and unrelenting. Initially, there is difficulty in swallowing solids but, typically, dysphagia for liquids follows within weeks. Impaction of food causes pain but more persistent pain implies infiltration of adjacent structures.

The lesion may be ulcerative, proliferative or scirrhoue, extending variably around the wall of the oesophagus to produce a stricture. Direct invasion of the surrounding structures and metastases to lymph nodes are more common than disseminated metastases. Weight loss, due to the dysphagia as well as to anorexia, is frequent. Oesophageal obstruction eventually causes difficulty in swallowing saliva, coughing and aspiration into the lungs.

Weight loss, anorexia and lymphadenopathy are the most common physical signs.

Investigations

Diagnosis

• Endoscopy provides histological proof of the carcinoma *(Fig. 13.18A)*.
Carcinoma of the oesophagus. A. Endoscopic image. B. Barium swallow, showing an irregular narrowed area (arrowed) at the lower end of the oesophagus. C. Endoscopic ultrasound. The central concentric circles are the probe. The arrow points to a break in the muscle layer and the soft tissue mass of the carcinoma.

- **Barium swallow** can be useful where the differential diagnosis of dysphagia includes a motility disorder such as achalasia (**Fig. 13.18B**).

**Staging**

The TNM staging system is used (see p. 383); it is similar to the one used for gastric cancer. Tumour invasion of the wall of the oesophagus (T), presence of tumour in lymph nodes (N) and metastases (M) are combined into stage categories. Tumours arising in the cervical, thoracic or abdominal oesophagus, including those that arise from within 5 cm from the gastro-oesophageal junction, share the same TNM staging criteria, but recent reclassification has differentiated between **squamous** and **adenocarcinoma** cancers.

- **CT scan** of the thorax and upper abdomen shows the volume of the tumour, local invasion, peritumoral and coeliac lymph node involvement, and metastases in the lung and elsewhere.
- **MRI** is equivalent to CT in local staging but not as good for pulmonary metastases.
- **Endoscopic ultrasound** has an accuracy rate of nearly 90% for assessing depth of tumour and infiltration, and of 80% for staging lymph node involvement. It is useful if CT has not already demonstrated that a cancer is too advanced for surgery. A fine-needle aspiration (FNA) of lymph nodes improves staging accuracy. Accurate T staging is necessary, as
cancers confined to the superficial mucosa can be removed endoscopically (*Fig. 13.18C*).

- **Laparoscopy** is useful if the tumour is at the cardia, to look for peritoneal and node metastases.
- **PET** after fluorodeoxyglucose is used principally to confirm distant metastases suspected on CT.

### Management

Although oesophageal SCC and adenocarcinoma are undoubtedly two different disease processes with independent tumour biology, the majority of trial data do not discriminate between the two. The influence of histology on treatment is therefore unclear and varies around the globe.

 Treatment is dependent on the age and performance status of the patient and the stage of the disease, with approximately 40% of all patients still alive 1 year after diagnosis. Five-year survival with stage 1 disease is 80% (T<sub>1</sub>/T<sub>2</sub>, N<sub>0</sub>, M<sub>0</sub>), stage 2 is 30%, stage 3 is 18% and stage 4 is 4%. Some 70% of patients present with stage 3 or greater disease, so that overall survival is 40% at 1 year and around 15% at 5 years. Management should be undertaken by multidisciplinary teams, including gastroenterologists, upper gastrointestinal surgeons, oncologists, palliative care physicians and dieticians.

- **Surgery** provides the best chance of a cure but should only be used when imaging (see above) has shown that the tumour has not infiltrated outside the oesophageal wall. Less than 40% of patients will have potentially resectable disease at the time of presentation. Patients must be evaluated preoperatively, particularly with regard to performance status (see p. 383), and surgery should be undertaken in designated units. Poor outcome data from surgery alone have challenged its role as monotherapy and it is more often used in conjunction with neo-adjuvant (preoperative) and adjuvant (postoperative) treatment. The role of surgery in early oesophageal SCC is less clear. As mentioned previously, endoscopic mucosal resection may be appropriate for early mucosal disease.

- **Preoperative (‘neo-adjuvant’) chemoradiation therapy** may benefit patients with stage 2b and 3 disease. Prolongation of survival has been shown in some studies. In the USA, neo-adjuvant chemoradiotherapy is preferred to the neo-adjuvant chemotherapy that is typically used in the UK.

- **Palliative therapy** is often the only realistic possibility. Dilatation is only of short-term benefit and the perforation risk is higher than for benign strictures. Combination of endoscopic dilatation with laser or brachytherapy (see p. 603) prolongs luminal patency and gives as good, if not better, functional results than stenting. Insertion of an expanding metal stent allows liquids and soft foods to be eaten.

- **Chemoradiation alone** is sometimes given but evidence of benefit is poor, except in early-stage SCC.

- **Nutritional support**, as well as support for the patient and their family, is vital in this
distressing condition.

### Other oesophageal tumours

Most other tumours are rare. **Gastrointestinal stromal tumours** (see p. 384) and **leiomyomas** (both submucosal tumours) are found usually by chance; 10% cause dysphagia or bleeding. Surgical removal is performed for symptomatic lesions or those over 3 cm, which are more likely to harbour malignancy. Small, benign tumours are relatively common and often do not require treatment.

**Kaposi’s sarcoma** is found in the oesophagus as well as the mouth (see p. 354) and hypopharynx in patients with AIDS.

The Stomach and Duodenum

Anatomy

The stomach occupies a small area immediately distal to the oesophagus (the cardia), the upper region (the fundus, under the left diaphragm), the mid-region or body and the antrum, which extends to the pylorus (see Fig. 13.8). It serves as a reservoir where food can be retained and broken up before being actively expelled into the proximal small intestine.

The smooth muscle of the wall of the stomach has three layers: outer longitudinal, inner circular and innermost oblique layers. There are two sphincters: the gastro-oesophageal sphincter and the pyloric sphincter. The latter is largely made up of a thickening of the circular muscle layer and controls the exit of gastric contents into the duodenum.

The duodenum has outer longitudinal and inner smooth muscle layers. It is C-shaped and the pancreas sits in the concavity. It terminates at the duodenojejunal flexure, where it joins the jejunum.

- **The mucosal lining** of the stomach can stretch in size with feeding. The greater curvature of the undistended stomach has thick folds or rugae. The mucosa of the upper two-thirds of the stomach contains parietal cells, which secrete hydrochloric acid, and chief cells, which secrete pepsinogen (which initiates proteolysis). There is often a colour change at the junction between the body and the antrum of the stomach, which can be seen macroscopically and confirmed by measuring surface pH.

- **The antral mucosa** secretes bicarbonate and contains mucus-secreting cells and G cells, which secrete gastrin, stimulating acid production. There are two major forms of gastrin, G17 and G34, depending on the number of amino-acid residues. G17 is the major form found in the antrum. Somatostatin, a suppressant of acid secretion, is also produced by specialized antral cells (D cells).

- **Mucus-secreting cells** are present throughout the stomach and secrete mucus and bicarbonate. The mucus is made of glycoproteins called mucins.

- The **‘mucosal barrier’**, made up of the plasma membranes of mucosal cells and the mucus layer, protects the gastric epithelium from damage by acid and, for example, alcohol, aspirin, non-steroidal anti-inflammatory drugs (NSAIDs) and bile salts. Prostaglandins stimulate secretion of mucus, and their synthesis is inhibited by aspirin and NSAIDs, which inhibit cyclo-oxygenase (see Fig. 24.30).

- **The duodenal mucosa** has villi like the rest of the small bowel, and also contains Brunner’s glands, which secrete alkaline mucus. This, along with the pancreatic and biliary secretions, helps to neutralize the acid secretion from the stomach when it reaches the duodenum.

Physiology
Acid secretion is central to the functionality of the stomach; factors controlling acid secretion are shown in Figure 13.19. Acid is not essential for digestion but does prevent some food-borne infections. It is under neural and hormonal control, and both stimulate acid secretion through the direct action of histamine on the parietal cell. Acetylcholine and gastrin also release histamine via the enterochromaffin cells. Somatostatin inhibits both histamine and gastrin release, and therefore acid secretion.
FIGURE 13.19 Pathophysiology of acid secretion. A. Control of acid secretion. Histamine stimulates the Gs protein via the H2 receptors and acts via cyclic adenosine monophosphate (cAMP). Prostaglandin E2 (PGE2) activates the Gi protein and inhibits acid secretion. Acetylcholine (ACh) acts via the vagus M3 receptors. ACh also acts via the enterochromaffin cell (ECL). Gastrin acts via the cholecystokinin B (CCKBB)–gastrin receptor, increasing the intracellular free calcium, and also via the ECL cell, stimulating histamine. Gs and Gi, stimulating and inhibiting G-proteins; GIP, gastric inhibitory polypeptide; VIP, vasoactive intestinal polypeptide.
Other major gastric functions are:

- reservoir for food
- emulsification of fat and mixing of gastric contents
- secretion of intrinsic factor
- absorption (of only minimal importance).

_Gastric emptying_ depends on many factors. There are osmoreceptors in the duodenal mucosa, which control gastric emptying by local reflexes and the release of gut hormones. In particular, intraduodenal fat delays gastric emptying by negative feedback through duodenal receptors.

**Gastritis and gastropathy**

‘Gastritis’ indicates inflammation associated with mucosal injury (although the term is often used loosely by endoscopists to describe ‘redness’), and ‘gastropathy’ indicates epithelial cell damage and regeneration without inflammation.

**Gastritis**

Several classifications of gastritis (e.g. Sydney classification) have been proposed but are controversial due to lack of correlation between endoscopic and histological findings. _H. pylori_ infection is the most common cause of gastritis, with autoimmune gastritis being seen in 5% of cases; the remaining causes include viruses (e.g. cytomegalovirus and herpes simplex), duodenogastric reflux and specific causes, e.g. Crohn's, more common in children than adults. Chronic inflammation, particularly if induced by _H. pylori_, can lead to gastric intestinal metaplasia, a precursor to gastric cancer. The role of surveillance in these patients is unclear.

**Autoimmune gastritis**

This affects the fundus and body of the stomach (pangastritis), leading to atrophic gastritis and loss of parietal cells, with achlorhydria and intrinsic factor deficiency causing the clinical syndrome of ‘pernicious anaemia’ (see pp. 528–529). Metaplasia, usually of the intestinal type, is almost always in the context of atrophic gastritis. Serum autoantibodies to gastric parietal cells are common and non-specific; antibodies to intrinsic factor are rarer and more significant (see p. 528).

**Gastropathy**

Gastropathy is usually caused by irritants (drugs, NSAIDs and alcohol), bile reflux and chronic congestion. Acute erosive/haemorrhagic gastropathy can also be seen after severe stress (stress ulcers); secondary to burns (Curling ulcers), trauma, shock or renal failure; and in portal hypertension (called portal gastropathy). The underlying mechanism for these ulcers is
unknown but may be related to an alteration in mucosal blood flow.

**Helicobacter pylori infection**

*Helicobacter pylori* is a slow-growing, spiral, Gram-negative, flagellate, urease-producing bacterium ([Fig. 13.20](#)), which plays a major role in gastritis and peptic ulcer disease. It colonizes the mucous layer in the gastric antrum, but is also found in the duodenum in areas of gastric metaplasia. *H. pylori* is found in greatest numbers under the mucous layer in gastric pits, where it adheres specifically to gastric epithelial cells. It is protected from gastric acid by the juxtamucosal mucous layer which traps bicarbonate secreted by antral cells, and ammonia produced by bacterial urease.

![Helicobacter pylori](image)

**Epidemiology**

The prevalence of *H. pylori* is high in developing countries (80–90% of the population) and much lower (20–50%) in developed countries. Infection rates are highest in lower-income groups. Infection is usually acquired in childhood; although the exact route is uncertain, it may be faecal–oral or oral–oral. The incidence increases with age, probably due to acquisition in childhood when hygiene was poorer (cohort effect) rather than infection in adult life, which is most likely far less than 1% per year in developed countries.

**Pathogenesis**

The pathogenetic mechanisms are not fully understood, with the majority of the colonized population remaining asymptomatic throughout their life. *H. pylori* is highly adapted to the stomach environment, exclusively colonizing gastric epithelium and inhabiting the mucous layer, or just beneath. It adheres by a number of adhesion molecules including BabA, which binds to the Lewis antigen expressed on the surface of gastric mucosal cells and causes gastritis in all infected subjects. Damage to the gastric epithelial cell is caused by the release of enzymes and the induction of apoptosis through binding to class II major histocompatibility complex (MHC) molecules. The production of urease enables the conversion of urea to ammonium and chloride, which are directly cytotoxic. Ulcers are most common when the
infecting strain expresses CagA (cytotoxic-associated protein) and VacA (vacuolating toxin) genes secondary to a more pronounced inflammatory and immune response. Expression of CagA and VacA is associated with greater induction of interleukin 8 (IL-8), a potent mediator of gastric inflammation. Genetic variations in the host are also thought to be involved; for example, polymorphisms leading to increased levels of IL-1β are associated with atrophic gastritis and cancer.

Results of *H. pylori* infection

- Inflammation (antral gastritis and gastric intestinal metaplasia).
- Peptic ulcers (duodenal and gastric).
- Gastric cancer (see pp. 381–382).

**Antral gastritis**

Antral gastritis is the usual effect of *H. pylori* infection. It is normally asymptomatic, although patients without ulcers do sometimes experience relief of dyspeptic symptoms after *Helicobacter* eradication. Chronic antral gastritis causes hypergastrinaemia due to gastrin release from antral G cells. The subsequent increase in acid output is usually asymptomatic but can lead to duodenal ulceration.

**Duodenal ulcer**

The prevalence of *H. pylori* infection in patients with duodenal ulcers (DUs; see Fig. 13.22A) is falling and in the developed world is now between 50% and 75%, whereas duodenal ulceration was once rare in the absence of *H. pylori* infection. This has been attributed to a decrease in prevalence of the bacterium and an increase in NSAID use. Eradication of the infection improves ulcer healing and decreases the incidence of recurrence.

The precise mechanism of duodenal ulceration is unclear, as only 15% of patients infected with *H. pylori* (50–60% of the adult population worldwide) develop duodenal ulcers. Factors that have been implicated include increased gastrin secretion, smoking, bacterial virulence and genetic susceptibility.

**Gastric ulcer**

Gastric ulcers (GUs; see Fig. 13.22B) are associated with a gastritis affecting the body as well as the antrum of the stomach (pangastritis), causing parietal cell loss and reduced acid production. The ulcers are thought to occur because of a reduction of gastric mucosal resistance due to cytokine production caused by the infection, or perhaps because of alterations in gastric mucus.

**Peptic ulcer disease**

A *peptic ulcer* consists of a break in the superficial epithelial cells penetrating down to the muscularis mucosa of either the stomach or the duodenum; there is a fibrous base and an
increase in inflammatory cells. *Erosions*, by contrast, are superficial breaks in the mucosa alone. DUs are most commonly found in the duodenal cap; the surrounding mucosa appears inflamed, haemorrhagic or friable (duodenitis). GUs are most commonly seen on the lesser curve near the incisura, but can be found in any part of the stomach.

**Epidemiology of peptic ulcer disease**

DUs affect approximately 10% of the adult population and are 2–3 times more common than GUs.

Ulcer rates are declining rapidly for younger men and increasing for older individuals, particularly women. Both DUs and GUs are common in the elderly. There is considerable geographical variation, with peptic ulcer disease being more prevalent in developing countries related to the high *H. pylori* infection. In the developed world, the percentage of NSAID-induced peptic ulcers is increasing as the prevalence of *H. pylori* declines.

**Clinical features of peptic ulcer disease**

The characteristic feature of peptic ulcer is recurrent, burning epigastric pain. It has been shown that if a patient points with a single finger to the epigastrium as the site of the pain, this is strongly suggestive of peptic ulcer disease. The relationship of the pain to food is variable and, on the whole, not helpful in diagnosis. The pain of a DU classically occurs at night (as well as during the day) and is worse when the patient is hungry, but this is not reliable. The pain of both GUs and DUs may be relieved by antacids.

Nausea may accompany the pain; vomiting is infrequent but can relieve the pain. Anorexia and weight loss may occur, particularly with GUs. Persistent and severe pain suggests complications, such as penetration into other organs. Back pain suggests a penetrating posterior ulcer. Severe ulceration can occasionally be symptomless, as many who present with acute ulcer bleeding or perforation have no preceding ulcer symptoms.

Untreated, the symptoms of a DU relapse and remit spontaneously. The natural history is for the disease to remit over many years due to the onset of atrophic gastritis and a decrease in acid secretion.

Epigastric tenderness is common in both ulcer and non-ulcer dyspepsia.

**Diagnosis of *Helicobacter pylori* infection**

Diagnosis of *H. pylori* is necessary if the clinician plans to treat a positive result. This is usually in the context of active peptic ulcer disease, previous peptic ulcer disease or mucosa-associated lymphoid tissue (MALT) lymphoma, or to ‘test and treat’ patients with dyspepsia under the age of 55 with no alarm symptoms (i.e. weight loss, anaemia, dysphagia, vomiting or family history of gastrointestinal cancer). *Examination* is usually unhelpful.

**Non-invasive methods**
• **Serological tests** detect immunoglobulin G (IgG) antibodies and are reasonably sensitive (90%) and specific (83%). They have been used in diagnosis and in epidemiological studies. IgG titres may take up to 1 year to fall by 50% after eradication therapy and therefore are not useful for confirming eradication or the presence of a current infection. Antibodies can also be found in the saliva but tests are not as sensitive or specific as serology.

• **13C-Urea breath test (Fig. 13.21)** is a quick and reliable test for *H. pylori* and can be used as a screening test. The measurement of $^{13}$CO$_2$ in the breath after ingestion of $^{13}$C-urea requires a mass spectrometer. The test is sensitive (90%) and specific (96%), but the sensitivity can be improved by ensuring the patient has not taken antibiotics in the 4 weeks before the test and PPIs in the previous 2 weeks.

![Figure 13.21](image.png)

**FIGURE 13.21** Metabolism of urea by *Helicobacter pylori* (Hp). The different tests available for the detection of *H. pylori* are shown.

• **Stool antigen test** is beginning to supersede breath testing as the method used to determine *H. pylori* status. A specific immunoassay, using monoclonal antibodies for the qualitative detection of *H. pylori* antigen, is now widely available. The overall sensitivity is 97.6% and specificity is 96%. The test is useful in the diagnosis of *H. pylori* infection and for monitoring efficacy of eradication therapy. Patients should be off PPIs for 2 weeks but can continue with H$_2$-blockers. Newer stool antigen tests are being developed that can be performed in the clinic setting, although at present the sensitivity and specificity are not as good as for those performed in the laboratory.

**Invasive methods (endoscopy)**

• **Biopsy urease test**. Gastric biopsies, usually antral unless additional material is needed to exclude proximal migration, are added to a substrate containing urea and phenol red. If *H.*
*pylori* is present, the urease enzyme that the bacteria produce splits the urea to release ammonia, which raises the pH of the solution and causes a rapid colour change (yellow to red). This enables patients’ *H. pylori* status to be determined before they leave the endoscopy suite. The test may be falsely negative if patients are taking PPIs or antibiotics at the time.

- **Histology.** *H. pylori* can be detected histologically on routine (Giemsa) stained sections of gastric mucosa obtained at endoscopy. The sensitivity is reduced if a patient is on PPIs, but less so than with the urease test. Sensitivity can be improved with immunohistochemical staining using an anti-*H. pylori* antibody.

- **Culture.** Biopsies obtained can be cultured on a special medium, and *in vitro* sensitivities to antibiotics can be tested. This technique is typically used for patients with refractory *H. pylori* infection to identify the appropriate antibiotic regimen; routine culture is rare.

### Investigation of suspected peptic ulcer disease

- **Patients under 55 years of age,** with typical symptoms of peptic ulcer disease who test positive for *H. pylori*, can start eradication therapy without further investigation.

- **Older patients** require endoscopic diagnosis (Fig. 13.22) and exclusion of cancer. All gastric ulcers must be biopsied to exclude an underlying malignancy and should be followed up endoscopically until healing has taken place.

![FIGURE 13.22 Endoscopic views in Helicobacter pylori infection. A. Duodenal ulcer with inflamed duodenal folds. B. Benign gastric ulcer.](image)

- **All patients with ‘alarm symptoms’** should undergo endoscopy.

### Management

#### Eradication therapy

Current recommendations are that all patients with duodenal and gastric ulcers should have *H. pylori* eradication therapy if the bacteria are present. Many patients have incidental *H. pylori* infection with no GU or DU. On balance, whether all such patients should have eradication therapy is controversial (see ‘Functional dyspepsia’, pp. 429–430).

The increase in the prevalence of GORD and adenocarcinoma of the lower oesophagus in
the last few years is currently unexplained, but has been postulated to be linked to eradication of \textit{H. pylori}; this seems unlikely but is not disproven.

Depending on local antibacterial resistance patterns, standard eradication therapies in the developed world are successful in approximately 90\% of patients. Re-infection is very uncommon (1\%) in developed countries. In developing countries, re-infection is more common, compliance with treatment may be poor and metronidazole resistance is high (>50\%, as it is frequently used for parasitic infections), so failure of eradication is common.

There are many regimens for eradication, but all must take into account that:

• Good compliance is essential.

• There is a high incidence of resistance to metronidazole and clarithromycin, particularly in some populations. Clarithromycin resistance has doubled in Europe in the last decade.

• Oral metronidazole has frequent side-effects.

• Bismuth chelate is unpleasant to take, even as tablets.

Metronidazole, clarithromycin, amoxicillin, tetracycline and bismuth are the most widely used agents. Resistance to amoxicillin (1–2\%) and tetracycline (<1\%) is low, except in countries where they are available without prescription, where resistance may exceed 50\%. Quinolones (such as ciprofloxacin), furazolidone and rifabutin are also used when standard regimens have failed (‘rescue therapy’). None of these drugs is effective alone; eradication regimens therefore usually comprise two antibiotics, given with powerful acid suppression in the form of a PPI. Bismuth-containing quadruple therapy is advocated as first-line treatment because of increasing clarithromycin resistance; the standard clarithromycin-based triple therapy has been replaced as the treatment of choice in areas where resistance is high.

\textbf{Example regimens}

• Omeprazole 20 mg + clarithromycin 500 mg and amoxicillin 1 g – all twice daily

• Omeprazole 20 mg + metronidazole 400 mg and clarithromycin 500 mg – all twice daily.

These should be given for 7 or 14 days. Two-week treatments increase the eradication rates but increased side-effects may reduce compliance.

In \textit{eradication failures} and in areas of clarithromycin resistance, bismuth chelate (120 mg 4 times daily), metronidazole (400 mg 3 times daily), tetracycline (500 mg 4 times daily) and a PPI (20–40 mg twice daily) for 14 days is used. Sequential courses of therapy are also used in such cases (5 days of PPI and amoxicillin, followed by a 5-day period of PPI with clarithromycin and tinidazole). With the increase in clarithromycin resistance, many are using this quadruple therapy for initial treatment.

Prolonged therapy with a PPI after a course of PPI-based 7-day triple therapy is not necessary for ulcer healing in most \textit{H. pylori}-infected patients. The effectiveness of treatment for uncomplicated duodenal ulcer should be assessed symptomatically. If symptoms persist, breath or stool testing should be performed to check eradication (off PPI therapy).

Patients with a risk of bleeding or those with complications, such as haemorrhage or perforation, should always have a $^{13}$C-urea breath test or stool test for \textit{H. pylori} 6 weeks after
the end of treatment to be sure that eradication has been successful. Long-term PPIs may be necessary if a rebleed would be likely to be fatal.

**General measures**

Stopping smoking should be strongly encouraged, as smoking slows mucosal healing.

Patients with gastric ulcers should be routinely re-endoscoped at 6 weeks to confirm mucosal healing and exclude an underlying gastric cancer. Repeat biopsies may be necessary.

### Complications of peptic ulcer disease

#### Haemorrhage

See page 386.

#### Perforation

The frequency of perforation (see also pp. 432–435) of peptic ulceration is decreasing, partly because of medical therapy. DUs perforate more commonly than GUs, usually into the peritoneal cavity; perforation into the lesser sac also occurs. Detailed management of perforation is described on pages 432-435. Laparoscopic surgery is usually performed to close the perforation and drain the abdomen. Conservative management using nasogastric suction, intravenous fluids and antibiotics is occasionally used in elderly and very sick patients.

#### Gastric outlet obstruction

The obstruction may be pre-pyloric, pyloric or duodenal. The obstruction occurs either because there is an active ulcer with surrounding oedema or because the healing of an ulcer has been followed by scarring. However, obstruction due to peptic ulcer disease and gastric malignancy are now uncommon; Crohn's disease or external compression from a pancreatic carcinoma is a more common cause. Adult hypertrophic pyloric stenosis is a very rare cause.

After gastric outlet obstruction, the stomach becomes full of gastric juice and ingested fluid and food, giving rise to the main symptom of vomiting, usually without pain, as the characteristic ulcer pain has abated owing to healing.

Vomiting is infrequent, projectile and large in volume; the vomitus contains particles of previous meals. On examination of the abdomen, there may be a succussion splash. The diagnosis is made by endoscopy but can be suspected from the nature of the vomiting; by contrast, psychogenic vomiting is frequent, small-volume and usually noisy.

Severe or persistent vomiting causes loss of acid from the stomach and a hypokalaemic metabolic alkalosis (see pp. 180–181). Vomiting will often settle with intravenous fluid and electrolyte replacement, gastric drainage via a nasogastric tube, and potent acid suppression therapy. Endoscopic dilatation of the pyloric region is useful, as is luminal stenting, and overall, 70% of patients can be managed without surgery.
Surgical treatment and its long-term consequences

Once the mainstay of treatment, surgery is now used in peptic ulcer disease only for complications including:

• recurrent uncontrolled haemorrhage
• perforation, which is oversewn.

No other procedure, such as gastrectomy or vagotomy, is required.

In the past, two types of operation were performed: a partial gastrectomy or a vagotomy. In the latter, either a truncal vagotomy with a pyloroplasty or gastro-jejunostomy was performed, or highly selective vagotomy or proximal gastric vagotomy, which did not require a bypass procedure.

**Long-term complications** of surgery, which are still seen occasionally, include:

• **Recurrent ulcer.** If this occurs, check for *H. pylori*; rule out Zollinger–Ellison syndrome (see p. 512). Malignancy needs to be excluded in all cases.

• **Dumping.** This term describes a number of upper abdominal symptoms (e.g. nausea and distension associated with sweating, faintness and palpitations) that occur in patients following gastrectomy or gastroenterostomy. It is due to ‘dumping’ of food into the jejunum, causing rapid fluid shifts from plasma to dilute the high osmotic load with reduction of blood volume. The symptoms are usually mild and patients adapt to them. It is rare for it to be a long-term problem, and if so, the symptoms usually have a functional element. Hypoglycaemia can also occur.

• **Diarrhoea.** This was chiefly seen after vagotomy. Recurrent severe episodes occurred in about 1% of patients. Antidiarrhoeals are the usual treatment.

• **Nutritional complications.** In the long term, almost any gastric surgery, but particularly gastrectomy, may be followed by:
  
  – iron deficiency, due to poor absorption
  – folate deficiency, usually due to poor intake
  – vitamin B<sub>12</sub> deficiency, due to intrinsic factor deficiency
  – weight loss, usually due to reduced intake.

### Other *H. pylori*-associated diseases

• **Gastric adenocarcinoma.** The incidence of distal (but not proximal) gastric cancer parallels that of *H. pylori* infection in countries with a high incidence of gastric cancer. Serological studies show that people infected with *H. pylori* have a higher incidence of distal gastric carcinoma (see p. 382).

• **Gastric B-cell lymphoma.** Over 70% of patients with gastric B-cell lymphomas (MALT) have *H. pylori*. *H. pylori* gastritis has been shown to contain the clonal B cell that eventually gives rise to the MALT lymphoma (see pp. 384 and 382).
NSAIDs, *Helicobacter* and ulcers

Aspirin and other NSAIDs deplete mucosal prostaglandins by inhibiting the cyclo-oxygenase (COX) pathway, which leads to mucosal damage. Cyclo-oxygenase occurs in two main forms: COX-1, the constitutive enzyme; and COX-2, inducible by cytokine stimulation in areas of inflammation. COX-2-specific inhibitors have less effect on the COX-1 enzyme in the gastric mucosa; they still produce gastric mucosal damage but less than with other conventional NSAIDs. Their use is limited by concern regarding cardiovascular side-effects.

Some 50% of patients taking regular NSAIDs will develop gastric mucosal damage and approximately 30% will have ulcers on endoscopy. Only a small proportion of patients have symptoms (about 5%) and only 1–2% have a major problem: that is, gastrointestinal bleed or perforation. Because of the large number of patients on NSAIDs, including low-dose aspirin for vascular prophylaxis, this is a significant problem, particularly in the elderly.

*H. pylori* and NSAIDs are independent and synergistic risk factors for the development of ulcers. In a meta-analysis, the odds ratio (OR) for the incidence of peptic ulcer was 61.1 in patients infected with *H. pylori* and also taking NSAIDs, compared with uninfected controls not taking NSAIDs.

### Management

- Stop the ingestion of NSAIDs.
- Give a PPI.
- Start *H. pylori* eradication therapy if the patient is *H. pylori*-positive.

In many people with severe arthritis, stopping NSAIDs may not be possible. Therefore use:

- **An NSAID** with low GI side-effects at the lowest dose possible (see pp. 665–666). If there is no cardiovascular risk, a COX-2 NSAID can be used (see p. 666).
- **Prophylactic cytoprotective therapy**, e.g. PPI or misoprostol (a synthetic analogue of prostaglandin E<sub>1</sub> 800 µg/day) for all high-risk patients, i.e. over 65 years, those with a peptic ulcer history, particularly with complications, and those on corticosteroid or anticoagulant therapy. PPIs reduce the risk of endoscopic duodenal and gastric ulcers and are better tolerated than misoprostol, which causes diarrhoea.

### Gastric tumours

**Adenocarcinoma**

Gastric cancer is currently the fourth most common cancer found worldwide and the second leading cause of cancer-related mortality. The incidence increases with age (peak incidence 50–70 years), and it is rare under the age of 30 years. The highest incidence of the disease is found in Eastern Asia, Eastern Europe and South America. The incidence in men is twice that
in women and varies throughout the world, being high in Japan (M: 53/100 000, F: 21.3/100 000) and Chile, and relatively low in the USA (M: 7/100 000, F: 2.9/100 000). In the UK, carcinoma of the stomach (see Fig. 13.1) is the eighth most common cancer (M: 16/100 000, F 9/100 000). The overall worldwide incidence of gastric carcinoma is falling, even in Japan, probably due to reductions in the incidence of Helicobacter and, before this, improvements in food storage. However, the incidence of proximal gastric cancers is increasing in the West and they have very similar demographic and pathological features to Barrett's-associated oesophageal adenocarcinoma.

### Epidemiology and pathogenesis

**H. pylori infection** and distal gastric cancer are strongly linked. *H. pylori* is recognized by the International Agency for Research in Cancer (IARC) as a group 1 (definite) gastric carcinogen. *H. pylori* infection causes chronic gastritis, which eventually leads to atrophic gastritis and pre-malignant intestinal metaplasia (*Fig. 13.23*). Much of the earlier epidemiological data (i.e. the increase of cancer in lower socioeconomic groups) can be explained by the intrafamilial spread of *H. pylori*. Epstein–Barr virus is detected in 2–16% of gastric cancers worldwide, but its role in aetiology is not well understood.
• **Dietary factors** may also be involved (as both initiators and promoters) and have separate roles in carcinogenesis. Diets high in salt probably increase the risk. Dietary nitrates can be converted into nitrosamines by bacteria at neutral pH; nitrosamines are known to be carcinogenic in animals but the evidence in human carcinogenesis is limited. Nitrosamines are also present in the stomach of patients with achlorhydria, who have an increased cancer risk.

• **Tobacco smoking** is associated with an increased incidence of stomach cancer.

• **Genetic abnormality** is also a factor. The most common abnormality is a loss of heterozygosity (LOH) of tumour suppressor genes such as *p53* (in 50% of cancers, as well as in pre-cancerous states) and the gene encoding adenomatous polyposis coli (*APC*) (in over one-third of gastric cancers). These abnormalities are similar to those found in colorectal cancers. Some rare families with diffuse gastric cancer have been shown to have mutations in the E-cadherin gene (*CDH-1*). There is a higher incidence of gastric cancer in blood group A patients.
• **First-degree relatives** of patients with gastric cancer have 2–3-fold increased relative risk of developing the disease, but this may be environmental rather than inherited.

• **Pernicious anaemia** carries a small increased risk of gastric carcinoma due to the accompanying atrophic gastritis.

• **Partial gastrectomy** (postoperative stomach) carries an increased risk of gastric cancer, whether performed for a GU or DU; this is probably due to untreated *H. pylori* infection.

### Screening

Earlier diagnosis has been advocated in an attempt to improve the poor prognosis of gastric cancer. (Screening is discussed on pp. 591–592.) Although the incidence of gastric cancer is falling in Japan, where aggressive screening by barium studies is followed by endoscopy if there is doubt, there is no evidence that screening has had an effect on overall mortality. Similarly, early investigation of dyspepsia has had little effect on mortality, possibly because of the relatively low prevalence of cancer.

### Early gastric cancer

Early gastric cancer is defined as a carcinoma that is confined to the mucosa or submucosa, regardless of the presence of lymph node metastases. It is associated with 5-year survival rates of approximately 90%, but many of these patients would have survived 5 years without treatment. In Japan, mass screening with mobile units has increased the proportion of early gastric cancers (EGC) diagnosed. In a large series of patients from the UK with gastric cancer, only 0.7% were identified as having EGC. They are usually detected by chance, as although EGC exists in Western populations, endoscopists do not readily recognize it at present.

### Pathology

There are two major types of gastric cancer:

• **Intestinal (type 1)** with well-formed glandular structures (differentiated). The tumours are polypoid or ulcerating lesions with heaped-up, rolled edges. Intestinal metaplasia is seen in the surrounding mucosa, often with *H. pylori*. This type is more likely to involve the distal stomach and occur in patients with atrophic gastritis. It has a strong environmental association.

• **Diffuse (type 2)** with poorly cohesive cells (undifferentiated) that tend to infiltrate the gastric wall. It may involve any part of the stomach, especially the cardia, and has a worse prognosis than the intestinal type. Loss of expression of the cell adhesion molecule E-cadherin is the key event in the carcinogenesis of diffuse gastric cancers. Unlike type 1 gastric cancers, type 2 cancers have similar frequencies in all geographic areas and occur in a younger population. Some 50% of gastric cancers in Western countries occur in the proximal stomach.
Clinical features

Symptoms

Around 50% of patients with EGC discovered at screening have no symptoms. Most patients with carcinoma of the stomach have advanced disease at the time of presentation. The most common symptom of advanced disease is epigastric pain, indistinguishable from the pain of peptic ulcer disease; it may be relieved by food and antacids. The pain can vary in intensity but may be constant and severe, and there may also be nausea, anorexia and weight loss. Vomiting is frequent and can be severe if the tumour encroaches on the pylorus. Dysphagia can occur with tumours involving the fundus. Gross haematemesis is unusual but anaemia from occult blood loss is frequent. No pattern of symptoms is suggestive of EGC.

Widely spreading submucosal gastric cancer causes diffuse thickening and rigidity of the stomach wall and is called ‘linitis plastica’.

Patients can present at a late stage with malignant ascites or jaundice due to liver involvement. Metastases also occur in bone, brain and lung, producing appropriate symptoms.

Signs

Weight loss is often the dominant feature. Nearly 50% of patients have a palpable epigastric mass with abdominal tenderness. A palpable lymph node is sometimes found in the supraclavicular fossa (Virchow's node, usually on the left side), and metastases are present in up to one-third of patients at presentation. This cancer is the most frequently associated with dermatomyositis (see p. 698) and acanthosis nigricans.

Diagnosis

• **Gastroscopy (Fig. 13.24)** allows biopsies to be taken for histological assessment. Positive biopsies can be obtained in almost all cases of obvious carcinoma, but a negative biopsy does not necessarily rule out the diagnosis. For this reason, 8–10 biopsies should be taken from suspicious lesions. Diffuse type gastric cancer infiltrates the submucosa and muscularis propria and can be undetected on endoscopy; multiple deep biopsies help.
Staging

- **CT scan of the chest and abdomen** with a gastric water load can demonstrate gastric wall thickening, lymphadenopathy and lung and liver secondaries, but has limited ability to determine the depth of local tumour invasion.

- **Endoscopic ultrasound** is useful for local staging to demonstrate the depth of penetration of the cancer through the gastric wall and extension into local lymph nodes. It complements CT and ultrasound but is most relevant to confirm that a cancer is confined to the superficial mucosa, before endoscopic resection.

- **Laparoscopy** is useful in patients being considered for surgery to exclude serosal disease.

- **PET and CT/PET** can be helpful in further delineation of the cancer.

The TNM classification is used. The tumour grade (T) indicates depth of tumour invasion, N denotes the presence or absence of lymph nodes, and M indicates presence or absence of metastases. TNM classification is then combined into stage categories 0–4. At presentation, two-thirds of patients are at stage 3 or 4: that is, advanced disease (Box 13.13). The histological grade of the tumour also determines survival.

Management

As with all cancers, treatment is discussed with a multidisciplinary team. Early non-ulcerated mucosal lesions can be removed endoscopically by either endoscopic mucosal resection or endoscopic submucosal dissection.

Surgery remains the most effective form of treatment if the patient is an operative candidate. Careful selection has reduced the numbers undergoing surgery and has improved the overall surgical 5-year survival rates to around 30%. Five-year survival rates in ‘curative’ operations are as high as 50%. Surgery, combined chemoradiotherapy and treatment of advanced disease are described on pages 635–636. The multinational MAGIC trial demonstrated the benefits of perioperative chemotherapy with epirubicin, cisplatin and infusional 5-fluorouracil (ECF) (see p. 636), where 5-year survival in operable gastric and lower oesophageal adenocarcinomas increased from 23% to 36%. An alternative regimen is oral epirubicin, oxaliplatin and capecitabine. Despite the improved results, the overall survival rate for a patient with gastric carcinoma has not dramatically improved, with a maximum 5-year survival rate of 10% overall. Palliative care, with relief of pain and counselling, is usually required.

Gastrointestinal stromal tumours (GIST)

Gastrointestinal stromal tumours (GISTs) are a subset of gastrointestinal mesenchymal tumours of varying differentiation. They are usually asymptomatic and found by chance but occasionally they can ulcerate and bleed. There are 200–900 new cases each year in the UK. GISTs mostly affect people between 55 and 65 years of age.

These tumours were previously classified as gastrointestinal leiomyomas, leiomyosarcomas, leiomyoblastomas or schwannomas. Truly benign leiomyomas do occur, mainly in the oesophagus, but GISTs are now recognized as a distinct group of mesenchymal tumours and comprise about 80% of gastrointestinal mesenchymal tumours. They are of stromal origin and are thought to share a common ancestry with the interstitial cells of Cajal. They have varying differentiation, with mutations occurring in the cellular proto-oncogene KIT (which leads to activation and cell-surface expression of the tyrosine kinase KIT (CD 117)) in 80%, and also in platelet-derived growth factor receptor-α (PDGFRA) in up to 10% of patients.

Management

Treatment is surgical as far as possible. These tumours generally grow slowly but may be malignant. Imatinib, a tyrosine kinase inhibitor (see pp. 601–602), is chosen for unresectable or metastatic disease, and is now used as adjunctive therapy after surgical removal of the primary in the absence of metastatic disease. Some patients are resistant to this; sunitinib can be used as an alternative agent over a short time period.

Primary gastric lymphoma
Mucosa-associated lymphatic tissue (MALT) lymphomas are indolent B-cell marginal zone lymphomas that primarily involve sites other than lymph nodes (gastrointestinal tract, thyroid, breast or skin). They constitute about 10% of all types of non-Hodgkin's lymphoma (NHL).

Aetiology

About 90% of cases are due to *H. pylori* infection. Chromosome abnormalities t(1;14)(p22;q32) and t(11;18)(q21;q21) have also been noted in this form of NHL.

Clinical features

Most patients are diagnosed in their 60s with stage I or stage II disease outside the lymph nodes. Patients have stomach pain, ulcers or other localized symptoms, but rarely have systemic complaints such as fatigue or fever.

Management

Eradication of *H. pylori* infection may resolve cases of local gastric involvement. After standard eradication regimens, 50% of patients show resolution at 3 months. Other patients may resolve after 12–18 months of observation. Stage III or IV disease is treated with surgery or chemotherapy with or without radiation. The prognosis is good, with an estimated 90% 5-year survival.

Gastric polyps

Gastric polyps are found in about 1% of endoscopies, usually by chance. They rarely produce symptoms, but larger lesions can result in anaemia or haematemesis.

Endoscopic biopsy is the usual approach to diagnosis and treatment is possible polypectomy based on histological finding. Occasional large or multiple polyps may require surgery.

- **Hyperplastic polyps** are by far the most common type. Most are <2 cm. The polyps are rarely pre-malignant, but may be accompanied by pre-malignant atrophic gastritis.

- **Adenomatous polyps** are usually solitary lesions in the antrum. Approximately 3% progress to gastric cancer, especially if >2 cm in diameter, but they are not a common cause of gastric cancer (compare this with colorectal cancer).

- **Cystic gland polyps** contain microcysts that are lined by fundic-type parietal and chief cells. They are located in the fundus and body of the stomach. They are found in otherwise normal subjects, but are especially common in familial polyposis syndromes and patients on PPIs. Their malignant potential is negligible, although low-grade dysplasia is seen in the absence of familial adenomatous polyposis coli (FAP), and high-grade dysplasia exclusively in its presence.

- **Inflammatory fibroid polyps** are benign spindle cell tumours infiltrated by eosinophils.
Excision of these polyps is indicated because of their propensity to enlarge and cause obstruction.

**Further reading**

---

**Acute and Chronic Gastrointestinal Bleeding**

This section should be read in conjunction with the descriptions of the specific conditions mentioned.

### Acute upper gastrointestinal bleeding

The cardinal features are haematemesis (the vomiting of blood) and melaena (the passage of black tarry stools, the black colour being due to blood altered by passage through the gut). Melaena can occur with bleeding from any lesion proximal to the right colon. Rarely, melaena can also result from bleeding from the right colon.

Following a bleed from the upper gastrointestinal tract, unaltered blood can appear *per rectum*, but the bleeding must be massive and is almost always accompanied by shock. The passage of dark blood and clots without shock is always due to lower gastrointestinal bleeding.

### Aetiology

Peptic ulceration is the most common cause of serious and life-threatening gastrointestinal bleeding (*Fig. 13.25*). The relative incidence of causes depends on the patient population; overall, incidence has fallen. In the developing world, haemorrhagic viral infections (see *Box 11.33*) can cause significant gastrointestinal bleeding.
Aspirin (even 75 mg/day) and other NSAIDs can produce ulcers and erosions. These agents are also responsible for gastrointestinal haemorrhage from both duodenal and gastric ulcers, particularly in the elderly. They are available over the counter in the UK and patients may not be aware that they are taking aspirin or an NSAID. Corticosteroids in the usual therapeutic doses have no influence on gastrointestinal haemorrhage. Anticoagulants and antiplatelet agents do not cause acute gastrointestinal haemorrhage per se, but bleeding from any cause is greater if the patient is anticoagulated.

**Clinical approach to the patient**

All cases with a recent (i.e. within 48 hours) significant gastrointestinal bleed should be seen in hospital. In many, no immediate treatment is required, as there has been only a small amount of blood loss. Approximately 85% of patients stop bleeding spontaneously within 48 hours.

Scoring systems have been developed to assess the risk of rebleeding or death.
Boxes 13.14 and 13.15 show the Rockall score, which is based on clinical and endoscopy findings. The Blatchford score uses the level of plasma urea, haemoglobin and clinical markers, but not endoscopic findings, to determine the need for intervention such as blood transfusion or endoscopy in gastrointestinal bleeding.

The following factors affect the risk of rebleeding and death:

- age
- evidence of co-morbidity, e.g. cardiac failure, ischaemic heart disease, chronic kidney disease and malignant disease
- presence of the classical clinical features of shock (pallor, cold peripheries, tachycardia and low blood pressure)
- endoscopic diagnosis, e.g. Mallory–Weiss tear, peptic ulceration, gastric antral vascular ectasia (GAVE; *Fig. 13.26*)

*Fig. 13.26*  Endoscopic view of gastric antral vascular ectasia (GAVE). An argon plasma coagulation catheter is shown at 6 o’clock.

- endoscopic stigmata of recent bleeding, e.g. adherent blood clot, spurting vessel
- clinical signs of chronic liver disease.

Bleeding associated with liver disease is often severe and recurrent if it is from varices. Liver failure can develop.
Management

Immediate management

This is shown in Box 13.16. In addition, stop NSAIDs, aspirin, clopidogrel and warfarin if patients are taking them. Stopping antiplatelets can be dangerous and may produce thrombosis; discuss this urgently with a cardiologist.

Box 13.16

Management of acute gastrointestinal bleeding

- Take history and perform examination. Note co-morbidity
- Monitor pulse and BP half-hourly
- Take blood for haemoglobin, urea, electrolytes, liver biochemistry, coagulation screen, group and crossmatching (2 units initially)
- Establish intravenous access – two large-bore i.v. cannulae
- Give blood transfusion/colloid if necessary. Indications for blood transfusion are:
  - a. Shock (pallor, cold nose, systolic BP below 100 mmHg, pulse >100 b.p.m.)
  - b. Haemoglobin <100 g/L in patients with recent or active bleeding
- Give oxygen therapy
- Perform urgent endoscopy in shocked patients/liver disease
- Continue to monitor pulse and BP
- Re-endoscope for continued bleeding/hypovolaemia
- Arrange surgery if bleeding persists

Many hospitals have multidisciplinary specialist teams with agreed protocols and the latter should be followed. Patients should be managed in high-dependency beds. Oxygen should be given and the patient should be kept nil by mouth until an endoscopy has been performed.

Patients with large bleeds and clinical signs of shock require urgent resuscitation. Details of the management of shock are given in Figure 25.24.

Blood volume

The major principle is to restore the blood volume rapidly to normal via one or more large-bore intravenous cannulae; plasma expanders or 0.9% saline are given until the blood becomes available (see pp. 1157–1158). Transfusion of red cell concentrates is used with a proposed transfusion threshold of 70 g/L. This has yet to be universally adopted.

Transfusion must be monitored to avoid overload leading to heart failure, particularly in the elderly. The pulse rate and venous pressure are guides to adequacy of transfusion. A central venous pressure line is inserted for patients with organ failure who require blood transfusion,
and in those most at risk of developing heart failure.

Haemoglobin levels are generally a poor indicator of the need to transfuse because anaemia does not develop immediately as haemodilution has not taken place. In most patients, the bleeding stops, albeit temporarily, so that further assessment can be made.

**Endoscopy**

Endoscopy will usually diagnose, stratify risk, and enable therapy to be performed if needed. Endoscopy should be carried out as soon as possible after the patient has been resuscitated. Patients with Rockall scores of 0 or 1 pre-endoscopy may be candidates for immediate discharge (see below) and outpatient endoscopy the following day, depending on local policy.

Endoscopy can detect the cause of the haemorrhage in 80% or more of cases. In patients with a peptic ulcer, if the stigmata of a recent bleed are seen (i.e. a spurting vessel, active oozing, fresh or organized blood clot or black spots), the patient is more likely to rebleed. Calculation of the post-endoscopy Rockall score (see Box 13.15) gives an indication of the risk of rebleeding and death.

**At first endoscopy:**

- Varices should be treated, usually with banding.
- Stenting is also used for bleeding varices but is not yet widely available (see p. 471). It is an alternative to a Sengstaken tube.
- Bleeding ulcers and those with stigmata of recent bleeding should be treated using two or three haemostatic methods: injection with adrenaline (epinephrine) and thermal coagulation (with heater probe, bipolar probe, or laser or argon plasma coagulation) or endoscopic clipping; dual and triple therapy is more effective than monotherapy in reducing rebleeding. Haemostatic powders have recently been developed that can be sprayed through a catheter during gastroscopy. These are useful in the more difficult bleeds, such as cancer-related bleeding and challenging ulcers.
- Antral biopsies should be taken to look for *H. pylori*. A positive biopsy urease test is valid but a negative test is not reliable. If the urease test is negative, gastric histology should always be performed.

**Drug therapy**

After diagnosis at endoscopy, an intravenous PPI (e.g. omeprazole 80 mg followed by infusion 8 mg/h for 72 h) should be given to all patients with actively bleeding ulcers or ulcers with a visible vessel, as it reduces rebleeding rates and the need for surgery.

**Uncontrolled or repeat bleeding**

Endoscopy should be repeated to assess the bleeding site and to treat, if possible. Embolization by an interventional radiologist may be necessary if the bleeding persists. If this is not available locally or is unsuccessful, surgery is used to control the haemorrhage primarily.
**Discharge policy**

The patient's age, diagnosis on endoscopy, co-morbidity, the presence or absence of shock and the availability of support in the community should be taken into consideration. In general, all patients who are haemodynamically stable and have no stigmata of recent haemorrhage on endoscopy (Rockall score pre-endoscopy 0, post-endoscopy <1) can be discharged from hospital within 24 hours. All shocked patients and patients with co-morbidity need longer inpatient observation.

**Specific conditions**

**Oesophageal varices**

These are discussed on page 471.

**Mallory–Weiss tear**

This is a linear mucosal tear occurring at the oesophago gastric junction and produced by a sudden increase in intra-abdominal pressure. It often follows a bout of coughing or retching, and is classically seen after alcoholic ‘dry heaves’. There may, however, be no antecedent history of retching. Most bleeds are minor and discharge is usual within 24 hours. The haemorrhage may be large but most patients stop spontaneously. Early endoscopy confirms diagnosis and allows therapy such as clipping if necessary. Surgery with oversewing of the tear is rarely needed.

**Chronic peptic ulcer**

Eradication of *H. pylori* is started as soon as possible (see p. 380). A PPI is continued for 4 weeks to ensure ulcer healing. Eradication of *H. pylori* should always be checked in a patient who has bled, and long-term acid suppression is given if *H. pylori* eradication cannot be achieved. If bleeding is not controlled, the patient should either undergo angiography and embolization or be referred directly for surgery.

**Gastric carcinoma**

Most of these patients do not have large bleeds but surgery is occasionally necessary for uncontrolled or repeat bleeding. Usually, surgery can be delayed until the patient has been fully evaluated (see p. 383). Oozing from gastric cancer is very difficult to control endoscopically. Radiotherapy can occasionally be successful but its effects are not immediate.

**Bleeding after percutaneous coronary intervention**

In the era of ever more aggressive percutaneous coronary intervention (PCI), the list of antithrombotic medication grows longer: glycoprotein IIb/IIIa inhibitors, unfractionated heparin, low-molecular-weight heparin, fondaparinux and platelet inhibitors (e.g. clopidogrel, prasugrel and ticagrelor). Taken in addition to the oral anticoagulants that this group of patients are often taking, these give rise to a gastrointestinal bleeding rate of approximately 2% of
patients undergoing PCI (who are on antiplatelet therapy, e.g. clopidogrel), and there is a high mortality of 5–10%. It has become increasingly evident in this patient group that gastroscopy should be performed on an urgent basis and not deferred for days or weeks. A bolus of intravenous PPI is administered, followed by an infusion; platelet infusion is given to counter the effect of clopidogrel. Management is difficult, as cessation of antiplatelet therapy has a high risk of acute stent thrombosis and also an associated high mortality. Using a risk assessment score (e.g. Blatchford), a reasonable approach is to stop all antiplatelet therapy in high-risk patients but continue it in low-risk ones. Co-prescribed proton pump inhibition does not decrease the antiplatelet effect of clopidogrel, as was first thought. These patients should be under the combined care of a cardiologist and a gastroenterologist.

### Prognosis

The mortality from gastrointestinal haemorrhage has not changed from 5–12% over the years, despite many changes in management, mainly because of a demographic shift to more elderly patients with co-morbidity. The lowest mortality rates are achieved in dedicated medical/surgical gastrointestinal units.

### Acute lower gastrointestinal bleeding

Massive bleeding from the lower gastrointestinal tract is rare and is usually due to diverticular disease or ischaemic colitis. Common causes of small bleeds are haemorrhoids and anal fissures. The causes of lower gastrointestinal bleeding are shown in **Figure 13.27**.

![Figure 13.27 Causes of lower gastrointestinal bleeding. The sites shown are illustrative – many of the lesions can be seen in other parts of the colon.](image-url)
Management

Most acute lower gastrointestinal bleeds start and stop spontaneously. The few patients who continue bleeding and are haemodynamically unstable need resuscitation using the same principles as for upper gastrointestinal bleeding (see p. 386). Surgery is rarely required.

A diagnosis is made using the history and examination, including rectal examination and the following investigations as appropriate:

- **Proctoscopy** (e.g. anorectal disease, particularly haemorrhoids)
- **Flexible sigmoidoscopy or colonoscopy** (e.g. inflammatory bowel disease, cancer, ischaemic colitis, diverticular disease, angiodysplasia)
- **Video capsule endoscopy** (Fig. 13.28)

![Angiodysplastic lesions (arrows) seen on video capsule endoscopy.](image)

- **Angiography** to seek vascular abnormality (e.g. angiodysplasia). The yield of angiography is low, so it is a test of last resort.

Isolated episodes of rectal bleeding in the young (<45 years) usually only require rectal examination and flexible sigmoidoscopy because the probability of a significant proximal lesion is very low, unless there is a strong family history of colorectal cancer at a young age. Individual lesions are treated as appropriate.

Chronic gastrointestinal bleeding

Patients with chronic bleeding usually present with iron deficiency anaemia (see pp. 524–526).

Chronic blood loss producing iron deficiency anaemia in all men, and all women after the menopause, is always due to bleeding from the gastrointestinal tract. The primary concern is to exclude cancer, particularly of the stomach or right colon, and coeliac disease. Occult stool tests are unhelpful.
**Diagnosis**

Chronic blood loss can occur with any lesion of the gastrointestinal tract that produces acute bleeding (see *Figs 13.25 and 13.27*). However, oesophageal varices usually bleed overtly and rarely present as chronic blood loss. Although uncommon in developed countries, hookworm is the most common worldwide cause of chronic gastrointestinal blood loss.

History and examination may indicate the most likely site of the bleeding, but if no clue is available, it is usual to investigate both the upper and lower gastrointestinal tract endoscopically at the same session (‘top and tail’), especially in males and postmenopausal females:

- **Upper gastrointestinal endoscopy** is usually performed first. Duodenal biopsies should always be taken to diagnose coeliac disease, even if coeliac serology has been performed.
- **Colonoscopy** follows and any lesion should be biopsied or removed, though it is unsafe to assume that colonic polyps are the cause of chronic blood loss.
- **Unprepared CT** scanning is a reasonable test to look for colon cancer in frail patients.
- **CT colonography** can be used as an alternative to colonoscopy.

If gastroscopy, colonoscopy and duodenal biopsy have not revealed the cause, investigation of the small bowel is necessary. **Capsule endoscopy** is the diagnostic investigation of choice but currently has no therapeutic ability. Positive diagnostic yield varies from 60% to 85%, depending on series. Bleeding lesions can be identified and later treated with balloon-assisted enteroscopy.

Occasionally, intravenous technetium-labelled colloid may be used to demonstrate a potential bleeding site in a Meckel’s diverticulum.

**Management**

The cause of the bleeding should be dealt with, if found. Oral iron is given to treat anaemia (see pp. 525–526), although intravenous infusions are occasionally required. Some patients will require maintenance with regular transfusion as a last resort.

**Further reading**

The Small Intestine

**Anatomy**

The small intestine extends from the duodenum to the ileocaecal valve. It is 3–6 m in length, and 300 m² in surface area. The upper 40% is the duodenum and jejunum; the remainder is the ileum. Its surface area is enormously increased by circumferential mucosal folds that bear multiple finger-like projections called villi. On the villi, the surface area is further increased by microvilli on the luminal side of the epithelial cells (enterocytes) ([Fig. 13.29](#fig13.29)).

![Structure of the small intestine](#fig13.29)

Each villus consists of a core containing blood vessels, lacteals (lymphatics) and cells (e.g. plasma cells and lymphocytes). The lamina propria contains plasma cells, lymphocytes, macrophages, eosinophils and mast cells. The crypts of Lieberkühn are the spaces between the...
bases of the villi.

Enterocytes are formed at the bottom of the crypts and migrate toward the tops of the villi, where they are shed. This process takes 3–4 days. On its luminal side, the enterocyte is covered by microvilli and a gelatinous layer called the glycocalyx. Scattered between the epithelial cells are mucin-secreting goblet cells and occasional intraepithelial lymphocytes and Paneth cells. Most of the blood supply to the small intestine is via branches of the superior mesenteric artery. The terminal branches are end arteries; there are no local anastomotic connections.

**Enteric nervous system**

The enteric nervous system (ENS) controls the functioning of the small bowel; it is an independent system that coordinates absorption, secretion, blood flow and motility. It is estimated to contain $10^8$ neurones (as many as the spinal cord), organized in two major ganglionated plexuses: the *myenteric plexus* between the muscular layers of the intestinal wall, and the *submucosal plexuses* associated with the mucosa. The ENS communicates with the central nervous system (CNS) via autonomic afferent and efferent pathways but can operate autonomously.

Coordination of small intestinal function involves a complex and only partly understood interplay between many neuroactive mediators and their receptors, ion channels, gastrointestinal hormones, nitric oxide and other transmitters. Acetylcholine, adrenaline (epinephrine), adenosine triphosphate (ATP), vasoactive intestinal peptide (VIP), and other hormones and opioids have been shown to have actions in the small bowel but the exact role of each is not yet clear.

**Gut motility**

The contractile patterns of the small intestinal muscular layers are primarily determined by the ENS. The CNS and gut hormones also have a modulatory role in motility. The interstitial cells of Cajal, which lie within the smooth muscle, appear to govern rhythmic contractions.

**During fasting**, a distally migrating sequence of motor events, termed the migrating motor complex (MMC), occurs in a cyclical fashion. The MMC consists of:

- a period of motor quiescence (*phase I*)
- a period of irregular contractile activity (*phase II*)
- a short (5–10-min) burst of regular phasic contractions (*phase III*).

Each MMC cycle lasts for approximately 90 minutes. In the duodenum, phase III is associated with increased gastric, pancreatic and biliary secretions. The role of the MMC is unclear, but the strong phase III contractions propel secretions, residual food and desquamated cells towards the colon. It is named the ‘intestinal housekeeper’.

**After a meal**, the MMC pattern is disrupted and replaced by irregular contractions. This seemingly chaotic pattern lasts typically for 2–5 hours after feeding, depending on the size and nutrient content of the meal. The irregular contractions of the fed pattern have a mixing
function, moving intraluminal contents to and fro and aiding the digestive process.

**Neuroendocrine peptide production**

The hormone-producing cells of the gut are scattered diffusely throughout its length and also occur in the pancreas.

Gut hormones play a part in the regulation and integration of the functions of the small bowel and other metabolic activities, including appetite. Their actions are complex and interactive, both with each other and with the ENS (*Box 13.17*).

### Physiology

In the small bowel, digestion and absorption of nutrients and ions takes place, as does the regulation of fluid absorption and secretion. The epithelial cells of the small bowel form a physical barrier that is selectively permeable to ions, small molecules and macromolecules. Digestive enzymes, such as proteases and disaccharidases, are produced by intestinal cells and expressed on the surface of microvilli; others, such as lipases produced by the pancreas, are associated with the glycocalyx. Some nutrients are absorbed most actively in specific parts of the small intestine: iron and folate in the duodenum and jejunum, and vitamin B$_{12}$ and bile salts in the terminal ileum, where they have specific receptors.

### General principles of absorption

**Simple diffusion**

This process is non-specific, requires no carrier molecule or energy, and takes place if there is a concentration gradient from the intestinal lumen (high concentration) to the bloodstream (low concentration). Vitamin B$_{12}$ can be absorbed from the jejunum by this means.

**Facilitated diffusion**

Absorption takes place down a concentration gradient but a membrane carrier protein is involved, conferring specificity on the process. Fructose transport is an example.

**Active transport**

Absorption occurs via a specific carrier protein, powered by cellular energy, allowing a
A substance to be transported against a concentration gradient. Many carrier proteins are powered by ion gradients across the enterocyte wall. For example, glucose crosses the enterocyte microvillous membrane from the lumen into the cell against a concentration gradient by using a **co-transporter** carrier molecule. This is the sodium/glucose co-transporter, SGLT1 (**Fig. 13.30**). The process is powered by the energy derived from the flow of Na⁺ ions from a high concentration outside the cell to a low concentration inside. The sodium gradient across the cell wall is maintained by a separate ATP-consuming Na⁺/K⁺ exchanger in the basolateral membrane. Glucose leaves the cell on the serosal side by facilitated diffusion via a sodium-independent carrier (GLUT-2) in the basolateral membrane.

**Fig. 13.30** Transcellular uptake of glucose across the intestinal epithelium. Glucose is co-transported across the apical membrane with sodium ions by the sodium-dependent glucose transporter (SGLT). This is secondary active transport, as the sodium is travelling down its electrochemical gradient. The sodium gradient is maintained by the primary active transport of sodium across the basolateral membrane by the Na⁺/K⁺ ATPase (thus intracellular Na⁺ is kept low). Transcellular transport of glucose is achieved by facilitated diffusion across the basolateral membrane as glucose is moved down its concentration gradient by GLUT-2.

Another active transport mechanism operates for Na⁺ absorption in the ileum using an Na⁺/H⁺ **exchange** mechanism, powered by the outwardly directed gradient of H⁺ across the cell membrane.

**Absorption of nutrients in the small intestine**

**Carbohydrate**
Dietary carbohydrate consists mainly of starch, with some sucrose and a small amount of lactose. Starch is a polysaccharide made up of numerous glucose units. In order to have a nutrient value, starch must be digested into smaller oligo-, di- and finally monosaccharides, which may then be absorbed. Polysaccharide hydrolysis begins in the mouth and is catalysed by salivary amylase, though the majority takes place under the action of pancreatic amylase in the upper intestine. The breakdown products of starch digestion are maltose and maltotriose, together with sucrose and lactose. These are further hydrolysed on the microvillous membrane by specific oligo- and disaccharidases to form glucose, galactose and fructose. These monosaccharides are then able to be transported across the enterocytes into the blood (see Fig. 13.30).

**Protein**

Dietary protein is digested by pancreatic proteolytic enzymes to amino acids and peptides prior to absorption. These enzymes are secreted by the pancreas as pro-enzymes and transformed to active forms in the lumen. Protein in the duodenal lumen stimulates the enzymatic conversion of trypsinogen to trypsin, and this, in turn, activates the other pro-enzymes, chymotrypsin and elastase.

These enzymes break down protein into oligopeptides. Some di- and tripeptides are absorbed intact by carrier-mediated processes, while the remainder are broken down into free amino acids by peptidases on the microvillous membranes of the enterocytes, prior to absorption into the cell by a variety of amino acid and peptide carrier systems.

**Fat**

Dietary fat consists mainly of triglycerides with some cholesterol and fat-soluble vitamins. Fat is emulsified by mechanical action in the stomach. Bile containing the amphipathic detergents, bile acids and phospholipids enters the duodenum following gall bladder contraction. These substances act to solubilize fat and promote hydrolysis of triglycerides in the duodenum by pancreatic lipase to yield fatty acids and monoglycerides. Bile acids, phospholipids and the products of fat digestion cluster together with their hydrophilic ends on the outside to form aggregations called mixed micelles. Trapped in the centre of the micelles are the hydrophobic monoglycerides, fatty acids and cholesterol. At the cell membrane, the lipid contents of the micelles are absorbed, while the bile salts remain in the lumen. Inside the cell, the monoglycerides and fatty acids are re-esterified to triglycerides. The triglycerides and other fat-soluble molecules (e.g. cholesterol, phospholipids) are then incorporated into chylomicrons to be transported into the lymph.

Any unabsorbed lipids that reach the ileum delay gastric emptying via peptide YY, which is secreted by the ileum (called the ‘ileal brake’). This delay allows more time for absorption of lipids in the small intestine.

Medium-chain triglycerides (MCTs, fatty acids of chain length 6–12) are transported via the portal vein with a small amount of long-chain fatty acid. Patients with pancreatic exocrine or bile salt insufficiency can therefore supplement their fat absorption with MCTs.
Bile salts are not absorbed in the jejunum, so the intraluminal concentration in the upper gut is high. They pass down the intestine to be absorbed in the terminal ileum and are transported back to the liver. This enterohepatic circulation prevents excess loss of bile salts (see p. 443).

The pathophysiology of fat absorption is shown in Figure 13.31. Interference with absorption can occur at all stages, as indicated, giving rise to steatorrhoea (>17 mmol or 6 g of faecal fat per day).

**Figure 13.31** Fat absorption in the small intestine. A. The pathophysiology of fat absorption. B. The formation of mixed micelles.

**Water and electrolytes**

Large amounts of water and electrolytes, partly dietary but mainly from intestinal secretions, are absorbed, coupled with absorption of monosaccharides, amino acids and bicarbonate in the upper jejunum. Water and electrolytes are also absorbed paracellularly (between the enterocytes) down electrochemical and osmotic gradients. Additional water and electrolytes are absorbed in the ileum and colon, where active sodium transport is not coupled to solute absorption. Secretion of fluid and electrolytes occurs together to maintain the normal functioning of the gut. Secretory diarrhoea (see p. 426) can occur because of defects in
intestinal secretory mechanisms.

**Water-soluble vitamins, essential metals and trace elements**
These are all absorbed in the small intestine. Vitamin B$_{12}$ (see pp. 529–530) and bile salts are absorbed by specific transport mechanisms in the terminal ileum; malabsorption of both these substances often occurs following ileal resection.

**Calcium**
Calcium absorption is discussed on [page 708].

**Iron**
Iron absorption is discussed on [pages 523–524].

**Response of the small bowel to antigens and pathogens**
The small bowel has a number of mechanisms to prevent colonization and invasion by pathogens while simultaneously preventing inappropriate responses to foreign antigens or the indigenous bacterial population. At the same time, commensal bacteria maintain the integrity of the small bowel and play a major role in host physiology.

**Mechanisms**

**Physical defence**
- The mucus layer.
- Continuous shedding of surface epithelial cells.
- The physical movement of the luminal contents.
- Colonization resistance – the ability of the indigenous microbiota to outcompete pathogens for a survival niche in the gut.

**Innate chemical defence**
- *Enzymes* such as lysozyme and phospholipase A$_2$, secreted by Paneth cells at the base of the crypts, help ensure an infection-free environment in the gut, even in the presence of commensal bacteria.
- *Antimicrobial peptides* are secreted from enterocytes and Paneth cells in response to pathogenic bacteria. These include *defensins*, which are 15–20 amino-acid peptides with potent activity against a broad range of pathogens, including Gram-positive and Gram-negative bacteria, fungi and viruses.
- *Trefoil peptides* are a family of small proteins secreted by goblet cells. They consist of a three-loop structure with intra-chain disulphide bonds, which makes the molecules highly resistant to digestion. Their actions include stabilization of mucus, promotion of cell migration to injured areas, and promotion of repair. Three trefoil factors (TFFs) are found in
humans (TFF1, TFF2 and TFF3), all of which have been implicated in the response to gastrointestinal injury in experimental models. Their molecular mode of action is not yet known.

**Innate immunological defence**

• *Humoral defence*. IgA is the principal mucosal antibody. It mediates mucosal immunity by agglutinating and neutralizing pathogens in the lumen and preventing colonization of the epithelial surface (*Fig. 13.32*). IgA is secreted from immunocytes in the lamina propria as dimers joined by a protein called the ‘joining chain’ (J-chain); in this form, it is known as polymeric IgA (pIgA). This pIgA is internalized by endocytosis at the basolateral membrane of enterocytes. It crosses the cell as a complex of pIgA/pIgAR and is secreted on to the mucosal surface.
**B-cell sensitization.** Antigens from the lumen of the bowel are transported by M cells and dendritic cells in the follicle-associated epithelium (FAE). This covers Peyer's patches in the 'dome' region that contain abundant virgin B cells, helper T cells and antigen-presenting cells. Activated B cells then produce IgA locally and are programmed to home back to the lamina propria. They travel through mesenteric lymph nodes and then via the thoracic duct to the blood and back to the small bowel and other mucosal surfaces (such as the airways), where they undergo terminal differentiation into plasma cells. Homing back to the gut is facilitated by the α4β7-integrin on gut-derived lymphocytes binding to MAdCAM-1, uniquely expressed on blood vessels in the gut.
• **Cellular defence.** T lymphocytes also provide host defence and initiate, activate and regulate adaptive immune responses. **Intestinal T lymphocytes** occur principally in three major compartments:

  – *Organized gut-associated lymphoid tissue (GALT)*, such as Peyer's patches, where mucosal T cell responses are generated, and after which cells leave the organized lymphoid tissue and home back to the mucosa.
  
  – *The lamina propria*, containing mostly CD4 cells.
  
  – The *surface epithelium*, where these lymphocytes are known as intraepithelial lymphocytes (IELs) and are mostly CD8 cells. T cells are sensitized to antigen in the Peyer's patch lymphoid tissue in a similar fashion to B cells, and pass through mesenteric lymph nodes into the thoracic duct and into the circulation, homing back to the small bowel to end up in the lamina propria or the epithelium. It is probable that IELs are cytotoxic cells, capable of killing virally or bacterially infected epithelial cells. CD4 cells in the lamina propria of healthy individuals are highly activated cells, probably protecting against low-grade infections, since loss of these cells, as in HIV infection, leads to colonization of the gut by protozoa such as cryptosporidia.

**Commensal bacteria**

The relationship between the hundred thousand billion microbes in the human gut and the host are only beginning to be appreciated. New molecular sequencing techniques have allowed the identification and classification of the gut microbiota. The use of metabonomics has aided the assessment of its functional output. There is increasing evidence that a reduction in the diversity of the gut microbiota is associated with a range of conditions, including inflammatory bowel disease and metabolic syndrome. Germ-free mice have essentially no mucosal immune system, showing that the abundant and activated immune system seen in healthy individuals is driven by the flora, without adverse effects. Bacteria also release chemical signals, such as lipopolysaccharide (LPS) and lipoteichoic acid, which are recognized by Toll-like receptors (TLRs) (see p. 127) present on a variety of intestinal cells, priming repair processes and enhancing the ability of the epithelium to respond to injury.

**Oral tolerance**

The immune system must guard against pathogens and toxins while avoiding an excessive response to the multiplicity of food antigens and commensal bacteria. The mechanisms by which tolerance occurs are undoubtedly multiple, including maintenance of barrier function to prevent excess antigen uptake, active inhibition via regulatory T cells, and dendritic cells that promote tolerogenic rather than immunogenic T-cell responses. All of these are likely to play a role in diseases such as coeliac disease, caused by an excessive T-cell response to gluten, or Crohn's disease, where tolerance to the indigenous bacterial population is defective.

**Clinical features of small bowel disease**
Regardless of the cause, the common presenting features of small bowel disease are listed below. However, 10–20\% of patients will have no diarrhoea or any other gastrointestinal symptoms.

- **Diarrhoea** is common and may be watery.
- **Steatorrhoea** occurs when the stool fat is >17 mmol/day (or 6 g/day). The stools are pale, bulky and offensive, and float (because of their increased air content), leaving a fatty film on the water in the pan and proving difficult to flush away.
- **Abdominal pain** and discomfort. Abdominal distension can cause discomfort and flatulence. The pain has no specific character or periodicity and is not usually severe.
- **Weight loss** is largely due to the anorexia that invariably accompanies small bowel disease. The calorie deficit due to malabsorption is small relative to the reduction in intake.
- **Nutritional deficiencies** of iron, vitamin B_{12}, folate or all of these, leading to anaemia, are the only common deficiencies. Occasionally, malabsorption of other vitamins or minerals occurs, causing bruising (vitamin K deficiency), tetany (calcium deficiency), osteomalacia (vitamin D deficiency), or stomatitis, sore tongue and aphthous ulceration (multiple vitamin deficiencies). Oedema due to hypoproteinaemia is due to low intake and intestinal loss of albumin (protein-losing enteropathy).

*Physical signs* are few and non-specific. If present, they are usually associated with anaemia and the nutritional deficiencies described above.

Abdominal examination is often normal, but sometimes distension or, rarely, hepatomegaly or an abdominal mass is found. Visible peristalsis and high-pitched bowel sounds can indicate chronic subacute obstruction of the small intestine: for example, that due to strictureing Crohn's disease. Gross weight loss, oedema and muscle wasting are seen only in severe cases. A neuropathy, not always due to B_{12} deficiency, can be present.
