### Investigation of small bowel disease

The emphasis in the investigation of malabsorption (*Fig. 13.33*) is on the structural features of the underlying disorder, rather than on the documentation of malabsorption itself.
Blood tests

• **Full blood count (FBC) and film.** Anaemia can be microcytic, macrocytic or normocytic, and the blood film may be dimorphic. Other abnormal cells (e.g. Howell–Jolly bodies, p. 553) may be seen in splenic atrophy associated with coeliac disease.

  – *Serum ferritin and iron saturation* should be measured to differentiate iron deficiency from anaemia of chronic disorder (see p. 525). Remember that ferritin is an acute phase protein and is therefore difficult to interpret in the context of an inflammatory response for any reason.
– Serum $B_{12}$ and serum and red cell folate should be measured. Red cell folate is a good indicator of the presence of small bowel disease. It is frequently low in both coeliac disease and Crohn's disease, which are the two most common causes of small bowel disease in developed countries.

- **Inflammatory markers.** The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) should be assessed.

- **Serum calcium** and alkaline phosphatase. Low serum calcium and raised alkaline phosphatase may indicate the presence of osteomalacia due to vitamin D deficiency.

- **Liver biochemistry** and serum albumin. Prothrombin time is also measured.

- **Immunological tests.** Measurement of serum antibodies to endomysium and tissue transglutaminase is useful for the diagnosis of coeliac disease. These should always be accompanied by an assessment of total immunoglobulin levels.

- **Human leukocyte antigen (HLA) testing.** This is useful in coeliac disease, particularly if doubt exists about the diagnosis.

### Investigation of small bowel anatomy

- **MRI enteroclysis.** This is cross-sectional imaging that does not involve radiation. It uses oral loading with water or a hypertonic solution to distend the small bowel lumen.

- **Small bowel barium follow-through** (see p. 363). This detects gross anatomical defects such as diverticula, strictures and Crohn's disease. Dilatation of the bowel and a changed fold pattern may suggest malabsorption but these are non-specific findings. Gross dilatation is seen in myopathic pseudo-obstruction. This is less used because of radiation.

- **Small bowel biopsy.** This is used to assess the microanatomy of the small bowel mucosa. Biopsies are usually obtained via an endoscope passed into the duodenum and should be well orientated for correct evaluation. The histological appearances are described in the sections on individual diseases. A smear of the jejunal juice or a mucosal impression should also be made when *Giardia intestinalis* infection is suspected.

- **Ultrasound.** This is a useful preliminary investigation, which can show thickened small bowel or distended loops.

- **CT scanning.** CT is used to look for small bowel wall thickening, diverticula, and extraintestinal features such as abscesses (e.g. in Crohn's disease).

- **Video capsule enteroscopy.** This technique is being widely used to visualize the small bowel lumen and mucosa directly along its entire length. It is particularly useful in the diagnosis of occult gastrointestinal bleeding.

### Tests of absorption

These are required only in *complicated* cases:

- **Fat malabsorption.** The confirmation of the presence of steatorrhoea is only occasionally necessary. Three-day faecal fat analysis, triglyceride breath tests and serum $\beta$-carotene are
now rarely performed. In rare cases when it is essential to confirm steatorrhoea, Sudan III staining of a faecal sample can be used.

- **Lactose tolerance test.** Testing is of little use in adults because lactose intolerance is rarely a clinical problem; patients who are upset by milk usually avoid it. (Note: 500 mL of milk contain 20 g of lactose). Formal testing involves giving an oral dose of 50 g of lactose and serial measurement of blood glucose over 2 h. There is a high incidence of lactase deficiency in many parts of the world (e.g. the Mediterranean countries and parts of Africa and Asia).

**Other tests**

- **Hydrogen breath test.** This is frequently used as a screening test to measure transit time and to detect small bowel bacterial overgrowth. Bacteria are present in the oral cavity so the mouth should be rinsed out with an antiseptic mouthwash beforehand. The appearance of a breath hydrogen peak after *oral glucose* is used to estimate mouth-to-caecum transit time. An earlier rise in the breath hydrogen after glucose indicates bacterial breakdown in the small intestine. This test is simple to perform and does not involve radioisotopes. However, interpretation is often difficult and sensitivity and specificity are low.

- **Tests for pancreatic insufficiency.** These are used in the differential diagnosis of steatorrhoea. Human pancreatic elastase 1 (E1) remains undegraded during intestinal transit so its concentration in faeces reflects exocrine pancreatic function. The **faecal elastase** test quantifies E1 in stool, allowing the diagnosis or exclusion of severe pancreatic exocrine insufficiency (see p. 500).

- **Other blood tests.** **Serum immunoglobulins** are measured to exclude immune deficiencies: in particular, IgA deficiency, which may lead to false-negative coeliac antibody tests. **Gut peptides** (e.g. VIP) are measured in high-volume secretory diarrhoea, and **chromogranins** A and B are raised in endocrine tumours.

- **Tests for protein-losing enteropathy (PLE)** (see p. 363). These tests are rarely required unless a low serum albumin is a major clinical feature.

- **Measurement of $\alpha_1$-antitrypsin clearance.** This is used to confirm protein-losing enteropathy (see p. 363). It does not require an isotope. Alpha$_1$-antitrypsin is a large molecule (>50 000 daltons), which is resistant to proteolysis. Simultaneous measurements of serum and stool concentration (24-h collection) are made.

- **Bile salt loss.** This can be demonstrated by giving oral **SeHCAT** (a synthetic taurine conjugate) and measuring the retention of the bile acid by whole-body counting at 7 days.

- **Stool tests.** **Faecal calprotectin** is 93% sensitive and 96% specific for inflammatory bowel disease in adults. Faecal lactoferrin is also an inflammatory marker.

**Malabsorption**

In many small bowel diseases, malabsorption of specific substances occurs, but these deficiencies do not usually dominate the clinical picture. An example is Crohn's disease, in
which malabsorption of vitamin $B_{12}$ can be demonstrated, but this is not usually the major problem; diarrhoea and general ill-health are the major features.

The major disorders of the small intestine that cause malabsorption are shown in **Box 13.18**.

**Box 13.18**

*Disorders of the small intestine causing malabsorption*

- Coeliac disease
- Dermatitis herpetiformis
- Tropical sprue
- Bacterial overgrowth
- Intestinal resection
- Whipple's disease
- Radiation enteropathy
- Parasite infestation (e.g. *Giardia intestinalis*)

**Coeliac disease (gluten-sensitive enteropathy)**

Coeliac disease is a condition in which there is inflammation of the mucosa of the upper small bowel that improves when gluten is withdrawn from the diet and relapses when gluten is reintroduced. Up to 1% of many populations are affected, though most have clinically silent disease.

**Aetiology**

Gluten is the entire protein content of the cereals wheat, barley and rye. Prolamins (gliadin from wheat, hordeins from barley, secalins from rye) are damaging factors. These proteins are resistant to digestion by pepsin and chymotrypsin because of their high glutamine and proline content and remain in the intestinal lumen, triggering immune responses.

**Immunology**

Gliadin peptides pass through the epithelium (para- and/or intracellularly) and are deaminated by tissue transglutaminase, which increases their immunogenicity. Gliadin peptides then bind to antigen-presenting cells, which interact with CD4$^+$ T cells in the lamina propria via HLA class II molecules DQ2 or DQ8. These T cells produce pro-inflammatory cytokines, particularly interferon-γ. CD4$^+$ T cells also interact with B cells to produce endomysial and tissue transglutaminase antibodies. Gliadin peptides also cause release of IL-15 from enterocytes, activating intraepithelial lymphocytes with a natural killer cell marker. This inflammatory cascade releases metalloproteinases and other mediators, which contribute to the villous
atrophy and crypt hyperplasia that are typical of the disease.

The mucosa of the proximal small bowel is predominantly affected, the mucosal damage decreasing in severity towards the ileum as gluten is digested into smaller ‘non-toxic’ fragments.

**Genetic factors**

There is an increased incidence of coeliac disease within families but the exact mode of inheritance is unknown; 10–15% of first-degree relatives will have the condition, although it may be asymptomatic. The concordance rate in identical twins is about 70%.

HLA-DQ2 (DQA1*0501, DQB1*0201) and HLA-DQ8 (DQA1*0301, DQB1*0302) are associated with coeliac disease. Over 90% of patients will have HLA-DQ2, compared with 20–30% of the general population. Studies in twins and siblings indicate that HLA genes are responsible for <50% of the genetic cause of the disease. Many unaffected people also carry these genes, so other factors must also be involved. Non-HLA genes may also contribute to coeliac disease: for example, chromosome regions 19p13.1, 11q, 5q31–33 and 6q21–22. The CD28/CTLA4/IL05 gene cluster has also shown linkage with coeliac disease.

**Environmental factors**

Breast-feeding and the age of introduction of gluten into the diet are significant. Rotavirus infection in infancy also increases the risk; adenovirus-12, which has sequence homology with α-gliadin, was suspected as a causative agent but this is now thought to be unlikely.

**Clinical features**

Coeliac disease can present at any age. In infancy, it sometimes appears after weaning on to gluten-containing foods. The peak period for diagnosis in adults is in the fifth decade, with a female preponderance. Many patients are asymptomatic (silent) and come to attention because of routine blood tests: for example, a raised MCV, or iron deficiency in pregnancy. The symptoms are very variable and often non-specific; they include tiredness and malaise, often associated with anaemia.

Gastrointestinal symptoms may be absent or mild. Coeliac disease should be tested for in all patients with symptoms suggestive of irritable bowel syndrome. Diarrhoea or steatorrhoea, abdominal pain and weight loss suggest more severe disease. Mouth ulcers and angular stomatitis are frequent and can be intermittent. Infertility and neuropsychiatric symptoms of anxiety and depression occur.

Rare complications include tetany, osteomalacia or gross malnutrition with peripheral oedema. Neurological symptoms, such as paraesthesia, ataxia (due to cerebellar calcification), muscle weakness or a polyneuropathy occur; the prognosis for these symptoms is variable. There is an increased incidence of atopy and autoimmune disease, including thyroid disease, type 1 diabetes and Sjögren syndrome. Other associated diseases include inflammatory bowel disease, primary biliary cholangitis, chronic liver disease, interstitial lung disease and
epilepsy. IgA deficiency is more common than in the general population. Long-term problems include osteoporosis, which occurs even in patients on long-term gluten-free diets.

**Physical signs** are usually few and non-specific, and are related to anaemia and malnutrition.

### Diagnosis

Small bowel biopsy is still considered to be the ‘gold standard’ for positive diagnosis and is therefore desirable in all but the most clear-cut cases, because treatment involves a life-long diet that is both expensive and socially limiting. However, with the increasing accuracy of serological tests, it is no longer necessary to take duodenal biopsies for suspected coeliac disease in patients without antibodies. For example, in patients undergoing endoscopy for iron deficiency anaemia with negative coeliac serology, the pretest value of small bowel histology is <0.03%.

If biopsies are to be taken, 4–6 forceps biopsies should be taken from the second part of the duodenum and the bulb because the disease is sometimes patchy and it can be difficult to orientate endoscopic biopsies for histological section. Endoscopic signs, including absence of mucosal folds, mosaic pattern of the surface and scalloping of mucosal folds, are often present; however, their absence is not conclusive because they are markers of relatively severe disease.

### Histology

Histological changes (**Fig. 13.34**) are of variable severity and, though characteristic, are not specific. Villous atrophy can be caused by other conditions, but coeliac disease is the most common cause of subtotal villous atrophy.
Histological examination shows crypt hyperplasia with chronic inflammatory cells in the lamina propria, and villous atrophy. The enterocytes become cuboidal with an increase in the number of intraepithelial lymphocytes. In the lamina propria, there is an increase in lymphocytes and plasma cells. The most severe histological change involving mucosal atrophy and hypoplasia is seen in patients who do not respond to a gluten-free diet.

In mild cases, the villous architecture is almost normal but there are increased numbers of intraepithelial lymphocytes.

**Serology**

Indications for testing include persistent diarrhoea, folate or iron deficiency, unexplained abnormal liver biochemistry, a family history of coeliac disease and associated autoimmune disease.

The most sensitive tests are for endomysial (EMA) and tissue transglutaminase (tTG) antibodies (95% sensitivity). Titres of either of these correlate with the severity of mucosal damage and so they can be used for dietary monitoring. Standard tests use IgA class antibodies. Selective IgA deficiency occurs in 2.5% of coeliac disease patients but only 0.25% of normals. In a few cases, this may render these tests falsely negative. In situations in which CD is strongly suspected in a patient negative for EMA antibodies, IgA levels should be measured; if low, IgG-based tests should then be used (e.g. deaminated gliadin peptide (DGP) antibody).
HLA typing

HLA-DQ2 is present in 90–95% of coeliac disease patients and HLA-DQ8 in about 8% – most of the rest. The absence of both alleles has a high negative predictive value for coeliac disease. HLA typing can be useful for risk assessment: for example, in patients already on a gluten-free diet, in whom serology would be negative.

Other investigations

- **Haematology**. Mild or moderate anaemia is present in 50% of cases. Folate deficiency is common, often causing macrocytosis. Vitamin B₁₂ deficiency is rare. Iron deficiency, due to malabsorption of iron and increased loss of desquamated cells, is common. A blood film may therefore show microcytes and macrocytes (i.e. a dimorphic picture), as well as hypersegmented polymorphonuclear leucocytes and Howell–Jolly bodies (see p. 553) due to splenic atrophy.

- **Biochemistry**. In severe cases, biochemical evidence of osteomalacia may be seen (low calcium and high phosphate) and there is hypoalbuminaemia.

- **Imaging**. A small bowel barium follow-through or MRI enteroclysis may show dilatation of the small bowel with slow transit. Folds become thicker, and in severe disease, total effacement is seen. Imaging is mainly used when a complication, such as lymphoma, is suspected.

- **Bone densitometry**. Dual energy X-ray absorptiometry (DXA) should be performed on all patients because of the risk of osteoporosis.

- **Capsule endoscopy** (see p. 362). This is used to look for gut abnormalities when a complication is suspected.

Management

**Replacement minerals and vitamins**, such as iron, folic acid, calcium and vitamin D, may be needed initially to replace body stores.

Management is with a gluten-free diet for life. Dietary elimination of wheat, barley and rye usually produces a clinical improvement within days or weeks. Morphological improvement often takes months, especially in adults. Oats are tolerated by most coeliacs but must not be contaminated with flour during their production. Meat, dairy products, fruits and vegetables are naturally gluten-free and are all safe.

**Gluten-free products** can be expensive, unless subsidized by national health services. Patient support organizations, such as the Coeliac Society (UK), are valuable as information sources and for advice about diet, recipes and gluten-free processed foods. Despite advice, many patients do not keep to a strict diet but maintain good health. The long-term effects of this low gluten intake are uncertain but osteoporosis can occur, even in treated cases.

The usual cause of **failure to respond** to the diet is poor compliance. Dietary adherence can be monitored by serial tests for EMA and tTG. If clinical progress is suboptimal, then a repeat
intestinal biopsy should be taken. If the diagnosis is equivocal on the diagnostic mucosal biopsy, or if the patient has already started on a gluten-free diet, then a gluten challenge, i.e. re-introduction of oral gluten, with evidence of jejunal morphological change, can confirm the diagnosis.

Patients should have **pneumococcal vaccinations** (because of splenic atrophy) once every 5 years (see p. 553).

### Complications

A few patients do not improve on a strict diet and are said to have **non-responsive coeliac disease**. Many of these patients are still ingesting gluten. A few of the others may have concomitant problems, such as microscopic colitis, inflammatory bowel disease, small bowel bacterial overgrowth or lactase deficiency.

A very small percentage will have the rare complication of **refractory coeliac disease** (RCD). In type 1 RCD, the lymphocytes are normal and the T-cell receptors are polyclonal, whilst in type 2, there are abnormal clonal lymphocytes with loss of CD8 and CD3 surface markers. The 5-year survival rates are 93% and 40–60%, respectively.

Very rarely, enteropathy-associated **T-cell lymphoma (EATCL)** (8–20% 5-year survival) or ulcerative jejunitis can occur as part of a spectrum of neoplastic T-cell disorders.

**Small bowel adenocarcinoma** is also increased in coeliac disease. **Ulcerative jejunitis** presents with fever, abdominal pain, perforation and bleeding.

Diagnosis of these conditions is with MRI or barium studies, but laparoscopy with full-thickness small bowel biopsies is often required. Steroids and immunosuppressive agents, such as azathioprine, are used in ulcerative jejunitis.

The incidence of **carcinoma of the oesophagus**, as well as that of extragastrointestinal cancers, is also increased. Malignancy seems to be unrelated to the duration of the disease but the incidence is reduced by a gluten-free diet.

### Dermatitis herpetiformis

This is an uncommon, blistering, subepidermal eruption of the skin associated with a gluten-sensitive enteropathy (see also p. 1370). Rarely, gross malabsorption occurs, but usually the jejunal morphological abnormalities are not as severe as in coeliac disease. The inheritance and immunological abnormalities are the same as for coeliac disease. The skin condition responds to dapsone but a gluten-free diet improves both the enteropathy and the skin lesion, and is recommended for long-term benefit.

### Non-coeliac gluten intolerance

There is a recognized group of patients who are sensitive to dietary wheat and gluten-containing foods but do not have coeliac disease, in so far as their coeliac serology is negative and duodenal biopsies are normal. These patients have a range of symptoms, including
diarrhoea, bloating and abdominal pain, which improve on avoidance of gluten. The mechanism is not yet clear.

### Tropical sprue

This condition presents with chronic diarrhoea and malabsorption, and occurs in residents of or visitors to tropical areas where the disease is endemic: most of Asia, some Caribbean islands, Puerto Rico and parts of South America. Epidemics occur, lasting up to 2 years; in some areas, repeated epidemics are seen at varying intervals of up to 10 years.

The term tropical sprue is reserved for severe malabsorption (of two or more substances) accompanied by diarrhoea and malnutrition. A mild degree of malabsorption, sometimes following an enteric infection, is quite common in the tropics; it is usually asymptomatic and is sometimes called tropical malabsorption.

### Aetiology

The aetiology is unknown but is likely to be infective because the disease occurs in epidemics and patients improve on antibiotics. A number of agents have been suggested but none has been unequivocally shown to be responsible. Different agents could be involved in different parts of the world.

### Clinical features

These vary in intensity and consist of diarrhoea, anorexia, abdominal distension and weight loss. The onset is sometimes acute and occurs either a few days or many years after being in the tropics. Epidemics can break out in villages, affecting thousands of people at the same time. The onset can also be insidious, with chronic diarrhoea and evidence of nutritional deficiency. The clinical features of tropical sprue vary in different parts of the world, particularly as different criteria are used for diagnosis.

### Diagnosis

Acute infective causes of diarrhoea must be excluded (see Box 13.23), particularly *Giardia*, which can produce a syndrome very similar to tropical sprue. Malabsorption should be demonstrated, particularly of fat and vitamin B\textsubscript{12}. The jejunal mucosa is abnormal, showing some villous atrophy (partial villous atrophy). In most cases, the lesion is less severe than that found in coeliac disease, although it affects the whole of the small bowel. Mild mucosal changes can be seen in asymptomatic individuals in the tropics.

### Management

Many patients improve when they leave the sprue area and take folic acid (5 mg daily). Most
patients also require an antibiotic to ensure a complete recovery (usually tetracycline 1 g daily for up to 6 months).

Severely ill patients require resuscitation with fluids and electrolytes for dehydration, and nutritional deficiencies should be corrected. Vitamin B\textsubscript{12} (1000 µg) is also given to all acute cases.

### Prognosis

The prognosis is excellent. Mortality is usually associated with water and electrolyte depletion, particularly in epidemics.

### Bacterial overgrowth

The gut contains many resident bacteria in the terminal ileum and colon. Anaerobic bacteria, e.g. *Bacteroides*, bifidobacteria, are 100–1000 times more abundant than aerobic bacterial (facultative anaerobes), such as *Escherichia*, *Enterobacter* and *Enterococcus*. This gut microflora has major functions, including metabolic ones, such as fermentation of non-digestible dietary residues into short-chain fatty acids as an energy source in the colon.

The microflora that influences epithelial cell proliferation is involved in the development and maintenance of the immune system and protects the gut mucosa from colonization by pathogenic bacteria. Bacteria also initiate vitamin K production.

The upper part of the small intestine is almost sterile, containing only a few organisms derived from the mouth. Gastric acid kills some ingested organisms and intestinal motility keeps bacterial counts in the jejunum low. The normal terminal ileum contains faecal-type organisms, mainly *Escherichia coli* and anaerobes, and the colon has abundant bacteria.

Bacterial overgrowth is normally found in association with a structural abnormality of the small intestine, such as a stricture or diverticulum, although it can occur occasionally in the elderly without such an abnormality. *E. coli* and/or *Bacteroides*, both in concentrations of greater than 10\textsuperscript{6}/mL, are found as part of a mixed flora. These bacteria are capable of deconjugating and dehydroxylating bile salts, so that unconjugated and dehydroxylated bile salts can be detected in small bowel aspirates.

### Clinical features

The clinical features of overgrowth are chiefly diarrhoea and steatorrhoea. There may also be symptoms caused by the underlying small bowel pathology. Steatorrhoea (see p. 394) occurs because of conjugated bile salt deficiency. Some bacteria can metabolize vitamin B\textsubscript{12} and interfere with its binding to intrinsic factor, leading to mild B\textsubscript{12} deficiency (see p. 528); it is rarely severe enough to produce a neurological deficit. Some bacteria produce folic acid, giving a high serum folate. Bacterial overgrowth has only minimal effects on the absorption of other substances. Confirmation of bacterial overgrowth is with the hydrogen breath test (see p.
Management

If possible, the underlying lesion should be corrected (e.g. a stricture should be resected). Where this is not possible, rotating courses of antibiotics are necessary, such as metronidazole, a tetracycline or ciprofloxacin. The response to antibiotics is unpredictable.
Small intestinal resection

Small intestinal resection is usually well tolerated, but massive resection leaving less than 1 m of small bowel in continuity is followed by the short bowel syndrome. The effects of resection depend on the amount and location of the resection and the presence or absence of the colon. Resection of the jejunum is better tolerated than ileal resection, where there is less adaptation, probably due to low levels of glucagon-like peptide 2 (GLP-2), which is a specific growth hormone for the enterocyte. Patients with an anatomically short small bowel after surgical resection should have close follow-up to ensure they do not become depleted of electrolytes or develop malnutrition. Management will depend on investigations, but might include the use of loperamide and codeine to reduce small intestinal transit time, high-dose PPI therapy to reduce gastric secretion, oral rehydration solution and, where necessary, parenteral electrolyte and calorie replacement.

Ileal resection

The ileum is the site of specific mechanisms for the absorption of bile salts and vitamin B\textsubscript{12}. Relatively small resections lead to malabsorption of these substances. Loss of the ileal brake (see p. 391) leads to diarrhoea. Removal of the ileocaecal valve increases the incidence of diarrhoea (\textit{Fig. 13.35}).
The following occur after ileal resection:

- **Bile-salt-induced diarrhoea.** Bile salts and fatty acids enter the colon and cause malabsorption of water and electrolytes (see pp. 426–427).

- **Steatorrhoea and gallstone formation.** Increased bile salt synthesis can compensate for loss of approximately one-third of the bile salts in the faeces. Greater loss than this results in decreased micelle formation and steatorrhoea, and lithogenic bile and gallstone formation.

- **Oxaluria and oxalate stones.** Bile salts in the colon cause increased oxalate absorption with oxaluria, leading to urinary stone formation.

- **$B_{12}$ deficiency.** Low serum $B_{12}$, macrocytosis and other effects of $B_{12}$ deficiency are seen.

**Investigations**

These include imaging of the small bowel (see pp. 362–363), measurement of $B_{12}$, and a bile salt retention (SeHCAT) test (p. 395). A hydrogen breath test may show rapid transit (p. 395). Many patients require $B_{12}$ replacement and some need a low-fat diet if there is steatorrhoea. Diarrhoea is often improved by colestyramine, which binds bile salts and reduces the level of diarrhoeogenic bile salts in the colon.
The ileum can compensate for loss of jejunal absorptive function. Jejunal resection may lead to gastric hypersecretion with high gastrin levels; the exact mechanism is unclear. Structural and functional intestinal adaptation takes place over the course of a year, with an increase in the absorption per unit length of bowel in both jejunum and ileum.

Massive intestinal resection (short bowel syndrome)

Intestinal failure results from obstruction, dysmotility, surgical resection, congenital defect, or disease-associated loss of absorption. It is characterized by the inability to maintain protein-energy, fluid, electrolyte or micronutrient balance. This most often occurs following resection for Crohn's disease, mesenteric vessel occlusion (see p. 402), radiation enteritis (see below) or trauma. There are two common situations.

**Shortened small intestine ending at a terminal small bowel stoma**

The major problem is sodium and fluid depletion; the majority of patients with ≤100 cm of jejunum remaining will require parenteral supplements of fluid and electrolytes, often with nutrients. Sodium losses can be minimized by increasing salt intake, restricting hypotonic fluids between meals, and administering oral glucose–electrolyte mixture with a sodium concentration of 90 mmol/L. Jejunal transit time can be increased and stomal effluent loss reduced by treatment with the somatostatin analogue octreotide, often used in combination with a PPI, loperamide and codeine phosphate. There is no benefit from a low-fat diet, but fat assimilation can be increased on treatment with colestyramine and synthetic bile acids.

Teduglutide, as GLP-2 analogue, reduces stomal output and the number of days of parenteral nutrition. More studies are needed.

**Shortened small intestine in continuity with colon**

Because of the absorptive capacity of the colon for fluid and electrolytes, only a small proportion of these patients require parenteral supplementation. Unabsorbed fat results in impairment of colonic fluid and electrolyte absorption, and so patients should be on a low-fat diet. A high carbohydrate intake is advised, as unabsorbed carbohydrate is metabolized anaerobically to short-chain fatty acids (SCFAs), which are absorbed; they also stimulate fluid and electrolyte absorption in the colon and act as an energy source (1.6 kcal/g). Patients are often treated with colestyramine to reduce diarrhoea and colonic oxalate absorption.

**Whipple's disease**

Whipple's disease is a rare infectious bacterial disease caused by *Tropheryma whipplei*. Some 87% of patients are males, and are usually white and middle-aged. Whipple's presents with arthritis and arthralgia, progressing over years to weight loss and diarrhoea with abdominal pain, and systemic symptoms of fever and weight loss. Peripheral lymphadenopathy and involvement of the heart, lung, joints and brain occur, simulating many neurological conditions.

Blood tests show features of chronic inflammation and malabsorption. Endoscopy typically
shows pale, shaggy duodenal mucosa with eroded, red, friable patches.

### Diagnosis

Diagnosis is made by small bowel biopsy. Periodic acid–Schiff (PAS)-positive macrophages are present but are non-specific. On electron microscopy, the characteristic trilaminar cell wall of *T. whipplei* can be seen within macrophages. *T. whipplei* antibodies can be identified by immunohistochemistry. A confirmatory polymerase chain reaction (PCR)-based assay is available.

### Management

Treatment is with antibiotics that cross the blood–brain barrier, such as 160 mg trimethoprim and 800 mg sulfamethoxazole (co-trimoxazole) daily for 1 year. This is preceded by a 2-week course of streptomycin and penicillin or ceftriaxone. Treatment periods of less than 1 year are associated with relapse in about 40%.

### Radiation enteritis

Radiation of >40 Gy will damage the intestine. The chronic effects of radiation are muscle fibre atrophy, ulcerative changes due to ischaemia, and obstruction due to radiation-induced fibrotic strictures.

- Pelvic irradiation is frequently used for gynaecological and urinary tract malignancies, and so the ileum and rectum are the areas most often involved.
- At the time of the irradiation, there may be nausea, vomiting, diarrhoea and abdominal pain, usually improving within 6 weeks of completion of therapy.

**Chronic radiation enteritis** is diagnosed if symptoms persist for ≥3 months. The prevalence is >15% of patients receiving radiotherapy that includes the abdomen. Abdominal pain due to obstruction is the main symptom. Malabsorption can be due to bacterial overgrowth in dilated segments and mucosal damage. Many patients suffer from increased bowel frequency. **Management** is symptomatic, although often unsuccessful in chronic radiation enteritis. Surgery should be avoided if possible, being reserved for obstruction or perforation.

**Acute radiation** damage to the rectum produces a **radiation proctitis** with diarrhoea and tenesmus, with or without blood. Local steroids sometimes help initially. When the acute phase heals, mucosal telangiectases form and may cause persistent bleeding. If there is resistant anaemia, these can be treated with argon plasma coagulation or, under a light anaesthetic, by packing the rectum with a formalin-soaked swab for 2 minutes, both of which destroy the telangiectases.

### Parasite infestation
• **Giardia intestinalis** (see pp. 306–307) not only produces diarrhoea but also can produce malabsorption with steatorrhoea. Minor changes are seen in the jejunal mucosa and the organism can be found in the jejunal fluid or mucosa.

• **Cryptosporidiosis** (see p. 307) can also produce malabsorption.

• **HIV infection** causes patients to be particularly prone to parasitic infestation (Box 13.19).

Other causes of malabsorption

- **Drugs that bind bile salts** (e.g. colestyramine) and some antibiotics (e.g. neomycin) produce steatorrhoea.
- **Orlistat** (see p. 210) is used in obesity to reduce fat absorption by inhibiting gastric and pancreatic lipase, so causing diarrhoea and steatorrhoea. A low-fat diet is also necessary, which leads to weight loss.
- **Thyrotoxicosis** causes diarrhoea, rarely with steatorrhoea, owing to increased gastric emptying and increased motility.
- **Zollinger–Ellison syndrome** is described on page 512.
- **Intestinal lymphangiectasia** produces diarrhoea and, rarely, steatorrhoea (see p. 402).
- **Lymphoma** that has infiltrated the small bowel mucosa causes malabsorption.
- **Diabetes mellitus** (see p. 1271) causes diarrhoea, malabsorption and steatorrhoea, sometimes due to bacterial overgrowth from autonomic neuropathy that leads to small bowel stasis.
- **Hypogammaglobulinaemia**, which is seen in a number of conditions including lymphoid nodular hyperplasia, causes steatorrhoea due either to an abnormal jejunal mucosa or to secondary infestation with *Giardia intestinalis*.

Miscellaneous intestinal diseases

**Protein-losing enteropathy**

Protein-losing enteropathy refers to intestinal conditions that lead to protein loss, and usually manifest with hypoalbuminaemia. The causes include Crohn's disease, tumours, Ménétrier's disease, a condition with giant rugal folds (*Fig. 13.36*), coeliac disease and lymphatic disorders (e.g. lymphangiectasia).
Usually, protein-losing enteropathy forms a minor part of the generalized disorder but, occasionally, hepatic synthesis of albumin cannot compensate for the protein loss, and peripheral oedema dominates the clinical picture. The investigations are described on page 395 and treatment is that of the underlying disorder.

**Meckel's diverticulum**

This is the most common congenital abnormality of the gastrointestinal tract, affecting 2–3% of the population. The diverticulum projects from the wall of the ileum approximately 60 cm from the ileocaecal valve. It is usually symptomless. However, 50% contain gastric mucosa that secretes hydrochloric acid, and peptic ulcers can occur and may bleed (see p. 384) or perforate.

Acute inflammation of the diverticulum also occurs and is indistinguishable clinically from acute appendicitis. Rarely, there is obstruction from an associated band.

Management is surgical removal, often laparoscopically.

**Tuberculosis**

Tuberculosis (TB; see also pp. 1106–1113) can affect the intestine, as well as the peritoneum (see p. 436). In developed countries, most patients are from ethnic minority groups, or are immunocompromised because of HIV or drugs. Intestinal TB is due to reactivation of primary disease caused by *Mycobacterium tuberculosis*. Bovine TB occurs in areas where milk is unpasteurized and is rare in Western countries.

**Clinical features**

These are abdominal pain, weight loss, anaemia, fever with night sweats, obstruction, right iliac fossa pain or a palpable mass. The ileocaecal area is most commonly affected, but the colon – and, rarely, other parts of the gastrointestinal tract – can be involved. One-third of
patients present acutely with intestinal obstruction or generalized peritonitis; 50% have X-ray evidence of pulmonary TB.

## Diagnosis

Differential diagnosis includes Crohn's disease and caecal carcinoma.

- **Small bowel follow-through** may show transverse ulceration, and diffuse narrowing of the bowel with shortening of the caecal pole.

- **Ultrasound, MRI or CT** shows additional mesenteric thickening and lymph node enlargement.

- **Histology and culture of tissue** is desirable but not always possible. Specimens can be obtained by colonoscopy or laparoscopy but laparotomy is required in some cases. The histological findings include chronic inflammation with caseating granuloma. Acid-fast bacilli may be seen on dedicated stains. However, the histology is not always distinguishable from that of Crohn's disease.

## Management

Drug treatment is similar to that for pulmonary TB (see pp. 1110–1113). Treatment should be started if there is a high degree of suspicion.

## Amyloidosis

Systemic amyloidosis may affect any part of the gastrointestinal tract (see also pp. 1288–1289). Rectal biopsy may be diagnostic. Occasionally, amyloid deposits occur as polypoid lesions. The symptoms depend on the site of involvement; amyloidosis in the small intestine gives rise to diarrhoea.

## Autoimmune rheumatic diseases

**Systemic sclerosis** (see pp. 695–697) most commonly affects the oesophagus (see p. 372), although the small bowel and colon are often found to be involved if investigated. There may be no symptoms of this involvement, but diarrhoea and steatorrhoea can occur due to bacterial overgrowth caused by reduced motility, dilatation and the presence of diverticula.

## Intestinal ischaemia

Intestinal ischaemia results from occlusion of arterial inflow, occlusion of venous outflow or failure of perfusion; these factors may act alone or in combination and usually occur in the elderly.

- **Arterial inflow occlusion** can be caused by atheroma, thrombosis and embolism (cardiac
arrhythmia), including cholesterol emboli (see pp. 753–754), aortic disease (occluding ostia of mesenteric vessels) or vasculitis (see pp. 699–702), thromboangiitis and Takayasu syndrome (see pp. 1054–1055).

- **Venous outflow occlusion** occurs in 5–15% of cases, usually in sick patients with circulatory failure.

- **Infarction without occlusion** can occur due to reduced cardiac output, hypotension and shock, causing reduced intestinal blood flow.

### Acute small intestinal ischaemia

An embolus from the heart in a patient with atrial fibrillation is the most common cause and usually occludes the superior mesenteric artery. Patients present with sudden abdominal pain and vomiting, with a distended and tender abdomen and absent bowel sounds. The patient is hypotensive and ill. Surgery is necessary to resect the gangrenous bowel. Mortality is high (up to 90%) and is related to coexisting disease, the development of multiorgan failure (MOF; see p. 1155) and massive fluid and electrolyte losses in the postoperative period. Survivors may go on to develop nutritionally inadequate short bowel syndrome (see pp. 399–400).

### Ischaemic colitis

See page 418.

### Chronic small intestinal ischaemia

This is due to atheromatous occlusion or cholesterol emboli of the mesenteric vessels, and is found particularly in the elderly. Good collateral circulation can minimize clinical effects. The characteristic symptom is postprandial abdominal pain and weight loss. Loud bruits may be heard but, as these are heard in normal subjects, they are of doubtful significance. The diagnosis is made using angiography.

### Eosinophilic gastroenteritis

In this condition of unknown aetiology there is eosinophilic infiltration and oedema of any part of the gastrointestinal mucosa. The gastric antrum and proximal small intestine are usually involved, hosting either a localized lesion (eosinophilic granuloma) or diffuse sheets of eosinophils in the serosal and submucosal layers. There is an association with asthma, eczema and urticaria.

The condition occurs mainly in the third decade. The clinical presentation depends on the site of gut involvement. Abdominal pain, nausea and vomiting, and upper gastrointestinal bleeding occur. Peripheral eosinophilia is present in only 20% of patients. Endoscopic biopsy is useful for making the diagnosis histologically. Radiology may demonstrate mass lesions.

Treatment is with corticosteroids for the widespread infiltration, particularly if peripheral eosinophilia is present.

In some adults, the condition appears to be allergic (allergic gastroenteritis) and is
associated with peripheral eosinophilia and high levels of plasma and tissue IgE. The relationship of eosinophilic oesophagitis (see pp. 373–374) to eosinophilic gastroenteritis is unclear.

**Intestinal lymphangiectasia**

Dilatation of the lymphatics may be primary or secondary to lymphatic obstruction, such as occurs in malignancy or constrictive pericarditis. Hypoproteinaemia with ankle oedema is the main feature. The rare primary form may be detected incidentally as dilated lacteals on a jejunal biopsy or it can produce steatorrhoea of varying degrees. White-tipped villi are seen on capsule endoscopy. Serum immunoglobulin levels are reduced, with low circulating lymphocytes. Management is with a low-fat diet, mid-chain triglycerides and fat-soluble vitamin supplements as required. Octreotide has a dramatic effect in a few primary cases, although the mechanism of action is unknown.

**Abetalipoproteinaemia**

This rare congenital disorder is due to a failure of apo B-100 synthesis in the liver and apo B-48 in the intestinal cell, so that chylomicrons are not formed. This leads to fat accumulation in the intestinal cells, lending a characteristic histological appearance to the jejunal mucosa. Clinical features include acanthocytosis (spiky red cells owing to membrane abnormalities), a form of retinitis pigmentosa, and mental and neurological abnormalities. The latter can be prevented by vitamin E injections.

**Tumours of the small intestine**

The small intestine is relatively resistant to the development of neoplasia and only 3–6% of all gastrointestinal tumours and less than 1% of all malignant lesions occur here. The reason for the rarity of tumours is unknown. Explanations include the fluidity and relative sterility of small bowel contents and the rapid transit time, reducing the time of exposure to potential carcinogens. It is also possible that the high population of lymphoid tissue and secretion of IgA in the small intestine protect against malignancy.

**Adenocarcinoma and lymphoma**

*Adenocarcinoma of the small intestine* is rare and found most frequently in the duodenum (in the periampullary region) and in the jejunum. It is the most common tumour of the small intestine, accounting for up to 50% of primary tumours.

*Lymphomas* are most frequently found in the ileum. These are of the non-Hodgkin's type and must be distinguished from peripheral or nodal lymphomas involving the gut secondarily.

In developed countries, the most common type of lymphoma is the B cell type arising from MALT (see pp. 395–396). These lymphomas tend to be annular or polypoid masses in the
distal or terminal ileum, whereas most T cell lymphomas are ulcerated plaques or strictures in the proximal small bowel.

A tumour similar to Burkitt's lymphoma also occurs and commonly affects the terminal ileum of children in North Africa and the Middle East.

**Predisposing factors for adenocarcinoma and lymphoma**

**Coeliac disease**

There is an increased incidence of lymphoma of the T cell type and adenocarcinoma of the small bowel, as well as an unexplained increase in all malignancies, both in the gastrointestinal tract and elsewhere. The reason for the local development of malignancy is unknown. It is now accepted that coeliac disease is a pre-malignant condition but there is no association with the length of the symptoms. Management with a gluten-free diet can reduce the risk of both lymphoma and carcinoma.

**Crohn's disease**

There is a small increase in the incidence of adenocarcinoma of the small bowel in Crohn's disease.

**Immunoproliferative small intestinal disease**

Immunoproliferative small intestinal disease (IPSID) is a rare B cell disorder in which there is proliferation of plasma cells in the lamina propria of the upper small bowel, producing truncated monoclonal heavy chains, without associated light chains. The α heavy chains are found in the gut mucosa on immunofluorescence and can also be detected in the serum. IPSID usually occurs in countries surrounding the Mediterranean, but it has also been found in developing countries in South America and the Far East. It predominantly affects people in lower socioeconomic groups in areas with poor hygiene and a high incidence of bacterial and parasitic infection of the gut. IPSID presents as a malabsorptive syndrome associated with diffuse lymphoid infiltration of the small bowel and neighbouring lymph nodes, progressing in some cases to a lymphoma. The condition has also been documented in the developed world.

Clinically, patients present with abdominal pain, diarrhoea, anorexia, weight loss and symptoms of anaemia. There may be a palpable mass, and an ultrasound followed by an MRI scan may detect a mass lesion. Endoscopic biopsy is useful where lesions are within reach. Ultrasound and CT may show bowel wall thickening and the involvement of lymph nodes, which is common with lymphoma. Wireless capsule endoscopy can be used where obstruction by the capsule is not likely, but cannot deliver histology.

---

**Management of small intestinal tumours**

**Adenocarcinoma**

Most patients are treated surgically with a segmental resection. The overall 5-year survival
rate is 20–35%; this varies with the histological grade and the presence or absence of lymph node involvement. Radiotherapy and chemotherapy are used in addition.

**IPSID**

If there is no evidence of lymphoma, antibiotics, such as tetracycline, should be tried initially. In the presence of lymphoma, combination chemotherapy is used; in one series, the 3–5-year survival rate was 58%.

**Lymphoma**

Most patients require surgery and radiotherapy with chemotherapy for more extensive disease. The prognosis varies with the type. The 5-year survival rate for T cell lymphomas is 25% but is better for B cell lymphomas, varying from 50% to 75%, depending on the grade of lymphoma.

**Carcinoid tumours**

These originate from the enterochromaffin cells (APUD cells) of the intestine. They make up 10% of all small bowel neoplasms, the most common sites being the appendix and terminal ileum. It is often difficult to be certain histologically whether a particular tumour is benign or malignant. A total of 10% of carcinoid tumours in the appendix present as acute appendicitis, secondary to obstruction. Surgical resection of the tumour is usually performed.

Most carcinoids do not secrete hormones or vasoactive compounds, and may present with liver enlargement due to metastases.

**Carcinoid syndrome** occurs in only 5% of patients with carcinoid tumours and only when there are liver metastases. Patients complain of spontaneous or induced bluish-red flushing, predominantly on the face and neck, sometimes leading to permanent changes with telangiectases.

Gastrointestinal symptoms consist of abdominal pain and recurrent watery diarrhoea. Cardiac abnormalities are found in 50% of patients and take the form of pulmonary stenosis or tricuspid incompetence. Examination of the abdomen reveals hepatomegaly. The tumours secrete a variety of biologically active amines and peptides, including serotonin (5-hydroxytryptamine, 5-HT), bradykinin, histamine, tachykinins and prostaglandins. The diarrhoea and cardiac complications are probably caused by 5-HT itself, but the cutaneous flushing is thought to be produced by one of the kinins, such as bradykinin. This is known to cause vasodilatation, bronchospasm and increased intestinal motility.

**Diagnosis of carcinoid syndrome**

- **Ultrasound examination** confirms the presence of liver secondary deposits.
- **Urine** shows a high concentration of 5-hydroxyindoleacetic acid (5-HIAA), which is the major metabolite of 5-HT.
• **Serum chromogranin A** is raised in nearly all hindgut tumours and 80–90% of symptomatic foregut and midgut tumours.

### Management of carcinoid syndrome

Treatment is with octreotide and lanreotide; both are octapeptide somatostatin analogues that inhibit the release of many gut hormones. They alleviate flushing and diarrhoea, and can control a carcinoid crisis. Interferon and other chemotherapeutic regimens also occasionally reduce tumour growth, but have not been shown to increase survival.

Most patients survive for 5–10 years after diagnosis.

### Peutz–Jeghers syndrome

This consists of mucocutaneous pigmentation (circumoral in 95% of patients, and on the hands in 70% and feet in 60%) and gastrointestinal polyps. It has an autosomal dominant inheritance. The gene **STK11** (also known as **LKB1**) that is responsible for Peutz–Jeghers codes for a serine protein kinase and can be used for genetic analysis. The brown buccal pigment is characteristic of the condition. The polyps, which are hamartomas, can occur anywhere in the gastrointestinal tract but are most frequent in the small bowel. They may bleed or cause small bowel obstruction or intussusception (50% of patients).

### Management

Management is by endoscopic polypectomy. Balloon enteroscopy may be necessary to reach all the small bowel polyps. Bowel resection should be avoided if possible, but may be necessary in patients presenting with gangrenous bowel due to intussusception. Follow-up is with yearly pan-endoscopy. There is an increased incidence of gastrointestinal cancers. Non-gastrointestinal cancers also occur with increased frequency, so yearly screening for uterine, ovarian and cervical cancer should start in the teens, and breast and testicular screening by the age of 20.

### Other tumours

Adenomas, lipomas and stromal tumours (see p. 384) are rarely found and are usually asymptomatic and picked up incidentally. They occasionally present with iron deficiency anaemia. In familial adenomatous polyposis (FAP), duodenal adenomas form in one-third of patients and may progress to adenocarcinoma. This is the most common cause of death in FAP patients who have been treated by prophylactic colectomy.

Inflammatory Bowel Disease

Two major forms of inflammatory bowel disease (IBD) are recognized:

• Crohn's disease (CD), which can affect any part of the gastrointestinal tract
• Ulcerative colitis (UC), which affects only the colon.

There is a degree of overlap between these two conditions in their aetiopathogenesis, clinical features, histological and radiological abnormalities; in 10% of cases of IBD causing colitis, a definitive diagnosis of either UC or CD is not possible and the diagnosis is termed colitis of undetermined type and (a)etiology (CUTE). It is clinically useful to distinguish between UC and CD because of differences in their management, although, in reality, they may represent two aspects of the same disease.

Another form of colitis related to microscopic inflammation is termed microscopic colitis; this is subdivided into lymphocytic and collagenous types (see pp. 414–415). The distinction between this and IBD is the absence of macroscopic evidence of inflammation.

Epidemiology

• The incidence of CD varies from country to country but is approximately 4–10 per 100 000 annually, with a prevalence of 25–100/100 000.
• The incidence of UC is stable at 6–15/100 000 annually, with a prevalence of 80–150/100 000.

Although both conditions have a worldwide distribution, the highest incidence rates and prevalence have been reported from Northern Europe, the UK and North America. Both race and ethnic origin affect the incidence and prevalence of CD and UC. Thus, in North America, prevalence rates of CD are lower in Hispanic and Asian people (4.1/100 000 and 5.6/100 000, respectively) compared with white individuals (43.6/100 000). Jewish people are more prone to IBD than any other ethnic group. Prevalence rates also change after migration; thus there is an increasing incidence of CD in the UK-born children of migrants from South-east Asia. Recent studies suggest that the incidence of both CD and UC is increasing in traditional low-prevalence areas such as South-east Asia.
Approximately 25% of patients are diagnosed before their 18th birthday and there is evidence that disease commencing in youth is more extensive and more aggressive than that occurring in older patients.

Aetiology and pathogenesis

Although the aetiology of IBD is unknown, it is increasingly clear that IBD represents the interaction between several co-factors: genetic susceptibility, the environment, the intestinal microbiota and host immune response (Fig. 13.37).

![Aetiopathogenesis of inflammatory bowel disease](image)

**FIGURE 13.37** The aetiopathogenesis of inflammatory bowel disease.

Genetic factors

CD and UC are complex polygenic diseases and having a positive family history is the largest independent risk factor for development of IBD. Up to 1 in 5 patients with CD and 1 in 6 patients with UC will have a first-degree relative with the disease. The monozygotic and dizygotic twin concordance rates for CD are 20–50% and 10%, respectively.

Genome-wide association studies have identified multiple susceptibility loci, and many of the underlying risk variants have been identified. The major genetic factors for CD include the **NOD2 (CARD 15)** gene (nucleotide oligomerization domain 2), the autophagy genes and the Th17 pathway (IL-23–type 17 helper T cells). The NOD2 protein on chromosome 16 is an intracellular sensor of bacterial peptidoglycan, present in bacterial cell walls (see below). NOD2 is expressed in epithelial cells, macrophages and endothelial cells. Individuals who are
homozygote or compound heterozygote for one of several mutations in the NOD2 gene have a significantly increased risk of developing ileal CD. Likewise, mutations in the autophagy genes ATG16L1 and IRGM (immunity-related GTP-ase M-protein) and IL-23 receptor gene increase CD risk, and mutations in genes associated with the mucosal barrier increase UC risk. However, the presence of IBD-associated genes in many unaffected individuals and the failure of the approximately 71 genetic susceptibility loci identified thus far to explain more than around one-fifth of the genetic risk of CD highlight the complexity of the genetic basis of IBD. Specific genetic defects in the IL-10 receptor pathway are associated with a severe form of extremely early-onset colitis and perianal disease in children.

Apart from susceptibility, HLA genes on chromosome 6 also appear to have a role in modifying the disease. The DRB*0103 allele is linked to a particularly aggressive course of UC and the need for surgery, as well as with colonic CD. DRB*0103 and MICA*010 are associated with perianal disease, and DRB*0701 with ileal CD. For the extraintestinal disease complications and HLA links, see page 407.

Environmental and other factors

• **Smoking.** Patients with CD are more likely to be smokers, and smoking has been shown to exacerbate CD and increase the risk of disease recurrence after surgery. By contrast, there is an increased risk of UC in non- or ex-smokers and nicotine has been shown to be an effective treatment in one small clinical trial.

• **NSAIDs.** NSAID ingestion is associated with both the onset of IBD and flares of disease in patients with an established diagnosis.

• **Hygiene.** Poor and large families living in crowded conditions have a lower risk of developing CD. A ‘clean’ environment may not expose the intestinal immune system to pathogenic or non-pathogenic microorganisms such as helminths, which seems to alter the balance between effector and regulatory immune responses.

• **Nutritional factors.** Many foods and food components have been suggested as playing a role in the aetiopathogenesis of IBD (e.g. high sugar and fat intake) but, unfortunately, the results of numerous studies designed to define risk have been equivocal. However, breast-feeding may provide protection against the development of IBD in offspring.

• **Psychological factors.** Factors such as chronic stress and depression seem to increase relapses in patients with quiescent disease.

• **Appendicectomy.** This appears to be ‘protective’ against the development of UC, particularly if performed for appendicitis or for mesenteric lymphadenitis before the age of 20. It also influences the clinical course of UC, with a lower incidence of colectomy and reduced need for immunosuppressive therapy. By contrast, appendicectomy may increase the risk of development of CD.

The intestinal microbiota

The gut is colonized by 10 times more bacterial organisms than there are host cells, there being
300–400 distinct bacterial species. The intestinal microbiota plays a crucial role in perpetuating intestinal inflammation, in both animal models of disease and patients with IBD. The number of mucosal adherent bacteria is increased in patients with CD compared to healthy subjects, and diversion of the bacterial component of the faecal stream induces clinical remission. However, there is also evidence of an immunoregulatory role for the commensal microbiota, which protects against intestinal inflammation and upregulates epithelial defence mechanisms in animal models of colitis.

Mechanisms by which the intestinal microbiota may relate to the aetiology of IBD include:

- **Intestinal dysbiosis.** There is an alteration in the bacterial flora in patients with CD. Although results vary due to differences in both the patient groups studied and the microbiological method utilized, the most consistent finding in patients with IBD is a reduced diversity of microbial species. In addition, higher concentrations of *Bacteroides* and *E. coli*, and lower concentrations of bifidobacteria and *Faecalibacterium prausnitzii* have been reported in faecal and mucosal samples from patients with CD compared to healthy controls. Lower concentrations of *F. prausnitzii* have been found in patients with active compared with quiescent disease, and low levels of this organism in CD resection specimens predict subsequent endoscopic disease recurrence.

- **Specific pathogenic organisms.** It has been shown that there is increased *E. coli* adherence to the ileal epithelial cells in CD, with evidence of invasion into the mucosa. *E. coli*’s type 1 pili adhere to a protein called carcinoembryonic antigen-related cell adhesion molecule 6 (CEACAM6). Many authors have also suggested a link between CD and *Mycobacterium paratuberculosis* (MAP), although recent PCR-based studies have failed to confirm this and therapeutic trials of anti-*Mycobacterium tuberculosis* (MTB) therapy were not effective.

- **Bacterial antigens.** Bacteria exert their influence by the interaction of ligands such as peptidoglycan-polysaccharides (PG-PS) and lipopolysaccharides (LPS) with host pattern recognition receptors such as the Toll-like receptor family (cell surface) and the NOD family (intracellular).

- **Defective chemical barrier or intestinal defensins** (see p. 392). Evidence suggests a decrease in human α defensin-1 (HD-1) in the mucosa of both CD and UC, and a lack of induction of HD-2, HD-3 and HD-5 in CD.

- **Impaired mucosal barrier function.** This may explain the presence of unusual and potentially pathogenic bacteria, such as MAP, *Listeria* and mucosal adherent *E. coli*. However, their presence does not necessarily imply causation of the disease, and they may reflect previous disease activity.

**The intestinal immune system**

IBD occurs when the mucosal immune system exerts an inappropriate response to luminal antigens, such as bacteria, which may enter the mucosa via a leaky epithelium *(Fig. 13.38)*. Bacterial ligands interact with the innate and acquired mucosal immune system via Toll-like receptors expressed on both epithelial and antigen-presenting cells. Deficiencies occur in the
clearance of invading bacteria by aspects of the innate immune system, such as neutrophils, which may allow inappropriate activation of the acquired immune system. In keeping with the genetic susceptibility loci identified, these findings highlight a deficiency in patients with IBD in a component of the inflammasome (an intracellular danger sensor of the innate immune system that can trigger caspase-1-dependent processing of inflammatory mediators, such as IL-1β and IL-18). In addition, individual bacterial species have distinct immunological effects mediated by dendritic cells (DCs), which sample bacteria from the intestinal lumen and direct the subsequent functional differentiation of naive T cells into effector or regulatory populations. IBD is associated with an imbalance in the relative numbers of intestinal homing effector (Th1 and Th17) and regulatory T cell populations, which disturbs the normal tolerance to the luminal antigenic load.

The pro-inflammatory cytokines released by these activated effector T cells stimulate macrophages to secrete pro-inflammatory cytokines, such as tumour necrosis factor-alpha (TNF-α), IL-1 and IL-6 in large quantities. These mechanisms result in increased adhesion molecule expression on the intestinal vascular endothelium, which facilitates the recruitment of leucocytes from the circulation and the release of chemokines, all of which lead to tissue
damage and also attract more inflammatory cells in a vicious circle.

Pathology

CD is a chronic inflammatory condition that may affect any part of the gastrointestinal tract from the mouth to the anus but has a particular tendency to affect the terminal ileum and ascending colon (ileocolonic disease) (Fig. 13.39). The disease can involve one small area of the gut, such as the terminal ileum, or multiple areas with relatively normal bowel in between (skip lesions). It may also involve the whole of the colon (total colitis), sometimes without macroscopic small bowel involvement. It is also associated with the development of perianal fistulae and fissures (Box 13.20).

![Diagram of Crohn's disease](image)

**FIGURE 13.39** Sites of Crohn's disease.

**Box 13.20**

**Anal and perianal complications of Crohn's disease**

- Fissure *in ano* (multiple and indolent)
- Haemorrhoids
- Skin tags
- Perianal abscess
- Ischiorectal abscess
- Fistula *in ano* (may be multiple)
**Anorectal fistulae**

*UC* can affect the rectum alone (proctitis), can extend proximally to involve the sigmoid and descending colon (left-sided colitis), or may involve the whole colon (extensive colitis) (*Fig. 13.40*). In a few of these patients, there is also inflammation of the distal terminal ileum (backwash ileitis).

![Diagram of the colon](image)

**Macroscopic changes**

In *CD*, the involved bowel is usually thickened and is often narrowed. Deep ulcers and fissures in the mucosa produce a cobblestone appearance. Intra-abdominal fistulæ and abscesses may be seen, which reflect penetrating disease. An early feature is aphthoid ulceration in the colon, usually seen at colonoscopy (*Fig. 13.41*); later, larger and deeper ulcers appear in a patchy distribution, again producing a cobblestone appearance.
In **UC**, the mucosa looks reddened and inflamed, and bleeds easily (friability). In severe disease, there may be extensive ulceration, with the adjacent mucosa appearing as post-inflammatory (pseudo-) polyps.

In **fulminant colonic disease** of either type, most of the mucosa is lost, leaving a few islands of oedematous mucosa (mucosal islands), and toxic dilatation occurs. On healing, the mucosa can return to normal, although there is usually some residual scarring.

### Microscopic changes

In **CD**, the inflammation extends through all layers (transmural) of the bowel, whereas in UC superficial inflammation limited to the mucosa is seen. In CD, there is an increase in chronic inflammatory cells and lymphoid hyperplasia, and in 50–60% of patients granulomas are present. These granulomas are non-caseating epithelioid cell aggregates with Langhans' giant cells.

In **UC**, the mucosa shows a chronic inflammatory cell infiltrate in the lamina propria. Crypt abscesses and goblet cell depletion are also seen.

These two diseases can usually be differentiated not only on the basis of clinical and radiological data but also on the histological differences seen in the rectal and colonic mucosa obtained by biopsy (**Box 13.21**).

It is occasionally not possible to distinguish between the two disorders, particularly if biopsies are obtained in the acute phase, and such patients are considered to have CUTE. Serological testing for anti-neutrophil cytoplasmic antibodies (ANCA) in UC and anti-Saccharomyces cerevisiae antibodies (ASCA) in CD may be of value in differentiating the two conditions (see pp. 408–409), although an exact diagnosis can sometimes be made only after examining a surgical colectomy specimen. Occasionally, examination of the colectomy specimen still does not lead to a diagnosis of CD or UC and the patient is labelled as having indeterminate colitis.

**Extraintestinal manifestations**

These occur with both diseases (Box 13.22). Joint complications are most common; the peripheral arthropathies are classified as:

- **Type 1 (pauciarticular)** attacks are acute and self-limiting (<10 weeks), and occur with IBD relapses; they are associated with other extraintestinal manifestations of IBD activity.
- **Type 2 (polyarticular)** arthropathy lasts longer (months to years), is independent of IBD activity and usually associated with uveitis.

---

### Box 13.22

**Extrагastrointestinal manifestations of inflammatory bowel disease**

- **Eyes:**
  - Uveitis
  - Episcleritis, conjunctivitis
- **Joints:**
  - Type I (pauciarticular) arthropathy
  - Type II (polyarticular) arthropathy
  - Arthralgia
  - Ankylosing spondylitis
  - Inflammatory back pain
- **Skin:**
  - Erythema nodosum
  - Pyoderma gangrenosum
- **Liver and biliary tree:**
  - Sclerosing cholangitis
  - Fatty liver
  - Chronic hepatitis
  - Cirrhosis
  - Gallstones
• Nephrolithiasis
• Venous thrombosis

Joint and other extragastrointestinal manifestations of IBD are shown in Box 13.22. There is an association of HLA DRB1*0103 with pauciarticular large-joint arthritis in UC and CD, and HLA-B44 with small-joint symmetrical arthritis. HLA-B27 is associated with sacroiliitis.

Differential diagnosis

Alternative causes of diarrhoea should be excluded (Box 13.23) and stool cultures (including Clostridium difficile toxin assay) must always be performed. However, symptoms persisting beyond 5 days are unlikely to be caused by infective gastroenteritis. Stool microscopy for parasitic diseases such as amoebiasis should be carried out in patients with a relevant travel history. CD should be considered in all individuals with evidence of vitamin malabsorption (e.g. megaloblastic anaemia) or malnourishment, as well as in children with reduced growth velocity. Ileocolonic tuberculosis (see p. 401) is common in developing countries, such as India, which makes a diagnosis of CD difficult. Microscopy and culture for TB of any available tissue is essential in these countries. A therapeutic trial of anti-TB therapy may be required. Lymphomas can occasionally involve the ileum and caecum, although they are rare in the patient population at risk from IBD.

Box 13.23

Causes of diarrhoea

Non-infective causes

• Inflammatory bowel disease
• Radiation proctitis or colitis
• Behçet's disease
• Diverticular disease
• Ischaemic colitis
• Gastrointestinal lymphoma
• Carcinoma of the colon (change in bowel habit)
• Malabsorption
• Gut resection
• Bile acid malabsorption
• Drugs – many, including
  – Laxatives
  – Metformin
– Anti-cancer drugs
– Statins
– Proton pump inhibitors
• Faecal impaction with overflow
• Irritable bowel syndrome and functional diarrhoea
• Endocrine causes:
  – Zollinger–Ellison syndrome
  – VIPoma
  – Somatostatinoma
  – Glucagonoma
  – Carcinoid syndrome
  – Thyrotoxicosis
  – Medullary carcinoma of thyroid
  – Diabetic autonomic neuropathy
• Factitious diarrhoea:
  – Purgative abuse
  – Dilutional diarrhoea

**Infective causes**
• Bacterial, e.g.
  – *Campylobacter jejuni*
  – *Salmonella* spp.
  – *Shigella*
  – *Escherichia coli* (see p. 276)
  – Staphylococcal enterocolitis
  – *Bacillus cereus*
  – *Clostridium perfringens, C. botulinum, C. difficile*
  – Gastrointestinal tuberculosis
• Viral, e.g.
  – Rotavirus
• Fungal, e.g.
  – Histoplasmosis
• Parasitic, e.g.
  – Amoebic dysentery (*Entamoeba histolytica*)
  – Schistosomiasis
  – *Giardia intestinalis*

**Crohn's disease**
Clinical features

The major symptoms are diarrhoea, abdominal pain and weight loss. Constitutional symptoms of malaise, lethargy, anorexia, nausea, vomiting and low-grade fever may be present and in 15% of these patients there are no gastrointestinal symptoms. Reduced growth velocity and delayed puberty may be the main presenting features in children. Despite the recurrent nature of this condition, some patients have an almost normal lifestyle. However, patients with extensive disease have frequent recurrences and progress from inflammatory to stricturing and penetrating disease. Approximately 50% of patients will require an intestinal resection within 5 years of diagnosis.

Clinical features are very variable and depend partly on the region of the bowel that is affected. The disease may present insidiously or acutely. Abdominal pain can be colicky, suggesting obstruction, but it usually has no special characteristics and sometimes in colonic disease only minimal discomfort is present. Diarrhoea occurs in 80% of all cases and in colonic disease it usually contains blood, making it difficult to differentiate from UC. Steatorrhoea can be present in small bowel disease. Diarrhoea can also be due to bile acid malabsorption, occurring as a consequence of ileal resection or ileal disease.

CD can also present as an emergency with acute right iliac fossa pain mimicking appendicitis. If laparotomy is undertaken, an oedematous, reddened terminal ileum is found. Other causes of an acute ileitis include infections such as Yersinia and TB.

CD is complicated by anal and perianal disease, and this is the presenting feature in 25% of cases, often preceding colonic and small intestinal symptoms (see Box 13.20). Enteric fistulae – for example, to bladder, vagina or abdominal wall – occur in 20–40% of cases.

Examination

Physical signs are few, apart from loss of weight and signs of malnutrition. Aphthous ulceration of the mouth is often seen. Abdominal examination may be normal, although tenderness and/or a right iliac fossa mass are occasionally found. The mass is due either to inflamed loops of bowel that are matted together or to an abscess, which may also cause psoas muscle irritation. The anus should always be examined to look for oedematous anal tags, fissures or perianal abscesses.

The presence of extraintestinal features of IBD should be assessed (see Box 13.22).

Investigations

Blood tests

• Anaemia is common and may be the normocytic, normochromic anaemia of chronic disease. However, deficiency of iron and/or folate also occurs. Despite terminal ileal involvement in CD, megaloblastic anaemia due to vitamin B_{12} deficiency is unusual, although serum B_{12} levels can be below the normal range.
Raised ESR and CRP are found, as are raised white cell and platelet counts.

Hypoalbuminaemia is present in severe disease as part of an acute phase response to inflammation associated with a raised CRP.

Liver biochemistry may be abnormal.

Blood cultures are required if septicaemia is suspected.

Serological tests may reveal negative perinuclear ANCA (pANCA) and positive ASCA (see p. 407).

**Stool tests**

Stool cultures, including *C. difficile* toxin assay, should always be performed if diarrhoea is present. Microscopy for parasites is essential in patients with a relevant travel history. Faecal calprotectin and lactoferrin are raised in active intestinal disease.

**Endoscopy and radiological imaging**

Colonoscopy is performed if colonic involvement is suspected, except in patients presenting with severe disease (in whom a limited unprepared sigmoidoscopy should be carried out). The findings vary from mild, patchy, superficial (aphthoid) ulceration to more widespread, larger and deeper ulcers that produce a cobblestone appearance (see Fig 13.41). Endoscopic assessment of the terminal ileum is essential in all patients with suspected CD. Two biopsies should be performed in five areas, including the rectum and terminal ileum.

Upper gastrointestinal endoscopy is required to exclude oesophageal and gastroduodenal disease in patients with relevant symptoms and is increasingly being performed in all patients at diagnosis to define the extent of disease accurately as a guide to prognosis.

Small bowel imaging is mandatory in patients with suspected CD. The technique used will depend on availability and local expertise. Techniques include barium follow-through, CT scan with oral contrast, small bowel ultrasound or MRI enteroclysis. An asymmetrical alteration in the mucosal pattern with deep ulceration, and areas of narrowing or structuring may be found. Although disease is commonly confined to the terminal ileum (Fig. 13.42), other areas of the small bowel can be involved, and skip lesions with normal bowel are seen between affected sites. Axial imaging allows the diagnosis of extraintestinal sepsis in patients presenting acutely and is therefore preferred in this situation.
• **Ultrasound scanning** provides a convenient radiation-free method for assessing disease activity in the ileum and colon and can be performed by appropriately trained gastroenterologists at the bedside.

• **Perianal MRI or endoanal ultrasound** is used to evaluate perianal disease.
• **Capsule endoscopy** is used in CD patients when radiological examination is normal. A patency capsule assessment is often performed first to exclude strictures of the small bowel that would constitute a contraindication to subsequent capsule endoscopy.

• **Radionuclide scans** with indium- or technetium-labelled leucocytes are used in some centres to identify small intestinal and colonic disease inflammation and to localize extraintestinal abscesses.

Disease activity

This can be assessed using simple parameters such as haemoglobin, white cell count, inflammatory markers (raised ESR, CRP and platelet count) and serum albumin. Formal clinical activity indices (e.g. CD Activity Index or Harvey Bradshaw Index) are used in research studies. Faecal calprotectin or lactoferrin has the potential to be a simple, cheap, non-invasive marker of disease activity in IBD and these tests are of value in predicting response to and failure of treatment.

### Medical management of Crohn's disease

See [Box 13.24](#).

---

**Box 13.24**

**Options for the medical treatment of Crohn's disease**

**Induction of remission**

• Oral or i.v. glucocorticosteroids

• Enteral nutrition

• Anti-tumour necrosis factor (TNF) antibodies

**Maintenance of remission**

• Azathioprine, mercaptopurine, methotrexate

• Anti-TNF antibodies

**Perianal disease**

• Surgical drainage of sepsis

• Ciprofloxacin and metronidazole

• Azathioprine

• Anti-TNF antibodies

---

**General considerations**

The aims of management are to induce and then maintain clinical remission and to achieve
mucosal healing in order to prevent disease progression and complications. Alternative causes for symptoms, such as gastroenteritis, extraintestinal sepsis, stricture formation, functional gastrointestinal disease or bile salt malabsorption, must be excluded before commencing immunosuppressive therapy. Patients with mild symptoms and no evidence of extensive disease may require symptomatic treatment only. Cigarette smoking should be stopped. Anaemia, if due to vitamin B$_{12}$, folic acid or iron deficiency, should be treated with the appropriate replacement. Patients who are intolerant of oral iron should receive an intravenous iron infusion. Most patients can be treated as outpatients, although severe attacks may require admission, and prophylaxis for thromboembolism (see p. 1056) should be given to all inpatients.

**Induction of remission**

**Glucocorticosteroids**

These are commonly used to induce remission in moderate and severe attacks of CD (oral prednisolone 30–60 mg/day). Mild to moderate ileocaecal disease should be treated with controlled-release corticosteroids, such as budesonide, which has reduced systemic availability and is associated with a lower frequency and intensity of steroidal side-effects. Overall remission/response rates vary from 60% to 90%, depending on type, site and extent of disease. Steroids should be avoided in patients with penetrating intestinal disease or perianal sepsis.

**Aminosalicylates**

These have been used but there is little evidence to support their efficacy in CD.

**Antibiotics**

Antibiotics (ciprofloxacin and metronidazole) are used for treating secondary complications of CD (e.g. abscess and perianal disease).

**Exclusive enteral nutrition**

This is the traditional treatment for moderate to severe attacks of CD in paediatric practice, but is under-utilized in adults due to issues with compliance to the diet. If administered as the sole source of nutrition for 28 days, rates of induction of remission are similar to those obtained with steroids. Relapse rates are high, however, particularly in those with colonic involvement.

**Refractory or fulminant disease**

Patients with symptoms that do not respond to conventional therapy should be re-assessed to exclude an alternative diagnosis such as a stricture or penetrating abscess. In patients with disease limited to the terminal ileum, surgical resection may be appropriate. In those with more extensive disease, remission should be induced with an anti-TNF agent, either as monotherapy or preferably in combination with an immunosuppressant such as azathioprine.
Maintenance of remission

All patients require regular monitoring to exclude persistent intestinal inflammation. Patients with disease that has a good prognosis (older age at diagnosis, no perianal disease, limited ulceration at index investigations, non-smoker) may not require maintenance therapy. Patients with disease that has a poor prognosis (young age at diagnosis, extensive small bowel disease, deep colonic ulceration, perianal/rectal disease, smoker) or that flares up after induction therapy is withdrawn require long-term maintenance immunosuppression. The goal of maintenance therapy is to prevent disease progression, as well as to reduce the need for corticosteroids, which are associated with a high burden of side-effects. Therapies that induce mucosal healing result in better outcomes. All maintenance therapies require careful monitoring to ensure optimal disease control and prevent side-effects. If there is ongoing evidence of disease activity, adherence should be confirmed and dose optimization or therapy escalation undertaken.

Conventional maintenance therapies

These include azathioprine (AZA, 2.5 mg/kg per day), mercaptopurine (MP, 1.5 mg/kg per day) and methotrexate (25 mg once a week until remission, then reduced to 15 mg per week) (Box 13.24). Long-term treatment with these drugs is necessary, as the rate of relapse on discontinuation is high. Patient education regarding side-effects and appropriate monitoring for complications is essential and may increase adherence. The key enzyme involved in AZA and MP metabolism is thiopurine methyl transferase (TPMT). This enzyme has a significant genetic variation and deficiencies can result in high circulating levels of thioguanine nucleotides with an increased risk of bone marrow depression. Assays of TPMT activity are available and should be performed before treatment. TPMT deficiency is not the only cause of bone marrow depression so 3-monthly blood counts should be performed on all patients. Metabolite measurement can be undertaken to assess adherence and ensure optimal dosing.

Anti-TNF agents

These have clear evidence of benefit in the induction and maintenance of remission in patients with CD. They are indicated in patients with disease refractory to conventional immunosuppressive therapy. Early use of anti-TNF therapy is indicated in selected patients with disease that has a poor prognosis (see above). They are also used to treat complex perianal/rectal disease once sepsis has been drained. Available anti-TNF agents include infliximab (a chimeric anti-TNF-α IgG1 monoclonal antibody), adalimumab (a fully humanized anti-TNF IgG1 monoclonal antibody) and certolizumab pegol (a PEGylated Fab’ fragment of a humanized anti-TNF antibody). They neutralize soluble TNF-α, bind to membrane bound TNF-α and induce immune cell apoptosis, although the exact mechanism of action is not defined. In clinical trials, they have been shown to exert a steroid-sparing effect and bring about complete mucosal healing in up to one-third of patients in the long term. This
results in a reduced need for hospital admission and surgery. These agents should always be used on a regular basis as maintenance therapy, as they are less effective and induce anti-drug antibodies if used episodically. In patients who are naive to azathioprine, combination therapy increases efficacy and reduces immunogenicity. Their use should be limited to clinicians experienced in the management of CD, as they are associated with significant complications, including opportunistic infections (such as TB), demyelination and malignancy.

**Novel biological therapies**

Novel therapies for the treatment of CD include the anti-α4β7 integrin therapy, vedolizumab, which acts to reduce leucocyte recruitment to the inflamed intestine. Therapies that target the IL-12/IL-23 pathway, such as ustekinumab, are currently in phase III trials. Recent preliminary studies using the oral anti-sense oligonucleotide, Mongersen, have shown promise. This agent binds to, and causes degradation of, SMAD7 messenger RNA, thereby restoring TGF-β1 signalling and decreasing the production of pro-inflammatory markers.

**Surgical management of Crohn's disease**

Studies prior to the introduction of biological agents suggest that up to 80% of patients will require an operation at some time during the course of their disease. Nevertheless, surgery should be avoided if possible and only minimal resections undertaken, as recurrence (15% per year) is almost inevitable without prophylactic maintenance therapy. The *indications for surgery* are:

- failure of medical therapy, with acute or chronic symptoms producing ill-health
- complications (e.g. toxic dilatation, obstruction, perforation, abscesses, enterocutaneous fistula)
- failure to grow in children despite medical treatment
- presence of perianal sepsis: an examination is performed under anaesthetic, the sepsis is drained, and a seton is inserted to ensure ongoing drainage.

In patients with small bowel disease, some strictures can be widened (stricturoplasty), whereas others require resection and anastomosis. It is essential to consider postoperative maintenance therapy in patients undergoing ileocolonic resection and anastomosis. All patients should refrain from smoking. There is some evidence that a 3-month course of metronidazole reduces relapse rates. Patients with a high risk of relapse (previous surgery, smoker, penetrating disease at the time of index surgery) should be evaluated for maintenance immunosuppressive therapy. Patients should undergo an ileocolonoscopy to assess the anastamosis for disease recurrence 6 months after surgery, when further therapy can be agreed with the patient.

When colonic CD involves the entire colon and the rectum is spared or minimally involved, a subtotal colectomy and ileorectal anastomosis may be performed. An eventual recurrence rate of 60–70% in the ileum, rectum or both is to be expected; however, two-thirds of these
patients retain a functional rectum for 10 years. If the whole colon and rectum are involved, a panproctocolectomy with an end ileostomy is the standard operation. CD patients are not suitable for a pouch operation (see p. 413), as recurrence in the pouch is high.

Problems associated with ileostomies include:

- mechanical problems
- dehydration, particularly if there is a short length of small bowel remaining
- psychosexual problems
- erectile dysfunction in men and reduced fecundity in women (due to prior pelvic surgery)
- recurrence of CD.

**Prognosis**

The majority of patients have inflammatory disease at diagnosis, although up to 20% will present with complicated disease, including strictures and penetrating disease. If disease is left untreated, its natural history is progression from inflammatory to stricturing and penetrating disease that may require surgery. Up to 50% of patients will require a surgical resection within the first 5 years of disease. The goal of therapy is to target early aggressive therapy at those patients with a poor prognosis. However, predicting disease prognosis at diagnosis is not easy. Features that imply a poor prognosis include young age at diagnosis (<20 years of age), extensive small bowel disease, complex perianal disease and deep ulceration at index colonoscopy.

**Ulcerative colitis**

**Clinical features**

The major symptom in UC is diarrhoea with blood and mucus, sometimes accompanied by lower abdominal discomfort. General features include malaise, lethargy and anorexia with weight loss, although these features are not as severe as with CD. Aphthous ulceration in the mouth may be seen. The disease can be mild, moderate or severe (Box 13.25), and in most patients runs a course of remissions and exacerbations. Disease extent is defined as limited to the rectum (proctitis), left-sided or extensive (see Fig. 13.40).

**Box 13.25**

**Definition and management of a severe attack of ulcerative colitis**

**Definition**

- Stool frequency: >6 stools/day with blood +++
• Fever: >37.5°C
• Tachycardia: >90 b.p.m.
• Erythrocyte sedimentation rate: >30 mm/h
• Anaemia: <100 g/L haemoglobin
• Albumin: <30 g/L

Management
• Admit to hospital
• Exclude enteric infection
• Confirm diagnosis with unprepared limited flexible sigmoidoscopy
• Assess fluid status
• Give prophylactic anticoagulation
• I.v. hydrocortisone 100 mg qds
• Monitor daily:
  – Stool frequency
  – Abdominal X-ray
  – Bloods (FBC/CRP/albumin)

Proctitis is characterized by the frequent passage of blood and mucus, urgency and tenesmus. There are normally few constitutional symptoms and the stool, when passed, may be solid. Patients are nevertheless greatly inconvenienced by the frequency of defecation.

In an acute attack of left-sided or extensive UC, patients have bloody diarrhoea, passing up to 10–20 liquid stools per day. Diarrhoea also occurs at night, with urgency and incontinence that is severely disabling for the patient. Patients with an acute severe flare of colitis (Box 13.25) require urgent admission for intensive therapy.

**Toxic megacolon** is a serious complication associated with acute severe colitis. The plain abdominal X-ray shows a dilated, thin-walled colon with a diameter of >6 cm; it is gas-filled and contains mucosal islands *(Fig. 13.43)*. It is a particularly dangerous stage of advanced disease, with impending perforation and a high mortality (15–25%). Urgent surgery is required in all patients in whom toxic dilatation has not resolved within 48 hours, with intensive therapy as above. The differential diagnosis includes an infectious colitis, e.g. with *C. difficile* and cytomegalovirus.
Examination

In general, there are no specific signs in UC. The abdomen may be slightly distended or tender to palpation. Tachycardia and pyrexia are signs of severe colitis and mandate admission. The anus is usually normal. Rectal examination will reveal the presence of blood. Sigmoidoscopy is usually abnormal, showing an inflamed, bleeding, friable mucosa. Very occasionally, rectal sparing occurs, with normal proctoscopy.

Investigations

Blood tests

• **White cell and platelet counts** are commonly raised in moderate to severe attacks, and iron deficiency anaemia is present.

• **ESR and CRP** are often raised; liver biochemistry may be abnormal, with hypoalbuminaemia occurring in severe disease.

• **pANCA** may be positive. This is contrary to CD, where pANCA is usually negative (see p. 409).

Stool tests and *C. difficile* toxin

These should always be performed to exclude infective causes of colitis. Stool microscopy to exclude amoebiasis is mandated in patients with a relevant travel history. Faecal calprotectin/lactoferrin will be elevated.
Colonoscopy

Endoscopy with mucosal biopsy is the ‘gold standard’ investigation for the diagnosis of UC. Colonoscopy also allows assessment of disease activity and extent. In patients with long-term colitis, chromoendoscopy is used to diagnose dysplasia. Full colonoscopy should not be performed in severe attacks of disease for fear of perforation; instead, a limited unprepared flexible sigmoidoscopy should be used to confirm diagnosis.

Imaging

A plain abdominal X-ray is essential in patients suffering acute severe attacks to exclude colonic dilatation. However, the extent of disease is not reliably assessed using this investigation. Other imaging modalities are rarely used in the assessment of patients with UC, as endoscopy is preferred. However, inflammation of the colonic wall is detected on ultrasound, as is the presence of free fluid within the abdominal cavity.

Medical management of ulcerative colitis

Wherever possible, patients with IBD should be managed in patient-focused IBD clinics with access to a full multidisciplinary team. The mainstay of treatment for mild and moderate disease of any extent is an aminosalicylate, which acts topically in the colonic lumen. The active moiety of these drugs is 5-aminosalicylic acid (5-ASA), which is absorbed in the small intestine. Therefore, the various aminosalicylate preparations are designed to deliver the active 5-ASA to the colon. This is achieved by binding of 5-ASA with an azo bond to sulfapyridine (sulfasalazine), 4-aminobenzoyl-β-alanine (balsalazide) or to 5-ASA itself (olsalazine), coating with a pH-sensitive polymer, packaging of 5-ASA in microspheres, or a combination of these. The azo bonds are broken down by colonic bacteria to release 5-ASA within the colon.

The mode of action of 5-ASA in IBD is unknown, although it may involve the intracellular peroxisome proliferator-activated receptor (PPAR)-γ signalling pathway. The aminosalicylates have been shown to be effective in inducing remission in mild to moderately active disease, and maintaining remission in all forms of disease. There is also evidence that they are chemopreventive for UC-associated colorectal cancer. 5-ASA can rarely cause renal disease.

Proctitis

Rectal 5-ASA suppositories are the first-line treatment. Topical steroids are less effective than 5-ASA preparations. Oral 5-ASA can be added to increase remission rates. Some cases of proctitis do not respond to 5-ASA treatment and require oral prednisolone.

Left-sided colitis

Topical 5-ASA enemas are the first-line treatment. The addition of an oral 5-ASA will increase remission rates. Patients who do not respond to this or have worsening symptoms require oral prednisolone.
**Extensive colitis**

Patients with mild to moderate symptoms can be treated with an oral 5-ASA at an adequate dose. The additional of a 5-ASA enema increases remission rates. Patients who do not respond to this or have worsening symptoms require oral prednisolone.

**Refractory/severe colitis of any extent**

Patients with colitis that is refractory to standard conventional therapies should be investigated to ensure adherence to therapy, confirm active colitis and exclude infection, including biopsies to exclude reactivation of CMV colitis. They should then receive biological therapy with either an anti-TNF agent (infliximab, adalimumab or golimumab) or an anti-integrin therapy (vedolizumab).

Patients with severe colitis (Box 13.25) and those who do not respond to oral prednisolone should be admitted to hospital and treated initially with hydrocortisone 100 mg i.v. 6-hourly, with s.c. low-molecular-weight heparin to prevent thromboembolism. Investigations to confirm the diagnosis and exclude enteric infection (see above) should be performed and full supportive therapy administered (intravenous fluids, and nutritional support via the enteral route if required). The incidence of concomitant *C. difficile* infection in patients admitted for severe colitis is increasing. This is associated with a significant increase in morbidity and must be excluded. The clinical status of patients should be monitored daily (fever, tachycardia, stool frequency), and daily FBC, CRP, and urea and electrolytes should be performed. Repeat abdominal X-rays are required if patients are not improving. Success or failure of medical treatment of a severe attack of UC must be judged by an experienced gastroenterologist and colorectal surgeon. If patients have not responded to intravenous steroids within 3 days, either salvage medical therapy or surgery is required. If patients respond to intravenous steroids, they should be switched to oral prednisolone after approximately 5 days, which they can be weaned off over 8–10 weeks. All patients who have been admitted for severe colitis should commence long-term maintenance therapy with a thiopurine (azathioprine/mercaptopurine).

**Salvage therapy**

Salvage therapy to avoid colectomy is required for patients with a CRP >45 mg/L or more than eight bowel motions after 3 days of intravenous hydrocortisone. Continuing steroid therapy alone in this situation will delay the inevitable colectomy and increase mortality. Salvage medical therapies with clear evidence of benefit in controlled clinical trials are intravenous ciclosporin 2 mg/kg per day as a continuous infusion or infliximab induction and maintenance therapy. Patients with extensive ulceration may require higher doses of induction infliximab. Patients with a low albumin level have been shown to have a lower response rate to salvage therapy. These agents should only be used by experienced gastroenterologists who are part of a multidisciplinary team with colorectal surgeons. Patients should be weaned off steroids rapidly, once salvage therapy has commenced, to reduce morbidity. Those who respond should be treated with oral ciclosporin or further infliximab infusions, as appropriate, while maintenance thiopurine therapy is commenced.
Surgical management of ulcerative colitis

While the treatment of UC remains primarily medical, surgery continues to have a central role because it may be life-saving, is curative and eliminates the long-term risk of cancer. The main indications for surgery are severe colitis that fails to respond to medical therapy, and chronic active therapy-refractory disease. Other indications are listed in Box 13.26. In expert centres, laparoscopic surgery is often used to improve postoperative pain, recovery time and cosmesis.

### Box 13.26

**Indications for surgery in ulcerative colitis**

**Fulminant acute attack**
- Failure of medical treatment
- Toxic dilatation
- Haemorrhage
- Imminent perforation

**Chronic disease**
- Incomplete response to medical treatment/steroid-dependent
- Dysplasia on surveillance colonoscopy

In acute disease, subtotal colectomy with end ileostomy and preservation of the rectum is the operation of choice. At a later date, a number of surgical options are available and are best carried out in a specialist colorectal centre. These include proctectomy with a permanent ileostomy; to avoid a permanent ileostomy, an ileo-anal pouch procedure can be performed (Fig. 13.44). The ileo-anal pouch is anastomosed to the anus at the dentate line following excision of the remaining rectum. One-third of patients, however, will experience ‘pouchitis’, inflammation of the pouch mucosa with clinical symptoms of diarrhoea, bleeding, fever and, at times, exacerbation of extracolonic manifestations (Fig. 13.45). The incidence of pouchitis is twice as high in patients with primary sclerosing cholangitis and is also raised in patients with a positive ANCA and backwash ileitis prior to colectomy. Two-thirds of pouchitis cases will recur as either acute relapsing or chronic unremitting forms. The mainstay of treatment is antibiotics (metronidazole with or without ciprofloxacin). Treatment is not always satisfactory and steroids may be required. The probiotic VSL#3 has been shown to be effective in preventing the onset of pouchitis and in maintaining remission in patients with antibiotic-treated pouchitis to induce mucosal healing.
Course and prognosis

One-third of patients with distal inflammatory proctitis due to UC will develop more proximal disease, with 5–10% developing total colitis. One-third of patients with UC will have a single attack and the others will follow a relapsing course. One-third of patients with UC will undergo colectomy within 20 years of diagnosis.

Cancer in inflammatory bowel disease

Patients with UC and extensive Crohn's colitis have an increased incidence of developing dysplasia and subsequent colon cancer. The risk of dysplasia is related to the extent and duration of disease, as well as the presence of untreated mucosal inflammation. A family history of colorectal cancer and the presence of primary sclerosing cholangitis also increase the risk. Appropriate colonoscopic screening strategies according to guidelines are used by
many, although evidence for overall benefit is still uncertain. A 40-year analysis of colonoscopy surveillance for neoplasia in UC, conducted at St Mark's Hospital in the UK, suggested that surveillance may have a significant role in reducing the risk of advanced and interval colorectal cancer.

**Mortality in inflammatory bowel disease**

Population-based studies demonstrate that mortality in UC is similar to that in the general population. The two exceptions are patients with severe colitis, who have a slightly higher mortality in the first year after diagnosis, and patients aged over 60 at the time of diagnosis. Although it is currently unclear whether there is a slightly higher overall mortality in patients with CD, those with extensive jejunal and ileal disease and those with gastric and duodenal disease have been shown to have a relatively higher mortality.

**Microscopic colitis**

Patients with this group of disorders present with chronic or fluctuating watery diarrhoea. Although the macroscopic features on colonoscopy are normal, the histopathological findings on biopsy are abnormal. There are three distinct forms of microscopic inflammatory colitis:

- **Microscopic UC.** There is a chronic inflammatory cell infiltrate in the lamina propria, with deformed crypt architecture and goblet cell depletion, with or without crypt abscesses. Treatment is as for UC; many patients respond to treatment with aminosalicylates alone.

- **Microscopic lymphocytic colitis.** There is surface epithelial injury, prominent lymphocytic infiltration in the surface epithelium and increased lamina propria mononuclear cells.

- **Microscopic collagenous colitis.** There is a thickened subepithelial collagen layer (>10 µm) adjacent to the basal membrane, and increased infiltration of the lamina propria with lymphocytes and plasma cells, and surface epithelial cell damage. It is predominantly a disorder of middle-aged or elderly females, and is associated with a variety of autoimmune disorders (arthritis, thyroid disease, limited cutaneous scleroderma and primary biliary cirrhosis).

The incidence of both microscopic lymphocytic and collagenous colitis is increased in patients with coeliac disease and this must be excluded. Treatment of microscopic and collagenous colitis is usually with budesonide. There is also evidence of benefit for aminosalicylates, bismuth-containing preparations and, if refractory, prednisolone and azathioprine. A small number of patients with microscopic lymphocytic and collagenous colitis have coexisting bile acid malabsorption and can thus respond to colestyramine. Prognosis is good.

The Colon and Rectum

### Anatomy

The large intestine starts at the caecum, on the posterior medial wall of which is the appendix.
The colon is made up of ascending, transverse, descending and sigmoid parts, which join the rectum at the rectosigmoid junction (Fig. 13.46).

FIGURE 13.46 Structure of the large intestine.

The muscle wall consists of an inner circular layer and an outer longitudinal layer. The outer layer is incomplete, coming together to form the taeniae coli, which produce the haustral pattern seen in the normal colon.

The mucosa of the colon is lined with epithelial cells and goblet cells. There are crypts but no villi, so that the surface is flat. A variety of cells, mainly lymphocytes and macrophages, are found in the lamina propria.

The blood supply to the colon is from the superior and inferior mesenteric vessels. The colon is innervated mainly by the enteric nervous system with input from the parasympathetic and sympathetic pathways. Spinal afferent neurones from the dorsal root ganglia innervate the entire colon.

The rectum is about 12 cm long. Its interior is divided by three crescentic circular muscles that produce shelf-like folds. These are the rectal valves, which can be seen at sigmoidoscopy. The anal canal has an internal and an external sphincter.

### Physiology of the colon

The main roles of the colon are the absorption of water and electrolytes (Box 13.27) and the propulsion of contents from the caecum to the anorectal region. Approximately 1.5–2 L of fluid pass the ileocaecal valve each day. Absorption is stimulated by short-chain fatty acids, which are produced predominantly in the right colon by the anaerobic metabolism of dietary fibre by bacterial polysaccharidase enzyme systems. Colonic contents are mixed, aiding absorption by non-propagative segmenting muscular contractions. High-amplitude propagative colonic contractions cause propulsion. Peristalsis is induced by the release of serotonin (5-HT) from
neuroendocrine cells in response to luminal distension. Serotonin activates the HT₄ receptors, which, in turn, results in the activation of sensory (calcitonin gene-related peptide, CGRP) neurones. Normal colonic transit time is 24–48 hours with normal stool weights of up to 250 g/day.

### Physiology of defecation

The role of the rectum and anus in defecation is complex. The rectum is normally empty. Stool is propelled into the rectum by propagated colonic contractions. A sensation of fullness, a desire to defecate and urgency to defecate are experienced with increasing volumes of rectal content (threshold 100 mL). The sensations are associated with rectal contraction and a relaxation of the internal anal sphincter, both of which serve to push the stool down into the proximal anal canal. This increases the defecatory urge, which can only be suppressed by vigorous contraction of the external sphincter and puborectalis. If conditions are appropriate for defecation, the subject sits or squats, contracts the diaphragm and abdominal muscles, and relaxes the pelvic floor muscles, including puborectalis, and the anal sphincter muscles, with the result that stool is expelled.

### Constipation

‘Constipation’ is a very common symptom, particularly in women and the elderly. A consensus definition used in research (the Rome III criteria) defines constipation as having two or more of the following for at least 12 weeks: infrequent passage of stools (<3/week), straining >25% of time, passage of hard stools, incomplete evacuation and sensation of anorectal blockage. According to these definitions, ‘constipation’ affects more than 1 in 5 of the population.

Other symptoms include abdominal bloating and/or discomfort (undistinguishable from the
irritable bowel syndrome), as well as local and perianal pain. The causes of constipation are shown in Box 13.28.

**Box 13.28**

**Causes of constipation**

**General**

- Inadequate fibre intake
- Immobility

**Metabolic/endocrine**

- Diabetes mellitus
- Hypercalcaemia
- Hypothyroidism
- Porphyria

**Functional**

- Irritable bowel syndrome
- Idiopathic slow transit

**Drugs**

- Opiates
- Antimuscarinics
- Calcium-channel blockers, e.g. verapamil
- Antidepressants, e.g. tricyclics
- Iron

**Neurological**

- Spinal cord lesions
- Parkinson's disease

**Psychological**

- Depression
- Anorexia nervosa
- Repressed urge to defecate

**Gastrointestinal disease**

- Intestinal obstruction and pseudo-obstruction
- Colonic disease, e.g. carcinoma, diverticular disease
• Aganglionosis, e.g. Hirschsprung's disease, Chagas' disease
• Painful anal conditions, e.g. anal fissure

**Defecatory disorders**

• Rectal prolapse, mucosal prolapse intussusception and solitary rectal ulcer syndrome
• Large rectocele
• Pelvic floor dyssynergia/anismus
• Megarectum

**Diagnosis**

This relies on the history. When there has been a recent change in bowel habit in association with other significant symptoms (e.g. rectal bleeding), a colonoscopy or CT of the pneumocolon is indicated. By these means, gastrointestinal causes, such as colorectal cancer and narrowed segments due to diverticular disease, can be excluded.

Constipation can be classified into three broad categories but there is much overlap:

• normal transit through the colon (59%)
• defecatory disorders (25%)
• slow transit (13%).

Defecatory disorders with slow transit can occur together (3%).

**Normal-transit constipation**

In normal-transit constipation, stool traverses the colon at a normal rate, the stool frequency is normal and yet patients believe they are constipated. This is likely to be due to perceived difficulties of evacuation or the passage of hard stools. Patients may complain of abdominal pain or bloating. Normal-transit constipation can be distinguished from slow-transit constipation by undertaking marker studies of colonic transit. Capsules containing 20 radio-opaque shapes are swallowed on days 1, 2 and 3 and an abdominal X-ray obtained 120 hours after ingestion of the first capsule. Each capsule contains shapes of different configuration and the presence of more than 4 shapes from the first capsule, 6 from the second and 12 from the third denotes moderate to severe slow transit *(Fig. 13.47).*
Defecatory disorders

A ‘paradoxical’ contraction, rather than the normal relaxation of puborectalis and the external anal sphincter and associated muscles during straining, may prevent evacuation (pelvic floor dyssynergia, anismus). These are mainly due to dysfunction of the anal sphincter and pelvic floor. An anterior rectocele is a common problem where there is a weakness of the rectovaginal septum, resulting in protuberance of the anterior wall of the rectum with trapping of stool if the diameter is >3 cm. In some patients, the mucosa of the anterior rectal wall prolapses downwards during straining (see p. 420), impeding the passage of stool, while in others there may be a higher mucosal intussusception.

In some patients, the rectum can become unduly sensitive to the presence of small volumes of stool, resulting in the urge to pass frequent amounts of small-volume stool and the sensation of incomplete evacuation.

The defecatory disorders can often be characterized by performing evacuation proctography and tests of anorectal physiology.
**Slow-transit constipation**

Slow-transit constipation occurs predominantly in young women who have infrequent bowel movements (usually less than once a week). The condition often starts at puberty and the symptoms include an infrequent urge to defecate, bloating, abdominal pain and discomfort. Some patients with severe slow-transit constipation have delayed emptying of the proximal colon and others a failure of ‘meal-stimulated’ colonic motility. Histopathological abnormalities have been demonstrated in the colons of some patients with severe slow-transit constipation, and some patients have coexisting disorders of small intestinal motility, consistent with a diagnosis of chronic idiopathic intestinal pseudo-obstruction (see p. 435).

**Management**

Any underlying cause should be treated. In patients with normal and slow-transit constipation, the main focus should be directed towards increasing the fibre content of the diet in conjunction with increasing fluid intake.

The use of laxatives should be restricted to cases where symptoms impact on the patient's quality of life. The types of laxatives available are listed in **Box 13.29**. Osmotic laxatives act by increasing the colonic inflow of fluid and electrolytes; this acts not only to soften the stool but also to stimulate colonic contractility. The *polyethylene glycols (macrogols)* have the advantage over the synthetic disaccharide lactulose in that they are not fermented anaerobically in the colon to gas that can distend the colon and cause pain. The osmotic laxatives are preferred to the stimulatory laxatives, which act by stimulating colonic contractility and by causing intestinal secretion. *Prucalopride* is a high-affinity 5-HT$_4$ agonist that increases colonic transit and is an effective therapy for refractory constipation.

---

**Box 13.29**

**Laxatives and enemas**

**Bulk-forming laxatives**

- Dietary fibre
- Wheat bran
- Methylcellulose
- Mucilaginous gums – sterculia
- Mucilaginous seeds and seed coats, e.g. ispaghula husk

**Stimulant laxatives**

(Stimulate motility and intestinal secretion)
• Phenolphthalein  
• Bisacodyl  
• Anthraquinones – senna and dantron (only for the terminally ill)  
• Docusate sodium  
• Methylnaltrexone (for opioid-induced constipation)  
• Lubiprostone  
• Prucalopride  
• Linaclotide  
• Sodium picosulfate  

**Osmotic laxatives**  
• Magnesium sulphate  
• Lactulose  
• Macrogols  

**Suppositories**  
• Bisacodyl  
• Glycerol  

**Enemas**  
• Arachis oil  
• Docusate sodium  
• Hypertonic phosphate  
• Sodium citrate

*Linacotide*, a minimally absorbed peptide agonist of guanylate cyclase-C receptor, works by activating the cystic fibrosis transmembrane conductance regulator to stimulate chloride secretion and increase gastrointestinal fluid secretion. Significant benefit over placebo has been shown in clinical trials. *Lubiprostone* is an orally active agonist for type 2 chloride channels and therefore also increases gastrointestinal fluid secretion.  

Patients with defecatory disorders should be referred to a specialist centre, as surgery may be indicated: for example, for anterior rectocele or internal anal mucosal intussusception. Anterior mucosal prolapse can be treated by injection, and those with pelvic floor dyssynergia (anismus) can benefit from biofeedback therapy.

**Miscellaneous colonic conditions**
Megacolon

The term ‘megacolon’ is used to describe a number of congenital and acquired conditions in which the colon is dilated. In many instances, it is secondary to chronic constipation; in some parts of the world, Chagas' disease is a common cause.

In all young patients with megacolon, Hirschsprung's disease should be excluded. In this condition, which presents in the first years of life, an aganglionic segment of the rectum (megarectum) gives rise to constipation and subacute obstruction. Occasionally, Hirschsprung's disease affecting only a short segment of the rectum can be missed in childhood. A preliminary rectal biopsy is performed and stained for ganglion cells in the submucosal plexus. In doubtful cases, a full-thickness biopsy should be obtained. A frozen section is stained for acetylcholinesterase, which is elevated in Hirschsprung's disease. Manometric studies show failure of relaxation of the internal sphincter, which is diagnostic of Hirschsprung's disease. This condition can be successfully treated surgically.

Treatment of other causes of a megacolon is similar to that of slow-transit constipation, but saline washouts and manual removal of faeces are sometimes required.

Faecal incontinence

Of the healthy population over the age of 65, 7% experience a degree of incontinence. Incontinence is classified as minor (inability to control flatus or liquid stool, causing soiling) or major (frequent and inadvertent evacuation of stool of normal consistency). The common causes of incontinence are shown in Box 13.30. Obstetric injury is a common cause and sphincter defects have been found in up to 30% of primiparous women. Endoanal ultrasonography or pelvic MRI is the investigation of choice in the assessment of anal sphincter damage (Fig. 13.48). Neurophysiological investigation of pudendal nerve function, anal sensation and anal sphincter function may be required to elicit the cause of the problem.

Box 13.30

Aetiology of faecal incontinence

- **Congenital:**
  - e.g. surgery for imperforate anus
- **Anal sphincter dysfunction:**
  - Structural damage: surgery – anorectal, vaginal hysterectomy; obstetric injury during childbirth; trauma; radiation; perianal Crohn's disease
  - Pudendal nerve damage: childbirth
  - Perineal descent: prolonged straining at stool
- **Rectal prolapse**
- **Faecal impaction** with overflow diarrhoea
• **Severe diarrhoea:**
  – e.g. ulcerative colitis, functional diarrhoea, irritable bowel syndrome

• **Neurological and psychological disorders:**
  – Spinal trauma (S2–S4)
  – Spina bifida
  – Stroke
  – Multiple sclerosis
  – Diabetes mellitus (with autonomic involvement)
  – Dementia
  – Psychological illness

---

**FIGURE 13.48** Endoanal ultrasound scan. Axial mid-canal image, showing a large tear between 10 and 1 o’clock (arrowed) following vaginal delivery, involving the external anal sphincter (EAS) and internal anal sphincter (IAS), and resulting in faecal incontinence. (Courtesy of Professor Clive Bartram, Princess Grace Hospital, London.)

Initial **management** of minor incontinence is bowel habit regulation. Loperamide is the most potent antidiarrhoeal agent, which also increases internal sphincter tone.

Biofeedback is effective in some people with faecal incontinence associated with impaired function of the puborectalis muscle and the external anal sphincter. Sacral spinal nerve stimulation has been shown to be effective in the treatment of patients with a functionally deficient but morphologically intact external anal sphincter. Surgery may be required for anal sphincter trauma and should only be carried out in specialist centres.
Ischaemic disease of the colon (ischaemic colitis)

Occlusion of branches of the superior mesenteric artery (SMA) or inferior mesenteric artery (IMA), often in the older age group, commonly presents with sudden onset of abdominal pain and the passage of bright red blood per rectum, with or without diarrhoea. There may be signs of shock and evidence of underlying cardiovascular disease. The anatomy of the vascular supply to the colon results in a watershed area at the splenic flexure, which is therefore the most common site affected. This condition has also been described in women taking the contraceptive pill, patients on nicorandil, and those with thrombophilia and small- or medium-vessel vasculitis.

Examination

On examination, the abdomen may be distended and tender. A straight abdominal X-ray often shows thumb-printing (a characteristic sign of ischaemic disease) at the splenic flexure. Patients are likely to display signs of cardiovascular shock and may have a lactic acidosis.

Differential diagnosis and investigations

The differential diagnosis includes other causes of acute colitis. Patients often require an urgent CT scan to exclude perforation. An unprepared flexible sigmoidoscopy is the diagnostic investigation of choice; biopsies showing epithelial cell apoptosis and lamina propria fibrosis are characteristic. A colonoscopy should be performed when the patient has fully recovered to exclude the formation of a stricture at the site of disease and confirm mucosal healing. Patients without evidence of underlying cardiovascular disease should be screened for thrombophilia and vasculitis.

Management

Most patients settle on symptomatic treatment. A few patients show progressive signs of peritonism and imminent perforation, and require urgent surgery.

Diverticular disease

Diverticula are frequently found in the colon and occur in 50% of patients over the age of 50 years. They are most frequent in the sigmoid, but can be present throughout the whole colon.

The term diverticulosis indicates the presence of diverticula; diverticulitis implies that these diverticula are inflamed; diverticular colitis refers to crescentic inflammation on the folds in areas of diverticulosis. It is perhaps better to use the more general term diverticular disease, as it is often difficult to be sure whether the diverticula are inflamed. The precise mechanism of diverticula formation is not known. There is thickening of the muscle layer and, because of high intraluminal pressures, pouches of mucosa extrude through the muscular wall
through weakened areas near blood vessels to form diverticula. An alternative explanation is cholinergic denervation with increasing age, which leads to hypersensitivity and increased uncoordinated muscular contraction. Diverticular disease seems to be related to the low-fibre diet eaten in developed countries and is rare in rural Africa.

Diverticulitis occurs when faeces obstruct the neck of the diverticulum, causing stagnation and allowing bacteria to multiply and produce inflammation. This can then lead to bowel perforation (peridiverticulitis), abscess formation, fistulae into adjacent organs, haemorrhage and even generalized peritonitis.

Clinical features and investigations

Diverticular disease is asymptomatic in 95% of cases and is usually discovered incidentally on colonoscopy or barium enema examination. No treatment other than advice to increase dietary fibre is required in those patients. In symptomatic patients, intermittent left iliac fossa pain or discomfort and an erratic bowel habit commonly occur, which are difficult to differentiate from the irritable bowel syndrome. In severe disease, luminal narrowing results in severe pain and constipation. In the absence of clinical signs of acute diverticulitis, a colonoscopy or ‘virtual colonoscopy’ (see p. 362) is the investigation of choice. Barium enema (Fig. 13.49) combined with flexible sigmoidoscopy is also used.
Management

Management of uncomplicated symptomatic disease is with a well-balanced (soluble and insoluble) fibre diet (20 g/day), with smooth muscle relaxants if required. Antibiotics and admission to hospital are not required for uncomplicated disease.

Acute diverticulitis

The pathophysiology of diverticulitis is associated with altered gut motility, increased luminal pressure and a disordered colonic microenvironment. Acute diverticulitis most commonly affects diverticula in the sigmoid colon. It presents with severe pain in the left iliac fossa, often
accompanied by fever and constipation. These symptoms and signs are similar to those of appendicitis but are located on the left side. On examination, the patient is often febrile with a tachycardia. **Abdominal examination** shows tenderness, guarding and rigidity on the left side of the abdomen. A palpable tender mass is sometimes felt in the left iliac fossa.

**Investigations**

- **Blood tests** often reveal a polymorphonuclear leucocytosis. The ESR and CRP are raised.
- **CT colonography** (**Fig. 13.50**) will show colonic wall thickening, diverticula and often pericolic collections and abscesses. There is usually a streaky increased density extending into the immediate pericolic fat with thickening of the pelvic fascial planes. These findings are diagnostic of acute diverticulitis (95% sensitivity and specificity) and differ from those of malignant disease. Sigmoidoscopy and colonoscopy are not performed during an acute attack.

![CT of lower abdomen, showing acute diverticulitis (arrowed). The bowel wall is thickened and there is loss of clarity of the pericolic fat. A narrow segment of bowel is seen to the left of the diseased segment.](image)

- **Ultrasound examination** is often more readily available and is cheaper. It can demonstrate thickened bowel and large pericolic collections, but is less sensitive than CT.

**Management**

Mild attacks can be treated on an outpatient basis using oral antibiotics such as ciprofloxacin and metronidazole. Patients with signs of systemic upset (fevers, tachycardia), significant abdominal pain or co-morbidity require bowel rest, intravenous fluids and intravenous antibiotic therapy. Recent large trials of 5-ASA therapy have shown minor benefit in
preventing recurrent diverticulitis. Repeat attacks often require surgery.

Complications of diverticular disease

- **Perforation** usually occurs in association with acute diverticulitis, and can lead to formation of a paracolic or pelvic abscess or generalized peritonitis. Surgery may be required.
- **Fistula formation** into the bladder, causing dysuria or pneumaturia, or into the vagina, causing discharge.
- **Intestinal obstruction** (see p. 435), usually after repeated episodes of acute diverticulitis.
- **Bleeding** is sometimes massive. In most cases, the bleeding stops and the cause of the bleeding can be established by colonoscopy and sometimes angiography. In rare cases, emergency segmental colectomy is required.
- **Mucosal inflammation** occurs in areas of diverticula, giving the appearance of a segmental colitis at endoscopy that may resemble Crohn's disease.

Anorectal disorders

**Pruritus ani**

Pruritus ani, or an itchy bottom, is common. Perianal excoriation results from scratching. Usually, the condition results from haemorrhoids or overactivity of sweat glands. Management consists of enhancing toilet hygiene, keeping the area dry and avoiding the use of perfumed moisturizing creams. Secondary causes include threadworm (*Enterobius vermicularis*) infestation, fungal infections (e.g. candidiasis) and perianal eczema, which should be treated appropriately.

**Haemorrhoids**

Haemorrhoids (primary – internal; second degree – prolapsing; third degree – prolapsed) usually cause rectal bleeding, discomfort and pruritus ani. Patients may notice red blood on their toilet paper and blood on the outside of their stools. They are the most common cause of rectal bleeding (see **Fig. 13.27**).

Diagnosis is made by inspection, rectal examination and proctoscopy.

**Management**

If symptoms are minor, no treatment is required apart from advice about avoiding constipation. Suppositories containing a local anaesthetic and corticosteroids are helpful. If symptoms are more severe, rubber band ligation or injection of a sclerosant can be used. Haemorrhoidal artery ligation operation (HALO) uses Doppler ultrasound to identify and ligate feeding arteries to the haemorrhoids. This technique may replace surgery.
**Anal fissures**

An anal fissure is a tear in the sensitive skin-lined lower anal canal distal to the dentate line, which produces pain on defecation. It can be an isolated primary problem in young to middle-aged adults or may occur in association with Crohn's disease or ulcerative colitis, in which case perianal abscesses and anal fistulae can complicate the fissure.

Diagnosis can usually be made on the history alone and confirmed on perianal inspection. Rectal examination is often not possible because of pain and sphincter spasm. The spasm not only causes pain but also impairs wound healing. In severe cases, proctoscopy and sigmoidoscopy should be performed under anaesthesia to exclude other anorectal disease. Initial treatment is with local anaesthetic gel and stool softeners. Use of 0.4% glyceryl trinitrate and 2% diltiazem ointments is of benefit. Botulinum toxin is used in chronic fissures but lateral subcutaneous internal sphincterotomy is also employed for severe cases.

**Fistula in ano and anorectal abscesses**

The anatomy of perianal fistulae may be simple or complex (*Fig. 13.51*). The fistulae usually present as abscesses and heal after the abscess is incised. In other cases, a small, discharging pilonidal sinus may be noted by the patient.
FIGURE 13.51 Perianal fistulae. A. Common sites. B. Fistulae and sepsis in Crohn's disease (arrowed). An MRI of the pelvis showing a complex extrasphincteric horseshoe tract with extension to the ischio-anal fossae (right; arrowed).

Endoanal ultrasonography, MRI and/or examination under anaesthetic are usually required to define the primary and any secondary tracks, exclude sepsis and detect any associated disease, such as Crohn's disease and tuberculosis. Management is with surgical incision and drainage with antibiotics.

**Rectal prolapse, intussusception and solitary rectal ulcer syndrome**

All these conditions are thought to be related, rectal prolapse being the unifying pathology. Some patients with solitary rectal ulcer syndrome (SRUS) do not have prolapse but strain excessively and ulcerate the anterior rectal wall, which is forced into the anus during attempts at defecation. Constipation and chronic straining may be precipitating causes. Patients commonly present with slight bleeding and mucus on defecation, tenesmus and a sensation of anal obstruction.
SRUS is commonly located on the anterior wall of the rectum within 13 cm of the anal verge, and is sometimes difficult to distinguish from cancer and Crohn's disease during endoscopic examination. SRUS has typical histological features of non-specific inflammatory changes with bands of smooth muscle extending into the lamina propria.

Asymptomatic SRUS should not be treated. Symptomatic patients should be advised to stop straining and measures should be taken to soften the stool. If rectal prolapse can be demonstrated during defecation, this should be repaired; in severe cases, surgical treatment by rectopexy may be indicated. Surgical treatment for complete rectal prolapse is also required.

**Colonic tumours**

### Colon polyps and polyposis syndromes

A colonic polyp is an abnormal growth of tissue projecting from the colonic mucosa. Polyps range from a few millimetres to several centimetres in diameter and are single or multiple, pedunculated, sessile or ‘flat’ (*Fig. 13.52*).
Many histological types of polyp are found in the colon (Box 13.31). However, adenomas are the precursor lesions in most cases of colon cancer.

Box 13.31

Classification of colorectal polyps and polyposis syndromes
Classification of colorectal polyps

Classification is summarized in **Box 13.31**.

**Sporadic adenomas**

An adenoma is a benign, dysplastic tumour of columnar cells or glandular tissue. Adenomas have tubular, tubulovillous or villous morphology. The vast majority of adenomas are not inherited and are termed ‘sporadic’. Although many sporadic adenomas do not become malignant in the patient's lifetime, they have a tendency to progress to cancer via increasing grades of dysplasia due to progressive accumulation of genetic changes (adenoma–carcinoma sequence). Factors favouring malignant transformation in colorectal polyps, and the relation between adenoma size and likelihood of cancer, are shown in **Box 13.32**.

**Box 13.32**

**Factors affecting risk of malignant change in an adenoma**

AD, autosomal dominant; AFAP, attenuated FAP; APC, adenomatous polyposis coli; AR, autosomal recessive; CRC, colorectal cancer; FAP, familial adenomatous polyposis; HNPCC, hereditary non-polyposis colorectal cancer; MLH-1, MutL homologue 1; MSH-2, MutS homologue 2; MYH-AP, MUT Y homologue-associated polyposis; PTEN, phosphatase and tensin homologue.
The progression from benign polyp to cancer is shown in Figure 17.2.

The likelihood of an adenoma being present increases with age; it is rare before the age of 30 years. By the age of 60–70, 5% of asymptomatic subjects will have a polyp of ≥1 cm, or cancer with no symptoms, and up to 50% will have at least one small <1 cm adenoma. Removal of polyps at colonoscopy and subsequent surveillance reduce the risk of development of colon cancer by approximately 80%. Techniques such as chromoscopy, using dye spray or narrow band imaging, are being used to assist in their detection (flat adenomas account for approximately 12% of all adenomas).

Polyps in the rectum and sigmoid often present with rectal bleeding. More proximal lesions rarely produce symptoms and most are diagnosed on barium enema, CT colonography or on colonoscopy performed for screening or for other reasons. Large villous adenomas can present with profuse diarrhoea with mucus and hypokalaemia.

Once a polyp has been found, it is almost always possible to remove it endoscopically. Surveillance guidelines dictate the frequency of repeat investigations:

- at 5 years, if 1 or 2 adenomas <1 cm are found
- at 3 years, if there are 3–4 small adenomas or at least 1 that is >1 cm
- at 1 year, if there are ≥5 small adenomas or there are ≥3, at least 1 of which is >1 cm.

If any doubt exists about the completeness of excision of any polyp, then an earlier repeat examination is suggested.

### Sessile serrated adenomas

Serrated polyps form a heterogeneous group of colorectal lesions that includes the benign hyperplastic polyps (HPs), and the pre-malignant sessile serrated adenoma (SSA) and traditional serrated adenoma (TSA). They are characterized by the saw-tooth appearance of the crypt epithelium. It is now recognized that approximately 30% of colorectal cancers (particularly those in the right colon) originate from these lesions. Progression of serrated polyps is thought to occur via a distinct pathway from the adenoma–carcinoma sequence, with involvement of **BRAF** gene mutations and gene promoter hypermethylation (CpG island methylator phenotype, or CIMP; see p. 423). Microsatellite instability can be detected in both the adenoma–carcinoma and the serrated pathways. Endoscopic resection of SSAs and TSAs with appropriate surveillance is recommended.
Inherited polyposis syndromes

About 5% of colorectal cancers have a well-defined single-gene basis.

Familial adenomatous polyposis

Familial adenomatous polyposis (FAP) is an autosomal dominant condition arising from germline mutations of the APC gene, located on chromosome 5q21–q22. More than 825 different mutations have been identified. Penetrance is virtually 100%. It is characterized by the presence of hundreds to thousands of colorectal and duodenal adenomas. The mean age of adenoma development is 16 years; the average age at which colorectal cancer develops is 39 years. Tracing and screening of relatives are essential, and affected individuals should be offered a prophylactic colectomy. Surgical options include colectomy and ileorectal anastomosis, which requires lifelong surveillance of the rectal stump, or a restorative proctocolectomy or pouch procedure with complete removal of rectal mucosa.

Cystic gland polyps, predominantly in the proximal stomach, and duodenal adenomas are frequently found in FAP, as well as other extraintestinal lesions such as osteomas, epidermoid cysts and desmoid tumours. The duodenal adenomas may progress to cancer and are the most common cause of death in colectomized patients with FAP. Congenital hypertrophy of the retinal pigment epithelium (CHRPE) occurs in many families with FAP. Other cancers in FAP include thyroid, pancreatic and hepatoblastomas.

APC gene mutations can be found in about 80% of families with FAP. Once the mutation has been identified in an index case, other family members can be tested for the mutation, and screening can then be directed at mutation carriers. If a mutation cannot be found in a known FAP case, all family members should undergo clinical screening with regular colonoscopy.

Attenuated FAP may be missed as it presents later (average age 44 years) and has fewer polyps (<100), which tend to occur on the right side of the colon rather than on the left. It may be indistinguishable from sporadic cases but the gene mutation is in the APC germline.

MYH-associated polyposis

MUT Y homologue-associated polyposis (MYH-AP) is an autosomal recessive inherited syndrome of multiple colorectal adenomas and cancer. MYH is a base-excision-repair gene that corrects oxidative DNA damage. MYH-AP may account for 7–8% of families with the FAP phenotype in whom APC mutations cannot be found. Subjects with multiple adenomas or an FAP phenotype without APC mutations and with a family history compatible with a recessive pattern of inheritance should be tested for MYH-AP.

Lynch syndrome

In Lynch syndrome (previously called hereditary non-polyposis colon cancer, HNPCC), polyps are formed in the colon and may progress rapidly to colon cancer. It affects 1 : 5000 people, causing 3–10% of colorectal cancer cases.

The disease is caused by a mutation in one of the DNA mismatch repair genes, usually
hMSH2 or hMLH1, although others (hMSH6, PMS1 and PMS) have been reported. Mismatch repair genes are responsible for maintaining the stability of DNA during replication. Inheritance is autosomal dominant. The defect in function of the mismatch repair mechanism causes naturally occurring, highly repeated, short DNA sequences known as microsatellites to be shorter or longer than normal, a phenomenon called microsatellite instability (MSI).

Onset of cancer is earlier than in sporadic cases, at age 40–50 or younger. Tumours have a predilection for the right colon, in contrast to sporadic cases. In contrast to FAP, the lifetime risk of colon cancer (penetrance of the gene) in mutation carriers is 70–80%. Other cancers are also more common in Lynch syndrome: stomach, small intestine, bladder, skin, brain and hepatobiliary system. Female patients are at risk for endometrial and ovarian cancer.

The diagnosis is made from the family history of colon cancer at a young age and the presence of associated cancers in the family. These are formalized in the various editions of the Amsterdam and the Bethesda criteria (Box 13.33).

**Box 13.33**

Diagnostic criteria for Lynch syndrome

**Modified Amsterdam criteria**

- One individual diagnosed with CRC (or extracolonic Lynch tumours) before age 50 years
- Two affected generations
- Three affected relatives, one a first-degree relative of the other two
- FAP excluded
- Tumours verified by pathological examination

**Bethesda guidelines**

- CRC diagnosed in patient who is younger than 50 years
- Presence of synchronous, metachronous CRC, or other Lynch tumours, irrespective of age
- CRC with the MSI-H histology diagnosed in a patient who is younger than 60 years
- CRC diagnosed in one or more first-degree relative with a Lynch-related tumour, with one of the cancers being diagnosed under the age 50 years
- CRC diagnosed in two or more first- or second-degree relatives with Lynch-related tumours, irrespective of age

**Turcot syndrome**

This consists of FAP or Lynch syndrome (HNPCC) with brain tumours.

**Gardner syndrome**
This involves, in addition to FAP, desmoid tumours, osteomas of the skull and other lesions.

**Hamartomatous polyps**

These are commonly large and stalked. The inherited syndromes show autosomal dominant inheritance and include:

- **Juvenile polyps**, which occur mainly in children and teenagers, and are found mainly in the colon; histologically, they show mucus retention cysts. Most are sporadic, but a syndrome of juvenile polyposis is defined as: >3–5 juvenile colonic polyps, juvenile polyps throughout the gastrointestinal tract, or any number of polyps with a family history. This is an autosomal dominant condition and the relevant gene has been identified (see Box 13.31). The polyps are a cause of bleeding and intussusception in the first decade of life. There is also an increased risk of colonic cancer (relative risk (RR) of 34), and surveillance and removal of polyps must be undertaken.

- **Peutz–Jeghers syndrome** (see p. 403).

- **PTEN hamartoma–tumour syndrome** (PHTS), which includes Cowden syndrome, Bannayan–Riley–Ruvalcaba syndrome and all syndromes caused by germline phosphatase and tensin homologue (PTEN) mutations. Cowden (multiple hamartoma) syndrome is associated with characteristic skin stigmata, and by intestinal polyps regarded as hamartomas but with a mixture of cell types. These patients have an increased risk of various extraintestinal malignancies (thyroid, breast, uterine and ovarian). These syndromes are uncommon and together account for <1% of colon cancer cases.

**Colorectal carcinoma**

Colorectal cancer (CRC) is the third most common cancer worldwide and the second most common cause of cancer death in the UK.

Each year approximately, 40 000 new cases are diagnosed in England and Wales (68% colon, 32% rectal cancer), and CRC is registered as the cause of death in about half this number. The prevalence rate per 100 000 (at all ages) is 53.5 for men and 36.7 for women. The incidence increases with age; the average age at diagnosis is 60–65 years. Approximately 20% of patients in the UK have distant metastases at diagnosis. The disease is much more common in westernized countries than in Asia or Africa.

Factors related to risk of colorectal cancer are shown in Box 13.34.

---

**Box 13.34**

**Risk factors in colorectal cancer**

**Increased risk**

- Increasing age
- Animal fat (saturated) and red meat consumption
- Sugar consumption
- Colorectal polyps
- Family history of colon cancer or colonic polyps
- Chronic inflammatory bowel disease
- Obesity (body and abdominal)
- Smoking
- Acromegaly
- Abdominal radiotherapy
- Ureterosigmoidostomy

**Decreased risk**
- Vegetable, garlic, milk, calcium consumption
- Exercise (colon only)
- Aspirin (including low-dose) and other NSAIDs
  NSAIDs, non-steroidal anti-inflammatory drugs.

**Genetics**

Most colorectal cancers develop as a result of progression from normal mucosa to adenoma to invasive cancer. This progression is controlled by the accumulation of abnormalities in a number of critical growth-regulating genes and can be divided into three main pathways:

- **Chromosomal instability (CIN).** CIN is the most common cause of conventional adenomas throughout the colon. This pathway involves the sequential accumulation of genetic mutations in tumour suppressor genes, usually initiated by a mutation in the gene encoding adenomatous polyposis coli (APC).

- **CpG island methylator phenotype.** CpG island methylator phenotype (CIMP) tumours arise via the serrated neoplasia pathway and have a marked predilection for the proximal colon. Following an initiating genetic mutation in the genes encoding *BRAF* or *KRAS*, these lesions progress via epigenetic silencing of tumour suppressor and mismatch repair (MMR) genes by promoter methylation (p. 421). This pathway is epitomized by the serrated polyposis syndrome.

- **Microsatellite instability.** Microsatellite instability (MSI) tumours are also more commonly located in the proximal colon. They arise from defective DNA repair through inactivation of mismatch repair genes, epitomised by the germline mutation of MMR genes seen in Lynch syndrome (HNPCC).

  This molecular classification can help to distinguish clinical characteristics, such as patient demographics, tumour distribution, response to therapy and prognosis.
Cancer families

A family history of CRC confers an increased risk to relatives. Family history is, next to age, the most common risk factor for CRC. FAP (Fig. 13.53) is the best-recognized syndrome predisposing to CRC but represents less than 1% of all colorectal cancers. Lynch syndrome (HNPCC) accounts for 3–10% of familial cancer (see p. 422).

![Figure 13.53 Percentages of colon cancer according to family risk. FAP, familial adenomatous polyposis; HNPCC, hereditary non-polyposis colorectal cancer (Lynch syndrome).](image)

Additionally, some colon cancers arise, at least in part, from an inherited predisposition, so-called familial risk (Box 13.35). Estimates of their frequency range from 10% to 30% of all CRC but the genes involved have yet to be identified. The risk of CRC can be estimated from a family history matched with empirical risk tables, so that appropriate advice regarding screening can be offered.

### Box 13.35

**Lifetime risk of colorectal cancer (CRC) in first-degree relatives of a CRC patient**
Most CRCs are, however, sporadic and occur in individuals without a strong family history. Their distribution is shown in Figure 13.54.

Pathology

CRC, which usually takes the form of a polypoid mass with ulceration, spreads by direct infiltration through the bowel wall. It involves lymphatics and blood vessels with subsequent spread, most commonly to the liver and lung. Synchronous cancers are present in 2% of cases. Histology is adenocarcinoma with variably differentiated glandular epithelium and mucin production. ‘Signet ring’ cells, in which mucin displaces the nucleus to the side of the cell, are relatively uncommon and generally have a poor prognosis.

Clinical features
Symptoms suggestive of colorectal cancer include change in bowel habit with looser and more frequent stools, rectal bleeding, tenesmus and symptoms of anaemia. A rectal or abdominal mass may be palpable. Cancers arising in the caecum and right colon are often asymptomatic until they present as an iron deficiency anaemia. Cancer may present with intestinal obstruction.

Patients aged over 35–40 years presenting with new large bowel symptoms should be investigated. Digital examination of the rectum is essential and examination of the colon should be performed in all cases.

**Investigations**

- **Colonoscopy** is the ‘gold standard’ for investigation and allows biopsy for histology. Biopsy of the tumour is mandatory, usually at endoscopy *(Fig. 13.55)*.

  ![Carcinoma in the ascending colon. A. Colonoscopic appearance of a large irregular ulcer. B. Histopathology showing an adenocarcinoma.](image)

- **Double-contrast barium enema** can visualize the large bowel but has now been superseded by CT colonography.

- **Endoanal ultrasound and pelvic MRI** are used for staging rectal cancer.

- **Chest, abdominal and pelvic CT** scanning evaluate tumour size, local spread, and liver and lung metastases, contributing to tumour staging.

- **PET scanning** is useful for detecting occult metastases and for evaluation of suspicious lesions found on CT or MRI.

- **MRI** is also useful for evaluating suspicious lesions found on CT or ultrasound, especially in the liver.

- **Serum carcinoembryonic antigen (CEA)** is of little use for primary diagnosis and should not be performed as a screening test. It is useful for follow-up; rising levels suggest recurrence.
• **Faecal occult blood (FOB) tests** are used for mass population screening.

### Management

Management should be undertaken by multidisciplinary teams working in specialist units. About 80% of patients with CRC undergo surgery (often laparoscopically). The operative procedure depends on the cancer site. Long-term survival relates to the stage of the primary tumour and the presence of metastatic disease. There has been a gradual move from using Dukes' classification to the TNM classification system (see *Box 24.58*). Long-term survival is only likely when the cancer is completely removed by surgery with adequate clearance margins and regional lymph node clearance.

- **Total mesorectal excision (TME)** is required for rectal cancers and removes the entire package of mesorectal tissue surrounding the cancer. A low rectal anastomosis is then performed. Abdomino-perineal excision, which requires a permanent colostomy, is reserved for very low tumours within 5 cm of the anal margin. TME combined with preoperative radiotherapy reduces local recurrence rates in rectal cancer to around 8% and improves survival. Pre- or postoperative chemotherapy reduces local recurrence rates but had no effect on survival in a recent study.

- **Segmental resection** and restorative anastomosis, with removal of the draining lymph nodes as far as the root of the mesentery, is used for cancer elsewhere in the colon. Surgery in patients with obstruction carries greater morbidity and mortality. Where technically possible, preoperative decompression by endoscopic stenting with a mesh-metal stent relieves obstruction, so surgery can be elective rather than emergency, and is probably associated with a decrease in morbidity and mortality.

- **Local transanal surgery** is very occasionally used for early superficial rectal cancers.

- **Surgical or ablative treatment of liver and lung metastases** prolongs life where treatment is technically feasible and the patient is fit enough to undergo the treatment.

- **Radiotherapy is not helpful** for colonic cancers proximal to the rectum because of difficulties in delivering a sufficient dose to the tumour without excess toxicity to adjacent structures, particularly the small bowel.

- **Adjuvant postoperative chemotherapy** improves disease-free survival and overall survival in stage III colon cancer (see pp. 636–637). Those with stage II tumours and advanced features such as vascular invasion may also benefit.

  Management of **advanced colorectal cancer** is discussed on pages 636–637.

### Follow-up

All patients who have surgery should have a total colonoscopy performed before surgery to look for additional lesions. If total colonoscopy cannot be achieved before surgery, a second ‘clearance’ colonoscopy within 6 months of surgery is essential. Patients with stage II or III disease should be followed up with regular colonoscopy and CEA measurements; rising levels
of CEA suggest recurrence. Annual CT scanning of the chest and abdomen to detect operable liver metastases should be performed for up to 3 years post surgery.

Screening for CRC

• **FOB tests** have been studied as a screening test for colorectal cancer. Several large randomized studies have demonstrated a reduction in cancer-related mortality of 15–33%. Immunologically based FOB tests are superior to the conventional guaiac-based systems. The disadvantage of screening with FOB is its relatively low sensitivity, which means many negative colonoscopies. In FOB test screen-positive patients in the UK National Bowel Cancer Screening Programme (NHS BCSP), about 10% have cancer, 40% have adenomas and the colon is normal in 50%.

• **Flexible sigmoidoscopy** screening has been shown to reduce the mortality from CRC, but not overall mortality.

• **Colonoscopy** is the ‘gold standard’ technique for examination of the colon and rectum and is the investigation of choice for high-risk patients. Universal screening strategies have been implemented in the UK for subjects between 60 and 69 who have a positive FOB. Cancer has been detected in 8–12% of patients, 75% of which was located in the left colon; 72% of detected cancers are at an ‘early’ stage (10% polyp cancer, 32% stage I and 30% stage II).

• **CT colonography** (‘virtual colonoscopy’; see Fig. 13.5) is increasingly being used.

**Further reading**

Diarrhoea

Diarrhoea is a common clinical problem and yet there is no uniformly accepted definition. Organic causes (stool weights >250 g/day) have to be distinguished from functional causes such as irritable bowel syndrome. Sudden onset of bowel frequency associated with crampy abdominal pains, and a fever, will point to an infective cause; bowel frequency with loose, blood-stained stools to an inflammatory basis; and the passage of pale, offensive stools that float, often accompanied by loss of appetite and weight loss, to steatorrhoea. Nocturnal bowel frequency and urgency usually point to an organic cause. Passage of frequent, small-volume stools (often formed) points to a functional cause (see pp. 428–432).

Pathophysiology

Osmotic diarrhoea

The gut mucosa acts as a semipermeable membrane and fluid enters the bowel if there are large quantities of non-absorbed hypertonic substances in the lumen. This occurs because the patient:

• has ingested a non-absorbable substance (e.g. a purgative, such as magnesium sulphate or magnesium-containing antacid)

• has generalized malabsorption, so that high concentrations of solute (e.g. glucose) remain in the lumen

• has a specific absorptive defect (e.g. disaccharidase deficiency or glucose-galactose malabsorption).

The volume of diarrhoea produced by these mechanisms is reduced by the absorption of fluid by the ileum and colon. The diarrhoea stops when the patient stops eating or the malabsorptive substance is discontinued.

Secretory diarrhoea

In this disorder, there is both active intestinal secretion of fluid and electrolytes, and decreased absorption. The mechanism of intestinal secretion is shown in Figure 13.56A.
**FIGURE 13.56** Mechanisms of diarrhoea. A. Small intestinal secretion of water and electrolytes. (a) *Cholera toxin* binds to its receptor (monosialoganglioside G) via fimbria (toxin co-regulated pilus) on its β-subunit. This activates the α subunit (of the G protein), which in turn dissociates and activates cyclic AMP (cAMP). The increase in cAMP activates intermediates (e.g. protein kinase and Ca\(^{2+}\)), which then act on the apical membrane, causing Cl\(^{-}\) secretion (with water) and inhibition of Na\(^{+}\) and Cl\(^{-}\) absorption. *Heat-labile* *E. coli enterotoxin* shares a receptor with cholera toxin. (b) *Heat-stable (HS) E. coli toxin* binds to its own receptor and activates guanylate cyclase (cGMP), producing the same effect on secretion. (c) *Clostridium difficile* activates the protein kinases via Ca\(^{2+}\)/calmodulin (Ca\(^{2+}\)/CM). (d) *Zona occludens toxin* is the product of the ZOT gene, which loosens tight junctions and is required for function of the cholera toxin. It has enterotoxic activity, producing secretion. Cholera and *E. coli* cause these effects without invasion of the cell. B. *Colonic mucosal cell.* This demonstrates one of the mechanisms by which an invasive pathogen (e.g. *Shigella*) acts. Following penetration, the pathogens generate cytotoxins, which leads to mucosal ulceration and cell death. ATP, adenosine triphosphate; G, G protein consisting of subunits α, β, γ; GC, guanylate cyclase; GMP, guanosine monophosphate; GTP, guanosine triphosphate; i, inhibitory; PKC, protein kinase C; s, stimulatory; VIP, vasoactive intestinal polypeptide.

Common causes of secretory diarrhoea are:
- enterotoxins (e.g. cholera, *E. coli* thermolabile or thermostable toxin, *C. difficile* toxin)
- hormones (e.g. vasoactive intestinal peptide in Verner–Morrison syndrome; see p. 512)
- bile salts (in the colon) following ileal resection
- fatty acids (in the colon) following ileal resection
- some laxatives (e.g. docusate sodium).

**Inflammatory diarrhoea (mucosal destruction)**
Diarrhoea occurs because of damage to the intestinal mucosal cell so that there is a loss of fluid and blood (*Fig. 13.56B*). In addition, there is defective absorption of fluid and electrolytes. Common causes are infective conditions (e.g. dysentery due to *Shigella*) and inflammatory conditions (e.g. ulcerative colitis and Crohn's disease).

**Abnormal motility**
Diabetic, post-vagotomy and hyperthyroid diarrhoea are all due to abnormal motility of the upper gut. Symptoms may be exacerbated by small bowel bacterial overgrowth.

* Causes of diarrhoea are shown in *Box 13.23*. It should be noted that the irritable bowel syndrome, colorectal cancer, diverticular disease and faecal impaction with overflow in the elderly do not cause ‘true’ organic diarrhoea (i.e. >250 g/day), even though patients may complain of diarrhoea. Worldwide, infection and infestation are major problems and these are discussed under the causative organisms in *Chapter 11.*

## Acute diarrhoea

Diarrhoea of sudden onset is very common, is often short-lived and requires no investigation or treatment. Although dietary causes should be considered, diarrhoea due to viral agents may also last 24–48 hours (see pp. 263–265). The causes of other infective diarrhoeas are shown on pages 273–279. Travellers' diarrhoea, which affects people travelling outside their own countries, particularly to developing countries, usually lasts 2–5 days; it is discussed on pages 277–279. Cholera is described on pages 288–289.

## Clinical features

Clinical features associated with the acute diarrhoeas include fever, abdominal pain and vomiting. If the diarrhoea is particularly severe, dehydration can be a problem; the very young and very old are at special risk from this.

## Investigations

Investigations are necessary if the diarrhoea has lasted more than 5–7 days. Stools (up to three) should be sent immediately to the laboratory for culture and examination for ova, cysts and parasites and for *C. difficile* toxin assay. If the diagnosis has still not been made, a sigmoidoscopy and rectal biopsy should be performed, with colonoscopy if necessary. Viral and bacterial infective diarrhoeas do not last more than 7–10 days; in this case, inflammatory bowel disease as a cause of the diarrhoea is a more likely diagnosis.

## Management

Oral fluid and electrolyte replacement is often necessary. Special oral rehydration solutions (e.g. sodium chloride and glucose powder) are available for use in severe episodes of diarrhoea, particularly in infants. Antidiarrhoeal drugs are thought to impair the clearance of any pathogen from the bowel but may be necessary for short-term relief (e.g. codeine phosphate 30 mg four times daily or loperamide 2 mg three times daily). Antibiotics are occasionally necessary for infective gastroenteritis, depending on the organism.
Chronic diarrhoea

This always needs investigation. The flow diagram in Figure 13.57 is illustrative; whether the large or the small bowel is investigated first will depend on the clinical story of, for example, bloody diarrhoea or steatorrhoea. The investigations and treatment are described in detail under the individual diseases. Colonoscopy with ileoscopy is usually the first investigation if stool cultures are negative and small bowel disease is not suspected.

---

**Clostridium difficile-associated diarrhoea (pseudomembranous colitis)**

Pseudomembranous colitis (see p. 277) may develop following the use of any antibiotic. Diarrhoea occurs in the first few days after taking the antibiotic or even up to 6 weeks after stopping the drug. The causative agent is *C. difficile* (see p. 277).
Bile acid malabsorption

Bile acid malabsorption is an under-diagnosed cause of chronic diarrhoea and many patients with this disorder are assumed to have the irritable bowel syndrome. Bile acid diarrhoea occurs when the terminal ileum fails to reabsorb bile acids. When present in increased concentrations in the colon, bile acids (particularly the dihydroxy bile acids: deoxycholate and chenodeoxycholate) lead to diarrhoea by reducing absorption of water and electrolytes and, at higher concentrations, inducing secretion as well as increasing colonic motility. A variety of causes of bile acid malabsorption are recognized (Box 13.36).

Box 13.36

Causes of bile acid diarrhoea

• Ileal resection
• Ileal disease, e.g. active or inactive Crohn's disease
• Primary bile acid diarrhoea
• Post-infective gastroenteritis
• Rapid small bowel transit
• Post-cholecystectomy

Bile acid malabsorption should be considered not only in patients with chronic diarrhoea of unknown cause, but also in those with diarrhoea and associated disease who are not responding to standard therapy (e.g. patients with terminal ileal Crohn's disease or microscopic inflammatory colitis).

Diagnosis is made using the SeHCAT test, in which a radio-labelled bile acid analogue is administered and percentage retention at 7 days calculated (<19% retention abnormal). Treatment is with bile salt sequestrants such as colestyramine, a resin that binds and inactivates the action of bile acids in the colon. The best treatment results are obtained in patients with a SeHCAT retention of <5%.

Factitious diarrhoea

Factitious diarrhoea accounts for up to 4% of new patients with diarrhoea attending gastroenterology clinics.

Purgative abuse

This is most commonly seen in females who surreptitiously take high-dose purgatives and are often extensively investigated for chronic diarrhoea. The diarrhoea is usually of high volume (>1 L daily) and patients may have a low serum potassium. Biochemical analysis of the stool may help diagnose laxative abuse. Management is difficult, as most patients deny purgative ingestion. Purgative abuse often occurs in association with eating disorders and patients may
need psychiatric help.

**Dilutional diarrhoea**

In this condition, raised stool weights occur as a consequence of patients deliberately diluting their stool with urine or tap water. The diagnosis is made by measuring stool osmolality and electrolyte concentrations in order to calculate the faecal osmolar gap.

**Diarrhoea in patients with HIV infection**

Chronic diarrhoea is a common symptom in HIV infection, but HIV's role in the pathogenesis of diarrhoea is unclear. *Cryptosporidium* (see p. 350) is the pathogen most commonly isolated. *Isospora belli* and microsporidia have also been found.

The cause of the diarrhoea is often not found and treatment is symptomatic. **Box 13.19** shows the conditions affecting the gastrointestinal tract in patients with AIDS.

**Functional Gastrointestinal Disorders**

There is a large group of gastrointestinal disorders that are termed ‘functional’ because symptoms occur in the absence of any demonstrable abnormalities in the digestion and absorption of nutrients, fluid and electrolytes, and no structural abnormality can be identified in the gastrointestinal tract, although there may be discernible abnormalities in neuromuscular function, such as dysmotility and visceral hypersensitivity, which are not routinely investigated.

**Box 13.37** lists some of the symptoms that are suggestive of a functional gastrointestinal disorder. Modern classification systems are based on the premise that, for each disorder, there is a symptom cluster that ‘breeds true’ across clinical and population groups. There is inevitably overlap, some symptoms being common to more than one disorder.

---

**Box 13.37**

**Chronic gastrointestinal symptoms suggestive of a functional gastrointestinal disorder**

- Nausea alone
- Vomiting alone
- Belching
- Chest pain unrelated to exercise
- Postprandial fullness
- Abdominal bloating
- Abdominal discomfort/pain (right or left iliac fossa)
- Passage of mucus *per rectum*
• Frequent bowel actions with urgency first thing in morning

**Box 13.38** lists the common functional gastrointestinal disorders, as defined by Rome III criteria. These conditions are extremely common worldwide, comprising 80% of patients seen in the gastroenterology clinic.

**Pathophysiology and brain–gut interactions**

People with functional gastrointestinal disorders (FGIDs) are characterized by having a greater gastrointestinal motility response to life events than normal subjects. There is, however, a poor association between measured gastrointestinal motility changes and symptoms in many of the FGIDs. Patients with FGID have been shown to have abnormalities in visceral sensation and to have a lower pain threshold when tested with balloon distension (visceral hyperalgesia). Visceral hypersensitivity possibly relates to:

• altered receptor sensitivity at the viscus itself
• increased excitability of the spinal cord dorsal horn neurones
• altered central modulation of sensations.
A systematic review of published studies suggests that 10% of patients who experience an acute infective gastroenteritis develop a degree of FGID. It is not clear whether this is caused by post-infectious bile salt malabsorption, alterations in the mucosal immune system or the use of antibiotics to treat the index infection.

The brain–gut axis describes a combination of intestinal motor, sensory and activities (Fig. 13.58). Thus, extrinsic (e.g. vision, smell) and intrinsic (e.g. emotion, thought) information can affect gastrointestinal sensation because of the neural connections from higher centres. Conversely, viscerotrophic events can affect central pain perception, mood and behaviour.

Psychological stress can exacerbate gastrointestinal symptoms, and psychological disturbances are more common in patients with FGIDs. These disturbances alter attitude to illness, promote healthcare seeking, and often lead to a poor clinical outcome. They have psychosocial consequences with poor quality of life at home and work. Early in life, genetic and environmental influences (e.g. family attitudes towards bowel training, verbal or sexual abuse, exposure to an infection) may affect psychosocial development (susceptibility to life stress, psychological state, coping skills, development of social support) or the development of gut dysfunction (abnormal motility or visceral hypersensitivity). Therefore, FGID should be regarded as a dysregulation of brain–gut function.

**Functional oesophageal disorders**

The criteria for diagnosis rest mainly on compatible symptoms. However, pathological gastro-
oesophageal reflux and eosinophilic oesophagitis may need to be excluded (see pp. 373–374).

**Globus**

This presents as:

- persistent or intermittent sensation of a lump or foreign body in the throat
- occurrence of the sensation between meals
- absence of dysphagia and pain on swallowing (odynophagia).

*Management* is with explanation and reassurance, and a trial of anti-reflux therapy. Antidepressants may be tried.

**Functional chest pain of presumed oesophageal origin**

This is characterized by episodes of mainly midline chest pain, not burning in nature, that are potentially of oesophageal origin and occur in the absence of a cardiological cause, gastro-oesophageal reflux and achalasia.

More than half of patients will respond to high-dose acid-suppression therapy in the first week; some will respond to nitrates and calcium-channel blockers.

Antidepressant therapy, e.g. amitriptyline or the selective serotonin reuptake inhibitor (SSRI) citalopram, have been shown to be effective.

**Functional gastroduodenal disorders**

**Functional dyspepsia**

This is the second most common functional gastrointestinal disorder (after irritable bowel syndrome). Patients can present with a spectrum of symptoms, including upper abdominal pain or discomfort, fullness, early satiety, bloating and nausea.

These patients have no structural abnormality as an explanation for their symptoms.

**Functional dyspepsia subgroups**

Two subgroups, based on the predominant (or most bothersome) single symptom, are suggested:

- *Epigastric pain syndrome*, with pain centred in the upper abdomen as the predominant (most bothersome) symptom.

- *Postprandial distress syndrome*, with an unpleasant or troublesome, non-painful sensation (discomfort) centred in the upper abdomen being the predominant symptom. This sensation may be associated with upper abdominal fullness, early satiety, bloating and nausea.

There is considerable overlap between these two groups.
Investigations

*Helicobacter pylori* infection should be excluded using a stool antigen test, but many young patients (<50 years) require no further investigation. Older patients or those with alarm symptoms require endoscopy. Gastroscopy often shows gastritis but it is doubtful whether this is the cause of the symptoms.

Management

The range of therapies prescribed for functional dyspepsia reflects the uncertain pathogenesis and the lack of satisfactory treatment options. Management is further confounded by high placebo response rates (20–60%). A proportion of patients will respond satisfactorily to reassurance, explanations and lifestyle changes. Proton pump inhibitors and prokinetic agents are used for patients with epigastric pain syndrome and postprandial distress syndrome, respectively. Reducing intake of fat, coffee and alcohol and stopping cigarette smoking help. SSRI medication is tried in refractory cases.

*H. pylori* eradication therapy has been shown to be effective in some patients with functional dyspepsia.

Aerophagia

Aerophagia refers to a repetitive pattern of swallowing or ingesting air and belching. It is usually an unconscious act unrelated to meals. Usually, no investigation is required. Explanation that the symptoms are due to swallowed air, and reassurance are necessary, as is treatment of associated psychiatric disease.

Functional vomiting

Functional vomiting is a rare condition in clinical practice, although chronic nausea is a frequent accompaniment in all functional gastrointestinal disorders. CNS pathology and migrainous syndromes (cyclical vomiting syndrome) should be considered and treated.

Clinical features

Clinically, functional vomiting is characterized by:

- frequent episodes of vomiting, occurring on at least 1 day a week
- absence of criteria for an eating disorder, rumination or major psychiatric disease
- absence of self-induced and medication-induced vomiting
- absence of abnormalities in the gut or CNS and of metabolic disease to explain the recurrent vomiting.
Investigations
Investigation is often not required but non-gastrointestinal disorders should always be excluded (see Box 13.1).

Management
Treatment is with anti-nausea drugs and antidepressants; behavioural therapy and psychotherapy are helpful. Dietary changes occasionally help.

Cyclical vomiting syndrome
This syndrome is characterized by typical bouts of intense vomiting lasting for hours to days, separated by periods with no symptoms. It can occur in children or adults. There is a link to migraine headaches but the cause is not known. In some cases, provocative triggers can be identified; for example, there is a specific syndrome associated with frequent cannabis use – cannabinoid hyperemesis syndrome.

Diagnosis of cyclical vomiting syndrome is by recognition of the pattern of symptoms and ruling out of other causes.

Management
Treatment is with antiemetics and intravenous rehydration and electrolyte replacement during bouts, with avoidance of triggers where these are known. Prophylactic treatment of migraine, when it coexists, may help.

Gastroparesis
Gastroparesis results when there is delayed gastric emptying. There are a number of known associations, such as diabetes, but many cases are primary. Symptoms include nausea, vomiting, early satiety, fullness, bloating and upper abdominal pain.

Management is directed at relief of symptoms and correction of nutritional deficiencies. Improvement of gastric emptying can sometimes be achieved by medical or surgical treatments, such as pro-motility agents or gastric pacemaker insertion. In diabetics, glycaemic control is helpful.

Functional bowel disorders

Irritable bowel syndrome
Irritable bowel syndrome (IBS) is the most common FGID. In Western populations, up to 1 in 5 people report symptoms consistent with IBS. Approximately 50% will consult their doctors
and, of these, up to 30% will be referred by their doctor to a hospital specialist. Up to 40% of all patients seen in specialist gastroenterology clinics will have IBS. Estimates in the UK put the annual cost of IBS to healthcare resources as £45.6 million; in the USA, the cost is higher at $8 billion. In the UK, approximately one-quarter of IBS patients take time off work for periods ranging from 7 to 13 days each year.

The factors that determine whether an IBS sufferer in the community seeks medical advice include higher illness attitude scores and higher anxiety and depression scores than non-consulters. Consulters perceive that their symptoms are more severe than those of non-consulters, and consulting behaviour may be determined by the number of presenting symptoms. Female consulters outnumber male consulters by a factor of 2–3 to 1.

**IBS – a multisystem disorder**

IBS patients suffer from a number of non-intestinal symptoms *(Box 13.39)*, which may be more intrusive than the classical features. IBS coexists with chronic fatigue syndrome (see pp. 899–900), fibromyalgia (see pp. 664–665) and temporomandibular joint dysfunction.

---

**Box 13.39**

**Non-gastrointestinal features of irritable bowel syndrome**

**Gynaecological symptoms**
- Painful periods (dysmenorrhoea)
- Pain following sexual intercourse (dyspareunia)

**Urinary symptoms**
- Frequency
- Urgency
- Passing urine at night (nocturia)
- Incomplete emptying of bladder

**Other symptoms**
- Joint hypermobility
- Back pain
- Headaches
- Bad breath, unpleasant taste in the mouth
- Poor sleeping
- Fatigue

---

The biopsychosocial conceptualization of the pathogenesis and clinical expression of FGIDs
(Fig. 13.58) is particularly relevant to IBS, and Box 13.40 lists some common factors that have been shown to trigger IBS symptoms. Infectious diarrhoea precedes the onset of IBS symptoms in 7–30% of patients. Whether this is a factor for all patients or just a small subgroup remains controversial. Risk factors in these patients have been shown to include female gender, severity and duration of diarrhoea, pre-existing adverse life events and high hypochondriacal anxiety and neurotic scores at the time of the initial illness. Symptoms of anxiety and depression are more common in IBS patients, and stress or adverse life events often precede the onset of chronic bowel symptoms.

### Box 13.40

**Some factors that can trigger onset of irritable bowel symptoms**

- Affective disorders, e.g. depression, anxiety
- Psychological stress and trauma
- Gastrointestinal infection
- Antibiotic therapy
- Sexual, physical or verbal abuse
- Pelvic surgery
- Eating disorders

### Diagnosis

Diagnostic criteria (Rome III 2006) state that, in the preceding 3 months, there should be at least 3 days/month of recurrent abdominal pain or discomfort associated with two or more of the following for at least 25% of the time:

1. improvement with defecation
2. onset associated with a change in frequency of stool
3. onset associated with a change in form (appearance) of stool.

These are useful for comparative studies.

Subgroups of IBS patients can be identified according to the criteria listed in Box 13.41.

### Box 13.41

**Subtyping irritable bowel syndrome by predominant stool pattern**
<table>
<thead>
<tr>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>IBS with constipation (IBS-C)</td>
<td>Hard lumpy stools &gt;25% and loose (mushy) or watery stools &lt;25% of bowel movements</td>
</tr>
<tr>
<td>IBS with diarrhoea (IBS-D)</td>
<td>Loose (mushy) or watery stools &gt;25% and hard or lumpy stools &lt;25% of bowel movements</td>

<tr>
<td>Unsubtyped IBS</td>
<td>Insufficient abnormality of stool consistency to meet criteria for IBS-C, D or M</td>
</tr>
</tbody>
</table>

The decision as to whether to investigate and the choice of investigations should be based on clinical judgement. Pointers to the need for thorough investigation are the presence of the above symptoms in association with rectal bleeding, nocturnal pain, fever and weight loss, and a clinical suspicion of organic diarrhoea. A raised stool calprotectin or lactoferrin would suggest inflammation needing further investigation.

## Management

Current strategies for the treatment of IBS include therapies that target central and end-organ pathways (*Box 13.42*); these are not mutually exclusive.

*Eluxadoline – a μ- and κ-opioid receptor agonist and δ-opioid receptor antagonist.

FODMAP, fermentable oligo-, di- and monosaccharides and polyols; SSRI, selective serotonin reuptake inhibitor.

Patients with IBS are often worried that their symptoms are due to a serious disease such as cancer. A positive diagnosis of IBS with an explanation of the symptoms and reassurance is often helpful and may require no further treatment. **Box 13.42** shows the overall management strategies used in IBS for those with severe and longstanding problems. Patients should be treated sympathetically and some may require psychiatric support.

### Pain/gas/bloat syndrome/midgut dysmotility

Disordered motility and visceral sensation that predominantly affects the small intestine or midgut result in symptoms of pain and bloating without altered defecation. Other symptoms include postprandial fullness, nausea and, on occasions, anorexia and weight loss.

**Management of patients with pain/gas/bloat syndrome** is not easy, and in some, pain can be chronic and severe. Narcotics should always be avoided. Central and end-organ-targeted treatment approaches should be combined: for example, the SSRI paroxetine combined with a prokinetic agent, such as domperidone, or a smooth muscle relaxant, such as mebeverine. Small bowel bacterial overgrowth can be a contributory feature that can be treated with non-absorbed antibiotics such as rifaximin. Recent research has highlighted the benefit of altering
the fermentable components of the diet. A diet with reduced fermentable oligo-, di- and monosaccharides and polyols (FODMAP) will exclude a range of food types, including garlic, onions, specific beans, fructose-containing fruit, wheat-containing products, and certain natural and synthetic sweeteners. Small sham-diet-controlled clinical trials have shown significant benefit in patients with functional symptoms but long-term randomized controlled studies are necessary.

Some patients with pain/gas/bloat syndrome have particularly severe and chronic symptoms, which may be nocturnal. A small subgroup of these has been shown to have manometric features consistent with a diagnosis of chronic idiopathic intestinal pseudo-obstruction (CIIP), and specifically of an enteric neuropathy. Full-thickness small intestinal biopsies confirm this diagnosis by showing a deficiency of α actin staining in the inner circular layer of smooth muscle. More appropriately, these patients should be considered as having a gastrointestinal neuromuscular disorder of the gut. About 10% of these individuals are subsequently found to have an underlying autoimmune overlap disorder (see p. 699).

Management of patients with neuromuscular disorders of the gut requires a multidisciplinary approach, with an emphasis on the management of pain, psychological state and nutrition. Patients with underlying autoimmune inflammatory mixed connective tissue disorders may benefit from primary treatment of these. Patients with intestinal failure as a result of CIIP need long-term parenteral nutrition.

### Functional diarrhoea

In this form of functional bowel disease, symptoms occur in the absence of abdominal pain. They commonly include:

- the passage of several stools in rapid succession, usually first thing in the morning; no further bowel action may occur that day, or defecation takes place only after meals
- a first stool of the day that is usually formed, the later ones being mushy, looser or watery
- urgency of defecation
- anxiety, and uncertainty about bowel function with restriction of movement (e.g. travelling)
- exhaustion after defecation.

Chronic diarrhoea without pain is caused by many diseases that are indistinguishable by history from functional diarrhoea. Features that are atypical of a functional disorder (e.g. large-volume stools, rectal bleeding, nutritional deficiency and weight loss) call for more extensive investigations.

Treatment of functional diarrhoea is with loperamide, often combined with a tricyclic antidepressant prescribed at night (e.g. clomipramine 10–30 mg).

### Further reading

The Acute Abdomen

This section deals with the acute abdominal conditions that cause the patient to be hospitalized within a few hours of the onset of pain (Box 13.43). If they are recognized quickly as an emergency, a reduction in morbidity and mortality can be achieved. Although a specific diagnosis should be attempted, the immediate problem in management is to decide whether an ‘acute abdomen’ exists and whether surgery is required.

*Percentages are approximate and vary in different communities.
History
This should include previous operations, any gynaecological problems and presence of any concurrent medical condition.

Pain
The onset, site, type and subsequent course of the pain should be determined as accurately as possible. In general, the pain of an acute abdomen can be either constant (usually owing to inflammation) or colicky (because of a blocked ‘tube’). The inflammatory nature of a constant pain will be supported by a raised temperature, tachycardia and/or a raised white cell count. If these are normal, then other causes (e.g. musculoskeletal, aortic aneurysm), even rare ones (e.g. porphyria), should be considered. Colicky pain can be due to an obstruction of the gut, biliary system, urogenital system or uterus. These cases will probably require conservative management initially, along with analgesics. If a colicky pain becomes a constant pain, then inflammation of the organ may have supervened (e.g. strangulated hernia, ascending cholangitis or salpingitis).

A sudden onset of pain suggests:
• perforation (e.g. of a duodenal ulcer)
• rupture (e.g. of an ectopic pregnancy)
• torsion (e.g. of an ovarian cyst)
• acute pancreatitis
• infarction (e.g. mesenteric).

Back pain suggests:
• pancreatitis
• rupture of an aortic aneurysm
• renal tract disease.

Inflammatory conditions (e.g. appendicitis) produce a more gradual onset of pain. With peritonitis, the pain is continuous and may be made worse by movement. Many inflammatory conditions can progress to those listed as having a sudden onset due to complications.

Vomiting
Vomiting may accompany any acute abdominal pain but, if persistent, suggests an obstructive lesion of the gut. The character of the vomit should be asked about. Does it contain blood, bile or small bowel contents?

Other symptoms
Any change in bowel habit or of urinary frequency should be documented and, in females, a gynaecological history, including last menstrual period, should be taken.

Physical examination
The general condition of the person should be noted. Does he or she look ill or shocked? Large volumes of fluid may be lost from the vascular compartment into the peritoneal cavity or into the lumen of the bowel, giving rise to hypovolaemia: that is, a pale, cold skin, a weak, rapid pulse and hypotension.

**The abdomen**

- **Inspection.** Look for the presence of scars, distension or masses.

- **Palpation.** The abdomen should be examined gently for sites of tenderness and the presence or absence of guarding. Guarding is involuntary spasm of the abdominal wall and indicates peritonitis. This can be localized to one area or may be generalized, involving the whole abdomen.

- **Bowel sounds.** Increased high-pitched, tinkling bowel sounds indicate fluid obstruction; this occurs because of fluid movement within the dilated bowel lumen. Absent bowel sounds suggest peritonitis. In an obstructed patient, absent bowel sounds may be due to strangulation, ischaemia or ileus. It is essential for the hernial orifices to be examined if intestinal obstruction is suspected.

**Vaginal and rectal examination**

Vaginal examination can be very helpful, particularly in diagnosing gynaecological causes of an acute abdomen (e.g. a ruptured ectopic pregnancy). Rectal examination is less helpful, as localized tenderness may be due to any cause; it may show blood on the glove.

**Other observations**

- **Temperature.** Fever is more common in acute inflammatory processes.

- **Urine.** Examine for:
  - blood – suggests urinary tract infection or renal colic
  - glucose and ketones – ketoacidosis can present with acute pain
  - protein and white cells – to exclude acute pyelonephritis.

- **Medical causes.** These should be borne in mind *(Box 13.44).*

**Box 13.44**

**Medical causes of acute abdomen**

- **Referred pain:**
  - Pneumonia
  - Myocardial infarction
- **Functional gastrointestinal disorders**
- **Renal causes:**
  - Pelviureteric colic
– Acute pyelonephritis

**Metabolic causes:**
– Diabetes mellitus
– Acute intermittent porphyria
– Lead poisoning
– Familial Mediterranean fever

**Haematological causes:**
– Haemophilia and other bleeding disorders
– Henoch–Schönlein purpura
– Sickle cell crisis
– Polycythaemia vera
– Paroxysmal nocturnal haemoglobinemia

**Vasculitis**

---

**Investigations**

- **Blood count.** A raised white cell count occurs in inflammatory conditions.

- **Serum amylase.** High levels (more than five times normal) indicate acute pancreatitis. Raised levels below this can occur in any acute abdomen and should not be considered diagnostic of pancreatitis.

- **Serum electrolytes.** These are not particularly helpful for diagnosis but are useful for general evaluation of the patient.

- **Pregnancy test.** A urine dipstick is used for women of childbearing age.

- **X-rays.** An erect chest X-ray is useful to detect air under the diaphragm caused by a perforation (Fig. 13.59). Dilated loops of bowel or fluid levels are suggestive of obstruction on abdominal X-ray (Fig. 13.60).
• **Ultrasound.** This is useful in the diagnosis of acute cholangitis, cholecystitis and aortic aneurysm, and in expert hands is reliable in the diagnosis of acute appendicitis.
Gynaecological and other pelvic causes of pain can be detected.

- **CT scan.** Spiral CT of the abdomen and pelvis is the most accurate investigation in most acute emergencies. It should be used more often to avoid unnecessary laparotomies.
- **Laparoscopy.** This is used increasingly as a diagnostic tool prior to proceeding with surgery, particularly in men and women over the age of 50 years. In addition, therapeutic manoeuvres, such as appendicectomy, can be performed.

### Acute appendicitis

This is a common surgical emergency and affects all age groups. Appendicitis should always be considered in the differential diagnosis if the appendix has not been removed.

Acute appendicitis mostly occurs when the lumen of the appendix becomes obstructed with a faecolith; however, in some cases, there is only generalized acute inflammation. If the appendix is not removed at this stage, gangrene occurs with perforation, leading to a localized abscess or to generalized peritonitis.

### Clinical features

Most patients present with abdominal pain; in many, it starts vaguely in the centre of the abdomen, becoming localized to the right iliac fossa in the first few hours. Nausea, vomiting, anorexia and occasional diarrhoea can occur.

Examination of the abdomen usually reveals tenderness in the right iliac fossa, with guarding due to the localized peritonitis. There may be a tender mass in the right iliac fossa. Although raised white cell counts, ESR and CRP are helpful, other laboratory tests can be less valuable. An ultrasound scan can detect an inflamed appendix and can also indicate an appendix mass or other localized lesion. CT is highly sensitive (98.5%) and specific (98% negative predictive value; 99.5% positive predictive value), and reduces the incidence of removal of a ‘normal’ appendix. With the use of these investigations, the incidence of ‘normal’ appendix histology has fallen to 15–20%.

### Differential diagnosis

- Non-specific mesenteric lymphadenitis – may mimic appendicitis.
- Acute terminal ileitis due to Crohn's disease or *Yersinia* infection.
- Gynaecological causes:
  - Inflamed Meckel's diverticulum
  - Functional bowel disease.

### Management

The appendix is removed by laparoscopic surgery. If an appendix mass is present, the patient
is usually treated conservatively with intravenous fluids and antibiotics. The pain subsides over a few days and the mass usually disappears over a few weeks. Interval appendicectomy is recommended at a later date to prevent further acute episodes.

## Gynaecological causes of an acute abdomen

### Ruptured ectopic pregnancy

The fallopian tube is the most common extrauterine site of implantation. Delayed diagnosis is the major cause of morbidity. Most patients will present with recurrent low abdominal pain associated with vaginal bleeding. Diagnosis is usually made with abdominal and transvaginal ultrasound. Most patients can be managed by laparoscopic salpingostomy or salpingectomy.

### Ovarian causes

- Rupture of ‘functional’ ovarian cysts in the middle of the cycle (Mittelschmerz).
- Torsion or rupture of ovarian cysts.

### Acute salpingitis

Most cases are associated with sexually transmitted infection. Patients commonly present with bilateral low abdominal pain, a fever and vaginal discharge. In the **Fitz-Hugh–Curtis syndrome**, *Chlamydia* infection tracks up the right paracolic gutter to cause a perihepatitis. Patients can present with acute right hypochondrial pain, fever and mildly abnormal liver biochemistry.

## Acute peritonitis

### Localized peritonitis

There is virtually always some degree of localized peritonitis with all acute inflammatory conditions of the gastrointestinal tract (e.g. acute appendicitis, acute cholecystitis). Pain and tenderness are largely features of this localized peritonitis. The treatment is for the underlying disease.

### Generalized peritonitis

This is a serious condition, resulting from irritation of the peritoneum owing to infection (e.g. perforated appendix) or from chemical irritation due to leakage of intestinal contents (e.g. perforated ulcer). In the latter case, superadded infection gradually occurs; *E. coli* and *Bacteroides* are the most common organisms.

The peritoneal cavity becomes acutely inflamed, with production of an inflammatory exudate that spreads throughout the peritoneum, leading to intestinal dilatation and paralytic ileus.
Clinical features

In perforation, the onset is sudden with acute, severe abdominal pain, followed by general collapse and shock. The patient may improve temporarily, only to become worse later as generalized toxaemia occurs.

When peritonitis is secondary to inflammatory disease, the onset is less rapid, the initial features being those of the underlying disease.

Investigations

Investigations should always include an erect chest X-ray. X-ray is used to detect free air under the diaphragm, and serum amylase is measured to diagnose acute pancreatitis, which is treated conservatively. Imaging with ultrasound and/or CT should always be performed for diagnosis.

Management

Peritonitis is treated surgically after adequate resuscitation and the re-establishment of a good urinary output. This includes insertion of a nasogastric tube, intravenous fluids and antibiotics. Surgery has a two-fold objective:

• peritoneal lavage of the abdominal cavity
• specific treatment of the underlying condition.

Complications

Any delay in the treatment of peritonitis produces more profound toxaemia and septicaemia, which may lead to development of multiorgan failure (see p. 1155). Local abscess formation can occur and should be suspected if a patient continues to remain unwell postoperatively, with a swinging fever, high white cell count and continuing pain. Abscesses are commonly pelvic or subphrenic, and can be localized and drained using ultrasound and CT scanning techniques.

Intestinal obstruction

Most intestinal obstruction is due to a mechanical block. Sometimes, the bowel does not function, leading to a paralytic ileus. This occurs temporarily after most abdominal operations and with peritonitis. Some causes of intestinal obstruction are shown in Box 13.45. The most common cause in adults is adhesions.

Box 13.45

Causes of intestinal obstruction
**Small intestinal obstruction**
- Adhesions (80% in adults)
- Hernias
- Crohn's disease
- Intussusception
- Obstruction due to extrinsic involvement by cancer

**Colonic obstruction**
- Carcinoma of the colon
- Sigmoid volvulus
- Diverticular disease

Obstruction of the bowel leads to bowel distension above the block, with increased secretion of fluid into the distended bowel. Bacterial contamination takes place in the distended stagnant bowel. In strangulation, the blood supply is impeded, leading to gangrene, perforation and peritonitis unless urgent treatment of the condition is undertaken.

**Clinical features**

The patient complains of abdominal colic, vomiting and constipation without passage of wind. In upper gut obstruction the vomiting is profuse, but in lower gut obstruction it may be absent.

Examination of the abdomen reveals distension with increased bowel sounds. Marked tenderness suggests strangulation, and urgent surgery is necessary. Examination of the hernial orifices and rectum must be performed. X-ray of the abdomen reveals distended loops of bowel proximal to the obstruction. Fluid levels are seen in small bowel obstruction on an erect film. In large bowel obstruction, the caecum and ascending colon are distended. An instant, water-soluble Gastrografin enema without air insufflation may help to demonstrate the site of the obstruction. CT can localize the lesion accurately and is the investigation of choice.

**Management**

Initial management is by resuscitation with intravenous fluids (mainly 0.9% saline with potassium) and decompression. Many cases will settle on conservative management, but an increasing temperature, raised pulse rate, increasing pain and a rising white cell count require urgent scanning and possible exploratory laparotomy.

Laparotomy with removal of the obstruction will be necessary in some cases of small bowel obstruction. If the bowel is gangrenous owing to strangulation, gut resection will be required. A few patients (e.g. those with Crohn's disease) may have recurrent episodes of incomplete intestinal obstruction that can be managed conservatively. In large bowel obstruction due to malignancy, a self-expanding metal stent can be used, followed by elective surgery. In
Critically ill patients, a defunctioning colostomy may be needed. Volvulus of the sigmoid colon can be managed by the passage of a flexible sigmoidoscope or a rectal tube to un-kink and deflate the bowel, but recurrent volvulus may require sigmoid resection.

**Acute colonic pseudo-obstruction**

A clinical picture mimicking mechanical obstruction may develop in patients who do not have a mechanical cause. In more than 80% of cases, it complicates other clinical conditions, such as:

- intra-abdominal trauma, pelvic, spinal and femoral fractures
- postoperative states (abdominal, pelvic, cardiothoracic, orthopaedic, neurosurgical)
- intra-abdominal sepsis
- pneumonia
- metabolic disorders (e.g. electrolyte disturbances, malnutrition, diabetes mellitus, Parkinson's disease)
- drugs – opiates (particularly after orthopaedic surgery), antidepressants, antiparkinsonian drugs.

Patients present with rapid and progressive abdominal distension and pain. X-ray shows a gas-filled large bowel. Management is of the underlying problem (e.g. withdrawal of opiate analgesia), together with a trial of intravenous neostigmine therapy. Patients should be monitored and consideration should be given to surgery if the diameter of the caecum exceeds 14 cm.

**The Peritoneum**

**Anatomy and physiology**

The peritoneal cavity is a closed sac lined by mesothelial cells; these produce surfactant, which acts as a lubricant within the peritoneal cavity. The cavity contains <100 mL of serous fluid containing <30 g/L of protein.

The mesothelial cells lining the diaphragm have gaps that allow communication between the peritoneum and the diaphragmatic lymphatics. Approximately one-third of fluid drains through these lymphatics, the remainder through the parietal peritoneum. These mechanisms allow particulate matter to be removed rapidly from the peritoneal cavity.

Complement activation is an early defence mechanism and is followed rapidly by upregulation of the peritoneal mesothelial cells and migration of polymorphonuclear neutrophils and macrophages into the peritoneum.

Mast cells release potent mediators of inflammation, including histamine and eicosanoids, and interact with T cells to generate an immune response.
The peritoneum-associated lymphoid tissue includes the omental milky spots, the lymphocytes within the peritoneal cavity and the draining lymph nodes. B cells with a unique CD5+ are common. This defence system plays a major role in localizing peritoneal infection.

Disorders affecting the peritoneum

Conditions that can affect the peritoneum are shown in Box 13.46.

Box 13.46

Diseases of the peritoneum

**Infective (bacterial) peritonitis**

- Secondary to gut disease, e.g. appendicitis
- Perforation of any organ
- Chronic peritoneal dialysis
- Spontaneous, usually in ascites with liver disease
- Tuberculosis

**Neoplasia**

- Secondary deposits (e.g. from ovary, stomach)
- Primary mesothelioma

**Vasculitis**

- Rheumatic autoimmune disease
- Polyserositis (e.g. familial Mediterranean fever)

**Peritonitis** can be acute or chronic, as seen in TB. Most cases of infective peritonitis are secondary to gastrointestinal disease, but it occurs occasionally without intra-abdominal sepsis in ascites due to liver disease. Very rarely, fungal and parasitic infections (e.g. amoebiasis, candidiasis) can also cause primary peritonitis. Peritonitis is discussed further on pages 434-435.

The peritoneum can be involved by secondary malignant deposits, and the most common cause of ascites in a young to middle-aged woman is an ovarian carcinoma.

A **subphrenic abscess** is usually secondary to infection in the abdomen and is characterized by fever, malaise, pain in the right or left hypochondrium and shoulder-tip pain. An erect chest X-ray may show gas under the diaphragm, impaired movement of the diaphragm on screening and/or a pleural effusion. Ultrasound is usually diagnostic. Percutaneous catheter drainage inserted under CT or ultrasound guidance and antibiotics constitute highly successful therapy.

**Ascites** is associated with all diseases of the peritoneum. The fluid that collects is an
exudate with a high protein content. It is also seen in liver disease. The mechanism, causes and investigation of ascites are discussed on pages 472–474.

### Peritoneal adhesions

Adhesions form as a result of abdominal or pelvic surgery, or inflammation in the abdominoperitoneal cavity. They cause a variety of conditions, including adhesive small bowel obstruction (ASBO), chronic abdominal pain, complications during future surgery, and female infertility when they involve the fallopian tubes or ovaries. There is no satisfactory medical or surgical treatment and so surgical techniques have been developed to minimize peritoneal injury.

### Retroperitoneal fibrosis (peri-aortitis)

This is a rare condition, in which there is a marked fibrosis over the posterior abdominal wall and retroperitoneum. It is associated with raised serum IgG4 levels (see p. 145) and is described on pages 760–761.

### Tuberculous peritonitis

This is the second most common form of abdominal TB. Three subgroups can be identified: wet, dry and fibrous.

- In patients with the **wet** type, ascitic fluid should be examined for protein concentration (>20 g/L) and tubercle bacilli (rarely found).
- In the **dry** form, patients present with subacute intestinal obstruction, which is due to tuberculous small bowel adhesions.
- In the **fibrous** form, patients present with abdominal pain, distension and ill-defined, irregular, tender abdominal masses.

The diagnosis of peritoneal TB can be supported by findings on ultrasound or CT screening (mesenteric thickening and lymph node enlargement). A histological diagnosis is not always required before instituting treatment. In some patients, careful laparoscopy (to avoid perforation) may have to be performed, and rarely laparotomy.

### Management

Drug treatment is similar to that for pulmonary TB (see pp. 1110–1113) and should be supervised by chest physicians who have experience in dealing with contacts.

Spider naevi
Gynecomastia

NB: Often patients with liver disease have very few signs.
The aetiology of liver disease differs from region to region. In the developed world, liver inflammation is most often due to obesity, the metabolic syndrome (non-alcoholic fatty liver disease, NAFLD), non-alcoholic steatohepatitis (NASH) and alcohol excess. In the developing world, chronic viral infection with either hepatitis B or hepatitis C is the leading cause of liver mortality. In England, liver disease is the fifth most common cause of premature mortality. Globally, about half a billion people suffer from chronic viral hepatitis. Health education and the improvement in public health, along with vaccination programmes, should help to stop the spread of viral infections and reduce risk factors for the metabolic syndrome.

Cirrhosis represents the final common pathway for liver diseases and is characterized by progressive fibrosis of the liver parenchyma, which leads to portal hypertension and deterioration of liver function. In decompensated cirrhosis, the median overall survival is 2
years, which is a far worse prognosis than for many cancers.

Imaging techniques enable the liver, biliary tree and pancreas to be visualized with precision, resulting in earlier diagnosis. Liver transplantation is an established therapy for both acute and chronic liver disease.

**Anatomy of the Liver and Biliary System**

**The liver**

The liver is the body's largest internal organ (1.2–1.5 kg) and is situated in the right hypochondrium. A functional division into the larger right lobe (containing caudate and quadrate lobes) and the left lobe is made by the middle hepatic vein. The liver is further subdivided into eight segments (*Fig. 14.1*) by divisions of the right, middle and left hepatic veins. Each segment has its own portal pedicle, permitting individual segment resection at surgery.

*FIGURE 14.1 Segmental anatomy of the liver. The eight hepatic segments are shown: I, caudate lobe; II–IV, left hemiliver; V–VIII, right hemiliver.*

The hepatic blood supply constitutes 25% of the resting cardiac output and is delivered via two main vessels, entering via the liver hilum (porta hepatis):

- **The hepatic artery**, a branch of the coeliac axis, supplies 25% of the hepatic blood flow. The hepatic artery autoregulates flow, ensuring a constant total blood flow.

- **The portal vein** drains most of the gastrointestinal tract and the spleen. It supplies 75% of hepatic blood flow. The normal portal pressure is 5–8 mmHg; flow increases after meals.

The blood from these vessels is distributed to the segments and flows into the sinusoids via
the portal tracts.

Blood leaves the sinusoids, entering branches of the hepatic vein, which join into three main branches before entering the inferior vena cava.

The **caudate lobe** is an autonomous segment, as it receives an independent blood supply from the portal vein and hepatic artery, and its hepatic vein drains directly into the inferior vena cava.

**Lymph,** formed mainly in the perisinusoidal space, is collected in lymphatics that are present in the portal tracts. These small lymphatics enter larger vessels, which eventually drain into the portal system.

The **acinus** is the functional hepatic unit. This consists of parenchyma supplied by the smallest portal tracts containing portal vein radicles, hepatic arterioles and bile ductules (**Fig. 14.2**). The hepatocytes near this triad (zone 1) are well supplied with oxygenated blood and are more resistant to damage than the cells nearer the terminal hepatic (central) veins (zone 3).

![Figure 14.2: The acinus. Zones 1, 2 and 3 represent areas supplied by blood, with zone 1 being best oxygenated. Zone 3 is supplied by blood remote from afferent vessels and is in the microcirculatory periphery of the acinus. The perivascular area (the star-shaped green area around the terminal hepatic venule (THV)) is formed by the most peripheral parts of zone 3 and is made up of several adjacent acini; it is the least well oxygenated area. PT, portal triad.](image)

The **sinusoids** lack a basement membrane and are loosely surrounded by specialist fenestrated endothelial cells and Kupffer cells (phagocytic cells). Sinusoids are separated by plates of liver cells (hepatocytes). The subendothelial space between the sinusoids and hepatocytes is the space of Disse, which contains a matrix of basement membrane constituents.
and stellate cells (see Fig. 14.21).

**Stellate cells** store retinoids in their resting state and contain the intermediate filament, desmin. When activated (to myofibroblasts), they are contractile and regulate sinusoidal blood flow. Endothelin and nitric oxide play a major role in modulating stellate cell contractility. Stellate cells are activated by a wide variety of inflammatory cytokines (such as tumour necrosis factor-alpha, TNF-α); once activated, they generate extracellular matrix proteins, including collagen, leading, eventually, to cirrhosis. Under appropriate conditions, stellate cells can also produce proteases that degrade the extracellular matrix, leading to reversal of fibrosis. The balance between collagen production and degradation is critical to the progression of liver scarring and cirrhosis development/resolution (see p. 466).

**The biliary system**

Bile canaliculi form a network between the hepatocytes. These join to form thin bile ductules near the portal tract, which, in turn, enter the bile ducts in the portal tracts. These then combine to form the right and left hepatic ducts, which leave each liver lobe. The hepatic ducts join at the porta hepatis to form the common hepatic duct. The cystic duct connects the gall bladder to the lower end of the common hepatic duct. The gall bladder lies under the right lobe of the liver and stores and concentrates hepatic bile; its capacity is approximately 50 mL. The common bile duct is formed at the junction of the cystic and common hepatic ducts and is 8 mm in diameter or less, passing through the head of the pancreas, and narrowing at its lower end to pass into the duodenum. The common bile duct and pancreatic duct open into the second part of the duodenum, most often through a common channel at the ampulla of Vater, which contains the muscular sphincter of Oddi. This contracts rhythmically and prevents all of the bile from entering the duodenum, by maintaining a higher pressure than the gall bladder in the fasting state.

**Functions of the Liver**

**Protein metabolism (see also page 186)**

**Synthesis and storage**

The liver is the principal site of synthesis of all circulating proteins, apart from γ-globulins (produced in the reticuloendothelial system). The liver receives amino acids from the intestine and muscles and, by controlling the rate of gluconeogenesis and transamination, regulates plasma levels. Plasma contains 60–80 g/L of protein, mainly albumin, globulin and fibrinogen.

Albumin has a half-life of 16–24 days, and 10–12 g is synthesized daily. Its main functions are to maintain intravascular oncotic (colloid osmotic) pressure, and to transport water-insoluble substances such as bilirubin, hormones, fatty acids and drugs. Reduced synthesis of albumin over prolonged periods produces hypoalbuminaemia and is seen in chronic liver disease and malnutrition. Hypoalbuminaemia is also found in hypercatabolic states (e.g. trauma, burns and sepsis) and in diseases associated with an excessive loss (e.g. nephrotic
syndrome or protein-losing enteropathy).

Transport or carrier proteins, such as transferrin and caeruloplasmin, acute phase and other proteins (e.g. α₁-antitrypsin and α-fetoprotein) are also produced in the liver.

The liver also synthesizes all coagulation factors (except for one-third of factor VIII) – that is, fibrinogen, prothrombin, factors V, VII, IX, X and XIII, proteins C and S, and antithrombin (see pp. 565–567), as well as components of the complement system. The liver stores large amounts of certain vitamins, particularly A, D and B₁₂, lesser amounts of others (vitamin K and folate), and minerals – iron in ferritin and haemosiderin, and copper.

**Degradation (nitrogen excretion)**

Amino acids are degraded by transamination and oxidative deamination to produce ammonia, which is then converted to urea and excreted by the kidneys. This is the major pathway for the elimination of nitrogenous waste. Failure of this process occurs in severe liver disease.

**Carbohydrate metabolism**

Glucose homeostasis and maintenance of blood sugar are major functions of the liver. It stores approximately 80 g of glycogen. In the immediate fasting state, blood glucose is maintained either by glucose release from glycogen breakdown (glycogenolysis) or by synthesis of new glucose (gluconeogenesis). Sources for gluconeogenesis are lactate, pyruvate, amino acids from muscles (mainly alanine and glutamine), and glycerol from lipolysis of fat stores. In prolonged starvation, ketone bodies and fatty acids are used as alternative sources of fuel as body tissues adapt to a lower glucose requirement (see p. 190).

**Lipid metabolism**

Fats are insoluble in water and are transported in plasma as protein–lipid complexes (lipoproteins). These are discussed in detail on pages 1277–1279.

The liver has a major role in the metabolism of lipoproteins. It synthesizes very-low-density lipoproteins (VLDLs) and high-density lipoproteins (HDLs). HDLs are the substrate for lecithin-cholesterol acyltransferase (LCAT), which catalyses the conversion of free cholesterol to cholesterol ester (see below). Hepatic lipase removes triglyceride from intermediate-density lipoproteins (IDLs) to produce low-density lipoproteins (LDLs) which are degraded by the liver after uptake by specific cell-surface receptors (see Fig. 28.3).

Triglycerides are mainly of dietary origin but are also formed in the liver from circulating free fatty acids (FFAs) and glycerol, and incorporated into VLDLs. Oxidation or de novo synthesis of FFAs occurs in the liver, depending on availability of dietary fat.

Cholesterol may be of dietary origin but most is synthesized from acetyl-coenzyme A (acetyl-CoA) in the liver, intestine, adrenal cortex and skin. It either occurs as free cholesterol or is esterified with fatty acids; this reaction is catalysed by LCAT. This enzyme is reduced in severe liver disease, increasing the ratio of free cholesterol to ester, which alters membrane structures. One result of this is the red cell abnormalities (e.g. target cells) seen in chronic liver disease. Phospholipids (e.g. lecithin) are synthesized in the liver. The complex
The interrelationships between protein, carbohydrate and fat metabolism are shown in **Figure 14.3**.

**Figure 14.3**  Interrelationships of protein, carbohydrate and lipid metabolism in the liver.

### Formation of bile

**Bile secretion and bile acid metabolism**

Bile consists of water, electrolytes, bile acids, cholesterol, phospholipids and conjugated bilirubin. Two processes are involved in bile secretion across the canalicular membrane of the hepatocyte – **bile salt-dependent** and **bile salt-independent** processes – each contributing about 230 mL/day. Another 150 mL/day is produced by bile ductule epithelial cells.

Bile formation requires uptake of bile acids and other organic and inorganic ions across the basolateral (sinusoidal) membranes by multiple transport proteins (sodium taurocholate co-transporting polypeptide (NTCP) and sodium-independent organic anion-transporting polypeptide 2 (OATP2); **Fig. 14.4**). This process is driven by sodium/potassium adenosine triphosphatase (Na+/K+-ATPase) in the basolateral membranes. Intracellular transport across hepatocytes is partly through microtubules and partly by cytosol transport proteins.
Bile acids are also synthesized in hepatocytes from cholesterol, the rate-limiting step being those catalysed mainly by cholesterol-7α-hydroxylase and the P450 enzymes (CYP7A1 and CYP8B1).

The bile acid receptor, farnesoid X, blocks bile acid formation from cholesterol and also regulates the transport proteins (NTCP, OATP2) that increase bile acid uptake by the liver. It is a target for a new class of therapeutic drugs, farnesoid X receptor (FXR) agonists (see pp. 442–443).

The canalicular membrane contains multispecific organic anion transporters, mainly ATPase-dependent (ATP binding cassette), the multidrug-resistant protein 2 (MRP2), multidrug-resistant protein 3 (MDR3) and the bile salt excretory pump (BSEP), which carry a broad range of compounds including bilirubin diglucuronide, glucuronidated and sulphated bile acids, and other organic anions against a concentration gradient into the biliary canaliculus. Na\(^+\) and water follow the passage of bile salts by diffusion across the tight junction between hepatocytes (a bile salt-dependent process). In the bile salt-independent process, water flow is due to other osmotically active solutes such as glutathione and bicarbonate.

Secretion of a bicarbonate-rich solution is stimulated mainly by secretin and inhibited by somatostatin. This involves several membrane proteins, including the Cl\(^-\)/HCO\(_3\)\(^-\) exchanger and the cystic fibrosis transmembrane conductance regulator that controls Cl\(^-\) secretion, and
water channels (aquaporins) in cholangiocyte membranes. The bile acids are excreted into bile and pass via the common bile duct into the duodenum. The two primary bile acids – cholic acid and chenodeoxycholic acid (Fig. 14.4) – are conjugated with glycine or taurine, which increases their solubility. Intestinal bacteria convert these acids into secondary bile acids, deoxycholic and lithocholic acid. Figure 14.5 shows the enterohepatic circulation of bile acids.

![FIGURE 14.5 Recirculation of bile acids. The bile salt pool is relatively small and the entire pool recycles 6–8 times via the enterohepatic circulation. Synthesis of new bile acids compensates for faecal loss.]

The average total bile flow is 600 mL/day. When fasting, half flows into the duodenum and half is diverted into the gall bladder. The gall bladder mucosa absorbs 80–90% of the water and electrolytes, but is impermeable to bile acids and cholesterol. Following a meal, the I cells of the duodenal mucosa secrete cholecystokinin, which stimulates contraction of the gall bladder and relaxation of the sphincter of Oddi, allowing bile to enter the duodenum. An adequate bile flow is dependent on bile salts being returned to the liver by the enterohepatic circulation.

Bile acids act as detergents; their main function is lipid solubilization. Bile acid molecules have both a hydrophilic and a hydrophobic end. In aqueous solutions they form micelles, with their hydrophobic (lipid-soluble) ends in the centre. Micelles are expanded by cholesterol and phospholipids (mainly lecithin), forming mixed micelles.
**Bile acid receptors in liver disease**

Bile acids have been identified as crucial cell signalling molecules that regulate multiple biological processes. Bile acids are endogenous ligands for FXR and TGR5, a G-protein coupled receptor. Gain- and loss-of-function studies have demonstrated that both are involved in the regulation of lipid and carbohydrate metabolism and inflammatory responses. These receptors may therefore be potential targets for treatment of non-alcoholic fatty liver disease (NAFLD). Furthermore, recent experimental and phase II studies have shown that the FXR agonist, obeticholic acid, may be beneficial in primary biliary cholangitis (PBC). Obeticholic acid also improves portal hypertension in rodents. It is hoped that these experimental and early-phase findings will translate into new treatments.

**Bilirubin metabolism**

Bilirubin is produced mainly from the breakdown of mature red cells by Kupffer cells in the liver and reticuloendothelial system; 15% of bilirubin is formed from catabolism of other haem-containing proteins, such as myoglobin, cytochromes and catalases.

Normally, 250–300 mg (425–510 mmol) of bilirubin are produced daily. The iron and globin are removed from haem and reused. Biliverdin is formed from haem and reduced to form bilirubin (see p. 521). The bilirubin produced is unconjugated and water-insoluble, due to internal hydrogen bonding, and is transported to the liver attached to albumin. Bilirubin dissociates from albumin and is taken up by hepatic cell membranes and transported to the endoplasmic reticulum by cytoplasmic proteins, where it is conjugated with glucuronic acid and excreted into bile. The microsomal enzyme, uridine diphosphoglucuronosyl transferase, catalyses the formation of bilirubin monoglucuronide and then diglucuronide. This conjugated bilirubin is water-soluble; it is actively secreted into biliary canaliculi and excreted into the intestine within bile (see Fig. 16.5). It is not absorbed from the small intestine because of its large molecular size. In the terminal ileum, bacterial enzymes hydrolyse the molecule, releasing free bilirubin, which is then reduced to urobinogen; some of this is excreted in the stools as stercobilinogen. The remainder is absorbed by the terminal ileum, passes to the liver via the enterohepatic circulation, and is re-excreted into bile. Urobilinogen bound to albumin enters the circulation and is excreted in urine via the kidneys. When hepatic excretion of conjugated bilirubin is impaired, a small amount is strongly bound to serum albumin and is not excreted by the kidneys; it accounts for persisting hyperbilirubinaemia after cholestasis has resolved.

**Hormone and drug inactivation**

The liver catabolizes hormones such as insulin, glucagon, oestrogens, growth hormone, glucocorticoids and parathyroid hormone. It is also the prime target organ for many hormones (e.g. insulin). It is the major site for the metabolism of drugs (see p. 487) and alcohol (see pp. 217–218). Fat-soluble drugs are converted to water-soluble substances that facilitate their excretion in the bile or urine. Cholecalciferol is converted to 25-hydroxycholecalciferol.
**Immunological function**

The liver plays a key role in the innate immune response and acts as a ‘sieve’ for bacterial and other antigens carried to it by the portal vein from the gastrointestinal tract (see p. 468).

Hepatocytes are responsible for biosynthesis of 80–90% of innate immune proteins, including complement components and many secreted pattern-recognition receptors (PRRs) expressed by host cells. Kupffer cells (KCs), which account for 80–90% of the total population of fixed tissue macrophages, are a critical component of the mononuclear phagocytic system and are central to both the hepatic and the systemic responses to pathogens. Following stimulation by endotoxin, the Kupffer cells release interleukin (IL)-6, IL-8 and TNF-α, and, in combination with liver sinusoidal cells, are responsible for the elimination of molecular wastes from the body.

In addition, liver lymphocytes are rich in innate immune cells, including natural killer and T cell receptor γδ T cells. Finally, non-parenchymal liver cells express high levels of membrane-bound PRRs, such as Toll-like receptor cells (TLRs). Not only does innate immunity in the liver play a key role in host defence against microbial infection and tumour formation, but it also contributes to the pathogenesis of acute and chronic liver diseases, including alcoholic liver disease (see pp. 480–482).

**Clinical Approach to the Patient with Liver Disease**

**Investigations**

Investigative tests can be divided into:

- **Blood tests:**
  - Liver ‘function’ tests: serum albumin and bilirubin; prothrombin time (PT)
  - Liver biochemistry: serum aspartate (AST) and alanine aminotransferases (ALT) – an increase reflects hepatocellular damage; serum alkaline phosphatase (ALP) and gamma-glutamyl transpeptidase (γ-GT) – an increase reflects cholestasis; total protein.
  - Viral markers.
  - Additional blood investigations; haematological, biochemical, immunological, markers of liver fibrosis and genetic analysis.

- **Urine tests** – for bilirubin and urobilinogen.

- **Imaging techniques** – to define gross anatomy.

- **Liver biopsy** – for histology.
Blood tests ordered for ‘liver function’ are usually processed by an automated multichannel analyser to produce serum levels of bilirubin, aminotransferases, alkaline phosphatase, γ-GT and total proteins. These routine tests are markers of liver damage but not actual tests of ‘function’ per se. Subsequent investigations are often based on these tests.

Blood tests
Useful blood tests for certain liver diseases are shown in Box 14.1.

Liver function tests

Serum albumin
This is a marker of synthetic function and is useful for gauging the severity of chronic liver disease: a falling serum albumin is a bad prognostic sign. In acute liver disease, initial albumin levels may be normal. Interpretation of a low albumin can be difficult when other causes of hypoalbuminaemia (e.g. malnutrition, urinary protein loss or sepsis) are present.

Bilirubin
Serum bilirubin is normally almost all unconjugated. In liver disease, increased serum bilirubin is usually accompanied by other abnormalities in liver biochemistry. Differentiation
between conjugated or unconjugated bilirubin is only necessary in congenital disorders of bilirubin metabolism (see below) or to exclude haemolysis.

**Prothrombin time**

Prothrombin time (PT) is also a marker of synthetic function. Because of its short half-life, it is a sensitive indicator of both acute and chronic liver disease. Vitamin K deficiency should be excluded as the cause of a prolonged PT by giving an intravenous bolus (10 mg) of vitamin K. Vitamin K deficiency commonly occurs in biliary obstruction, as the low intestinal concentration of bile salts results in poor absorption of vitamin K.

Prothrombin times vary in different laboratories, depending upon the thromboplastin used in the assay. The International Normalized Ratio (INR) was developed to standardize anticoagulation with coumarin derivatives but is very variable in liver disease, and causes large differences when included in prognostic scores for cirrhosis across different centres. A rising INR in patients with liver disease that is not corrected by vitamin K is a poor prognostic sign.

**Liver biochemistry**

**Aminotransferases**

These enzymes (often referred to as transaminases) are contained in hepatocytes and leak into the blood with liver cell damage. Two enzymes are measured:

- **Aspartate aminotransferase** (AST) is primarily a mitochondrial enzyme (80%; 20% in cytoplasm) and is also present in heart, muscle, kidney and brain. High levels are seen in hepatic necrosis, myocardial infarction, muscle injury and congestive cardiac failure.

- **Alanine aminotransferase** (ALT) is a cytosol enzyme, more specific to the liver, so that a rise only occurs with liver disease.

  The ALT : AST ratio is a useful clinical indicator.
  - In viral hepatitis, ALT is greater than AST unless cirrhosis is present, in which case AST is greater than ALT.
  - In alcoholic liver disease and steatohepatitis, the AST is often greater than the ALT.
  - In patients with viral hepatitis, an AST : ALT ratio of more than 1 indicates cirrhosis.
  - In patients with liver disease without cirrhosis, in whom AST is greater than ALT, alcohol or obesity is the most likely aetiological agent.

**Alkaline phosphatase**

Alkaline phosphatase (ALP) is present in hepatic canalicular and sinusoidal membranes, and also in bone, intestine and placenta. If necessary, its origin can be determined by electrophoretic separation of isoenzymes or bone-specific monoclonal antibodies. In clinical practice, if the γ-GT is also abnormal, the ALP is presumed to come from the liver.

Serum ALP is raised in both intrahepatic and extrahepatic cholestatic disease of any cause,
due to increased synthesis. In cholestatic jaundice, levels may be 4–6 times the normal limit. Raised levels also occur with hepatic infiltrations (e.g. metastases) and in cirrhosis, frequently in the absence of jaundice. The highest serum levels due to liver disease (>1000 IU/L) are seen with hepatic metastases and PBC.

γ-Glutamyl transpeptidase

This is a microsomal enzyme present in liver, and also in many tissues. Its activity can be induced by many drugs such as phenytoin, warfarin and rifampicin, and by alcohol. If the ALP is normal, a raised serum γ-GT can be a useful guide to alcohol intake (see p. 921). However, mild elevations of γ-GT are common, even with minimal alcohol consumption, and it is also raised in fatty liver disease. In the absence of other liver function test abnormalities, a slightly raised γ-GT can safely be ignored. In cholestasis, the γ-GT rises in parallel with the ALP, as it has a similar pathway of excretion. This is also true of 5-nucleotidase, another microsomal enzyme that can be measured in blood.

Total proteins and globulin fraction

The globulin fraction is often raised in autoimmune hepatitis; if it falls, it indicates successful therapy.

Viral markers

Viruses are a major cause of liver disease. Virological studies have a key role in diagnosis; markers are available for most common viruses that cause hepatitis.

Additional blood investigations

Haematological tests

A full blood count may show thrombocytopenia. Thrombocytopenia is a common finding in cirrhosis and is often aggravated by alcohol-induced bone marrow suppression. A low platelet count (below the lower limit of normal – 150 × 10^9/L) should be regarded as indicative of cirrhosis, unless another cause can be found. In alcohol excess, red blood cells are often macrocytic.

Biochemical tests

• α₁-Antitrypsin enzyme deficiency can produce cirrhosis.

• α-Fetoprotein is normally produced by the fetal liver. Its reappearance in increasing and high concentrations in adults indicates hepatocellular carcinoma. Increased concentrations in pregnancy in blood and amniotic fluid suggest fetal neural tube defects. Blood levels are also slightly raised with regenerative liver tissue in patients with hepatitis, chronic liver disease and also teratomas.

• Urinary copper is raised, and serum copper and caeruloplasmin are low in Wilson's disease (see p. 479).
Immunological tests

Serum immunoglobulins
Increased γ-globulins are thought to result from reduced phagocytosis by sinusoidal and Kupffer cells of the gut-absorbed antigens. These antigens then stimulate antibody production in the spleen, lymph nodes and portal tract lymphoid and plasma cell infiltrates. In PBC, the predominant raised serum immunoglobulin is IgM, while in autoimmune hepatitis it is IgG. IgG4 is raised in autoimmune pancreatitis/cholangitis (see p. 506 and Box 8.12).

Serum autoantibodies
• *Anti-mitochondrial antibody (AMA)* in serum is found in over 95% of patients with PBC (see p. 475). Several different AMA subtypes are described, depending on their antigen specificity, and are also found in autoimmune hepatitis and other autoimmune diseases. AMA is demonstrated by an immunofluorescent technique and is neither organ- nor species-specific. The M2 subtype is specific for PBC.
• *Nucleic, smooth muscle (actin), liver/kidney microsomal antibodies* can be found in serum, often in high titre, in patients with autoimmune hepatitis. These serum antibodies are also present in other autoimmune conditions and other liver diseases.
• *Anti-nuclear cytoplasmic antibodies (ANCA)* can be found in the serum of patients with primary sclerosing cholangitis (see pp. 476–477).

Markers of liver fibrosis
Fibrosis plays a key role in the outcome of many chronic liver diseases, and accurate assessment of fibrosis is critical for the appropriate management of many liver disorders. A variety of different systems have been developed to assess the extent of liver fibrosis and these range from algorithms of varying degrees of complexity that use standard haematological and biochemical tests, to novel biomarkers. Simple algorithms include the APRI (aspartate aminotransferase to platelet ratio index) score, while more complex commercial tests include the fibrotest algorithm. Novel biomarker-based algorithms include those based on measurements of hyaluronic acid, procollagen III amino terminal peptide and tissue inhibitor of metalloproteinase I (TIMP-1), all combined in the enhanced liver fibrosis (ELF) test. In general, these markers have been developed for chronic hepatitis C but they are often successfully applied to other liver disorders. The current assays have a high sensitivity/specificity for the detection or absence of cirrhosis but are less effective at detecting intermediate levels of fibrosis. Combining mechanical non-invasive fibrosis tests, such as transient elastography (see p. 446), with fibrosis markers allows many patients to avoid a liver biopsy to assess fibrosis.

Genetic analysis
These tests are performed routinely for haemochromatosis (*HFE* gene) and for α1-antitrypsin
deficiency. Markers are also available for the most frequent abnormal genes in Wilson's disease (see p. 479).

Urine tests

*Dipstick tests* are available for *bilirubin* and *urobilinogen*. Bilirubinuria is due to the presence of conjugated (soluble) bilirubin; it is found in patients with jaundice due to hepatobiliary disease, but is absent if unconjugated bilirubin is the major cause of jaundice. The presence of urobilinogen in urine is of little value in practice but suggests haemolysis or hepatic dysfunction.

Imaging techniques

**Ultrasound examination**

This is a non-invasive, safe and relatively cheap technique. It involves the analysis of the reflected ultrasound beam detected by a probe moved across the abdomen. The normal liver appears as a relatively homogeneous structure. The gall bladder, common bile duct, pancreas, portal vein and other structures in the abdomen can be visualized. *Abdominal ultrasound is useful in:*

- Detection of extrahepatic obstruction (the bile duct is usually dilated, particularly in advanced disease). Note that opiates may cause biliary dilatation without obstruction, and so scans in injecting drug users often show extrahepatic biliary dilatation.
- Assessment of a jaundiced patient (to exclude obstruction) (see p. 450).
- Assessment of hepatomegaly/splenomegaly.
- Detection of gallstones (see *Fig. 15.2*).
- Assessment of focal liver disease – lesions >1 cm.
- Assessment of portal and hepatic vein patency.
- Assessment of the hepatic parenchyma – diffuse fatty infiltration often leads to a ‘bright’ appearance on ultrasound but experience is required to distinguish this from normal variation.
- Identification of cirrhosis – in advanced cirrhosis, the liver edge is irregular and the spleen is often enlarged. Note that a normal ultrasound does not exclude cirrhosis.
- Assessment of lymph node enlargement.

Other abdominal masses can be delineated and biopsies obtained under ultrasonic guidance.

**Colour Doppler ultrasound**

This will demonstrate vascularity within a lesion, and the direction of portal and hepatic vein blood flow.

**Ultrasound contrast agents**

These are mostly based on the production of microbubbles within flowing blood. They enhance
the detection of vascularity, allowing the detection of abnormal circulation within liver nodules, and giving a more specific diagnosis of hepatocellular carcinoma.

**Hepatic stiffness (transient elastography)**

Using an ultrasound transducer, a vibration of low frequency and amplitude is passed through the liver, the velocity of which correlates with hepatic stiffness. Stiffness (measured in kPa) increases with worsening liver fibrosis (sensitivity and specificity 80–95%, compared to liver biopsy). Elastography can reliably exclude cirrhosis and there is some evidence to show that, in cirrhosis, increasing liver stiffness is associated with a higher risk of complications. Elastography is less effective for determining lesser degrees of fibrosis but, particularly when combined with non-invasive fibrosis tests (see above), it can be used to exclude cirrhosis reliably. It cannot be employed in the presence of ascites and morbid obesity, and is affected by inflammatory tissue and congestion.

Acoustic radiation force impulse is incorporated into standard B mode ultrasonography and has similar physical principles to transient elastography.

**Computed tomography examination**

Computed tomography (CT), during or immediately after intravenous contrast, shows both arterial and portal venous phases of enhancement, enabling more precise characterization of a lesion and its vascular supply (*Fig. 14.6*). Retrospective analysis of data allows multiple overlapping slices to be obtained with no increase in the radiation dose, providing excellent visualization of the size, shape and density of the liver, pancreas, spleen, lymph nodes and lesions in the porta hepatis. Multiplanar and three-dimensional reconstruction in the arterial phase can create a CT angiogram, often making formal invasive angiography unnecessary. CT also provides guidance for biopsy. It has advantages over ultrasound in detecting calcification and is useful in obese subjects, although ultrasound is usually the imaging modality used first to investigate liver disease.
FIGURE 14.6 Use of contrast-enhanced spiral CT. A. Unenhanced. B. Arterial phase (note high-density contrast in the aorta (thick arrow)). There is an irregular mass (thin arrow) in the posterior aspect of the right lobe of the liver, which is only well seen on this early arterial phase enhanced scan. C. Portal venous phase scan through the right lobe of the liver.

Magnetic resonance imaging
Magnetic resonance imaging (MRI) produces cross-sectional images in any plane within the body and does not involve radiation. It is the most sensitive investigation for focal liver disease but can also assess fibrosis. Diffuse liver disease alters the T1 and T2 characteristics. Other fat-suppression modes, such as short T1 inversion recovery (STIR), allow good differentiation between haemangiomas and other lesions. Contrast agents such as intravenous gadolinium, which allow further characterization of lesions, are suitable for those with iodine allergy, and provide angiography and venography of the splanchnic circulation. Use of these agents has superseded direct arteriography.

Magnetic resonance cholangiopancreatography
Magnetic resonance cholangiopancreatography (MRCP) involves the manipulation of data acquired by MRI. A heavily T2-weighted sequence enhances visualization of the ‘water-filled’ bile ducts and pancreatic ducts to produce high-quality images of ductal anatomy. This non-invasive technique is replacing diagnostic (but not therapeutic) endoscopic retrograde cholangiopancreatography (see p. 501), and is usually the next test to be applied if a biliary abnormality is present on ultrasound examination.

Plain X-rays of the abdomen
These are rarely requested but may show:
- gallstones – 10% contain enough calcium to be seen
- air in the biliary tree owing to its recent instrumentation, surgery, or a fistula between the intestine and the gall bladder
- pancreatic calcification
- rarely, calcification of the gall bladder (porcelain gall bladder).

Radionuclide imaging – scintiscanning
In a $^{99m}$Tc-IODIDA scan, technetium-labelled iododiethyl IDA is taken up by the hepatocytes and excreted rapidly into the biliary system. Its main uses are in the diagnosis of:
- acute cholecystitis
- jaundice due to either biliary atresia or hepatitis in the neonatal period.

Endoscopy
Upper gastrointestinal endoscopy is used for diagnosis and treatment of varices, detection of portal hypertensive gastropathy, and for detection of associated lesions such as peptic ulcers.
Colonoscopy may show portal hypertensive colopathy. Capsule endoscopy can identify small intestinal varices.

**Endoscopic retrograde cholangiopancreatography**

Endoscopic retrograde cholangiopancreatography (ERCP) outlines the biliary and pancreatic ducts (see p. 501).

**Angiography**

This is performed by selective catheterization of the coeliac axis and hepatic artery. It outlines the hepatic vasculature and the abnormal vasculature of hepatic tumours, but spiral CT and MRI have replaced diagnostic angiography. The portal vein can be demonstrated with increased definition using subtraction techniques that have replaced splenoportography (by direct splenic puncture).

In *digital vascular imaging* (DVI), contrast given intravenously or intra-arterially can be detected in the portal system using computerized subtraction analysis.

*Hepatic venous cannulation* allows abnormal hepatic veins to be diagnosed in patients with Budd–Chiari syndrome and is also used to measure portal pressure indirectly. There is a 1:1 relationship of occluded (by balloon) hepatic venous pressure with portal pressure in patients with alcoholic or viral-related cirrhosis. The height of portal pressure has prognostic value for survival in cirrhosis: a difference of the occluded minus the free hepatic venous pressure (hepatic venous pressure gradient, HVPG) of 20% or more from baseline values, or <12 mmHg, has been associated with protection from rebleeding, and prevention of other complications of cirrhosis.

**Liver biopsy**

Histological examination of the liver is valuable in the differential diagnosis of diffuse or localized parenchymal disease and its severity. Liver biopsy can be performed on a day-case basis. The indications and contraindications are shown in *Box 14.2*. The mortality rate is less than 0.02% when the technique is performed by experienced operators.

---

**Box 14.2**

**Indications for and contraindications to liver biopsy**

**Diagnosis**

- Multiple parenchymal liver diseases
- Abnormal liver tests of unknown aetiology
- Fever of unknown origin
- Focal or diffuse abnormalities on imaging studies (rarely for HCC)
- Unexplained hepatomegaly
Drug-related liver disease
Post liver transplant

**Prognosis**
- Staging of known parenchymal liver disease, e.g. hepatitis B/C, NAFLD, PBC, AIH, PSC
- Haemochromatosis and alcohol-induced liver disease

**Management**
- Development of treatment plans based on histological analysis

**Usual contraindications to percutaneous needle biopsy**
- Uncooperative patient
- Prolonged INR (>1.5)*
- Platelets <60 × 10^9/L*
- Ascites
- Extrahepatic cholestasis

AIH, autoimmune hepatitis; HCC, hepatocellular carcinoma; INR, International Normalized Ratio; NAFLD, non-alcoholic fatty liver disease; PBC, primary biliary cholangitis; PSC, primary sclerosing cholangitis.

Liver biopsy guided by ultrasound or CT is performed under a local anaesthetic via a percutaneous approach in the right intercostal space. A transjugular approach is used when liver histology is essential for management but coagulation abnormalities or ascites prevent the percutaneous approach.

Most complications of liver biopsy occur within 24 hours (usually in the first 2 hours). They are often minor, and include abdominal or shoulder pain that settles with analgesics. Minor intraperitoneal bleeding can occur but this settles spontaneously. Rare complications include major intraperitoneal bleeding, haemothorax and pleurisy, biliary peritonitis, haemobilia and transient septicaemia. Haemobilia produces biliary colic, jaundice and melaena within 3 days of the biopsy.

**Further reading**

**Clinical features of liver disease**

**Symptoms**

**Acute liver disease**
This may be asymptomatic and anicteric. Symptomatic disease, often viral, produces malaise, anorexia and fever. Jaundice (see below) may appear as the illness progresses.

**Chronic liver disease**

Patients may be asymptomatic or experience non-specific symptoms, particularly weakness, anorexia and fatigue. Specific symptoms include:

- right hypochondrial pain due to liver distension
- abdominal distension due to ascites
- ankle swelling due to fluid retention
- haematemesis and melena from gastrointestinal haemorrhage
- pruritus due to cholestasis – often an early symptom of PBC
- gynaecomastia, loss of libido andamenorrhea due to endocrine dysfunction
- confusion and drowsiness due to neuropsychiatric complications (portosystemic encephalopathy).

**Signs**

**Acute liver disease**

There may be few signs, apart from jaundice and an enlarged liver. Jaundice is a yellow discoloration of the skin and mucous membranes, and is best seen in the conjunctivae and sclerae. In the cholestatic phase of the illness, pale stools and dark urine are present. Spider naevi and palmar erythema usually indicate chronic disease but can occur in severe acute disease.

**Chronic liver disease**

The physical signs are shown in *Figure 14.7*. However, physical examination is occasionally normal in patients with advanced chronic liver disease.
The skin
The chest and upper body may show **spider naevi**. These are telangiectases that consist of a central arteriole with radiating small vessels (resembling a spider's legs). They are found in the distribution of the superior vena cava and more than five are diagnostic. They may also occur in pregnancy.

In haemochromatosis, the skin may have a slate-grey appearance.

The hands may show **palmar erythema**, indicative of a hyperdynamic circulation; it is also seen in pregnancy, thyrotoxicosis or rheumatoid arthritis. Clubbing occasionally occurs, and a Dupuytren's contracture is often seen in alcoholic cirrhosis, though the association is with alcohol consumption rather than liver disease itself.

**Xanthomas** (cholesterol deposits) are seen in the palmar creases or above the eyes in PBC.

The abdomen
Initial hepatomegaly will be followed by a small liver in well-established cirrhosis. Splenomegaly occurs with portal hypertension.

The endocrine system
**Gynaecomastia** (occasionally unilateral) and testicular atrophy may be found in males.
Gynaecomastia is probably related to altered oestrogen metabolism, often combined with spironolactone treatment. Additional physical signs in decompensated cirrhosis are shown in Figure 14.7.

**Jaundice**

Jaundice (icterus) is detectable clinically when the serum bilirubin is >50 µmol/L (3 mg/dL). It may be divided into:

- **haemolytic jaundice** – increased bilirubin load for the liver cells
- **congenital hyperbilirubinaemias** – defects in conjugation
- **cholestatic jaundice** – including hepatocellular (parenchymal) liver disease and large duct obstruction.

### Haemolytic jaundice

The increased breakdown of red cells (see p. 521) leads to an increase in production of bilirubin. The resulting jaundice is usually mild (serum bilirubin of 68–102 µmol/L, or 4–6 mg/dL), as normal liver function can easily manage the increased bilirubin. Unconjugated bilirubin is not water-soluble and therefore does not pass into urine: hence ‘acholuric jaundice’. Urinary urobilinogen is increased.

The causes are those of haemolytic anaemia (pp. 531–533), and clinical features of anaemia, jaundice, splenomegaly, gallstones and leg ulcers may be seen.

Investigations show haemolysis (p. 532) and elevated unconjugated bilirubin, but normal serum ALP, transferases and albumin. Serum haptoglobulins are low.

### Congenital hyperbilirubinaemias (non-haemolytic)

**Unconjugated types**

**Gilbert syndrome**

This is the most common familial conjugated hyperbilirubinaemia and affects 2–7% of the population. It is asymptomatic and usually detected incidentally with a raised bilirubin (17–102 µmol/L, or 1–6 mg/dL). All other liver biochemistry is normal and there are no signs of liver disease. There is a family history of jaundice in 5–15% of patients. Most patients have reduced levels of UDP-glucuronosyl transferase (UGT-1) activity, the enzyme that conjugates bilirubin with glucuronic acid.

Mutations occur in the gene (UGT1A1 promoter region) encoding this enzyme, with an expanded nucleotide repeat consisting of two extra bases in the upstream 5′ promoter element. This abnormality appears to be necessary for the syndrome, but is not in itself sufficient for clinical manifestation (phenotypic expression).
Establishing the diagnosis is necessary to provide reassurance and prevent unnecessary investigations. The raised unconjugated bilirubin is diagnostic and rises on fasting and during mild illness. The reticulocyte count is normal, excluding haemolysis, and no treatment is necessary.

**Crigler–Najjar syndrome**

This is very rare. Only patients with type II (autosomal dominant) disease, with a decrease in rather than absence (type I – autosomal recessive) of UGT survive into adult life. Liver histology is normal. Transplantation is the only effective treatment.

Conjugated types

**Dubin–Johnson and Rotor syndromes**

Dubin–Johnson and Rotor syndromes (autosomal recessive) are due to defects in hepatic bilirubin handling. The prognosis is good in both. In the Dubin–Johnson syndrome, the liver is black owing to melanin deposition.

**Benign recurrent intrahepatic cholestasis**

This is rare and presents in early adulthood. Recurrent attacks of acute cholestasis occur without progression to chronic liver disease. Jaundice, severe pruritus, steatorrhoea and weight loss develop. Serum γ-GT is normal. Benign recurrent intrahepatic cholestasis may be associated with intrahepatic cholestasis of pregnancy (see p. 1304).

**Progressive familial intrahepatic cholestasis syndromes**

Progressive familial intrahepatic cholestasis (PFIC) syndromes are a heterogeneous group of autosomal recessive conditions defined by defective secretion of bile acids (see Figs 14.4 and 15.1).

- In **type 1** (PFIC1), with cholestasis in the first weeks of life, the γ-GT is normal.
- In **type 2** (PFIC2), there is frequently a non-specific giant cell hepatitis that progresses to cholestasis; again, γ-GT is normal.
- In **type 3** (PFIC3), deficient canalicular phosphatidylcholine transport and accumulation of toxic bile acids cause liver damage, which can lead to cirrhosis.

   Liver transplantation is the only cure for these syndromes.

**Cholestatic jaundice (acquired)**

This condition can be divided into extrahepatic and intrahepatic cholestasis. The causes are shown in *Figure 14.8*.

- **Extrahepatic cholestasis** is due to large duct obstruction of bile flow at any point in the biliary tract distal to the bile canaliculi.
• **Intrahepatic cholestasis** occurs because of failure of bile secretion, which may be caused by intrinsic defects in bile secretion or inflammation in the intrahepatic ducts.

**FIGURE 14.8** Causes of jaundice.

Clinically, in both types, there is jaundice with pale stools and dark urine, and the serum bilirubin is conjugated. However, intrahepatic and extrahepatic cholestatic jaundice must be differentiated, as their clinical management is entirely different.

### Differential diagnosis of jaundice

Jaundice may occur in previously healthy people who have an acute hepatic illness or may develop in patients with cirrhosis who have ‘decompensated’ (see p. 448). The management of decompensated cirrhosis is described on page 467 but all patients with jaundice should be questioned closely about risk factors for chronic liver disease to determine whether this is a true acute presentation rather than an ‘acute on chronic’ illness. The history often gives a clue to the diagnosis. Certain causes of jaundice are more likely in particular categories of people.

For example, a young person is more likely to have infectious hepatitis, so questions should be asked about drug and alcohol misuse, and sexual behaviour. An elderly person with gross weight loss is more likely to have a carcinoma. All patients may complain of malaise. Abdominal pain occurs in patients with biliary obstruction by gallstones, and sometimes with an enlarged liver there is pain resulting from distension of the capsule.

Questions should be appropriate to the particular situation, and the following aspects of the history should be covered:

• **Country of origin.** The incidence of hepatitis B virus (HBV) and hepatitis C virus (HCV) infection is increased in many parts of the world (see pp. 454–455).
• **Duration of illness.** A history of jaundice with prolonged weight loss in an older patient suggests malignancy. A short history, particularly with a prodromal illness of malaise, suggests an infectious hepatitis.

• **Recent outbreak of jaundice.** An outbreak in the community suggests hepatitis A virus (HAV).

• **Intravenous drug use, or recent injections or tattoos.** These all increase the chance of HBV and HCV infection.

• **Men having sex with men.** This increases the chance of HBV and HCV infection.

• **Female sex workers.** This increases the chance of HBV infection.

• **Medical treatment in the developing world.** There is an increased risk of HBV and HCV due to poorly sterilized equipment or administration of unscreened blood or blood products.

• **Alcohol consumption.** A history of drinking habits should be taken, although many patients often understate their consumption.

• **Drugs (particularly those taken in the previous 2–3 months).** Many drugs, including over-the-counter and herbal preparations, cause jaundice (see pp. 487–488).

• **Travel.** Certain areas have a high risk of hepatitis A virus (HAV) infection, as well as hepatitis E virus (HEV), but HAV is common in the UK and HEV is common in travellers to the Indian subcontinent.

• **Family history.** Patients with, for example, Gilbert's disease may have family members who experience recurrent jaundice.

• **Recent surgery.** Surgery on the biliary tract or for carcinoma is relevant.

• **Environment.** People engaged in recreational activities in rural areas, as well as farm and sewage workers, are at risk for leptospirosis, hepatitis E and exposure to chemicals.

• **Fevers or rigors.** These are suggestive of cholangitis or possibly a liver abscess.

### Clinical features

The signs of acute and chronic liver disease should be looked for (see pp. 447–448). Certain additional signs may be helpful:

• **Hepatomegaly.** A smooth, tender liver is seen in hepatitis and in extrahepatic obstruction, but a knobbly, irregular liver suggests metastases or cirrhosis. Causes of hepatomegaly are shown in **Box 14.3.**

### Box 14.3

**Causes of hepatomegaly**

**Apparent**
• Low-lying diaphragm
• Riedel's lobe
• Cirrhosis (early)

**Inflammation**
• Hepatitis
• Schistosomiasis
• Abscesses (pyogenic or amoebic)

**Cysts**
• Hydatid
• Polycystic

**Metabolic**
• Fatty liver
• Amyloid deposition
• Glycogen storage disease

**Haematological**
• Leukaemias
• Lymphoma
• Myeloproliferative disorders
• Thalassaemia

**Tumours**
• Primary and secondary carcinoma

**Venous congestion**
• Heart failure
• Constrictive pericarditis
• Hepatic vein occlusion

**Biliary obstruction**
• (Particularly extrahepatic)

**Splenomegaly.** This indicates portal hypertension when signs of chronic liver disease are present. The spleen can also be ‘tipped’ occasionally in viral hepatitis. In alcoholic cirrhosis, in particular, the spleen may not be grossly enlarged and may not be palpable

**Ascites.** This is found in cirrhosis but can also be due to other causes (see *Box 14.19*).
   A palpable gall bladder occurs with a carcinoma of the pancreas obstructing the bile duct.
Generalized lymphadenopathy suggests a lymphoma.

Cold sores are often seen with a herpes simplex virus hepatitis.

**Investigations**

Jaundice is not itself a diagnosis and the cause should always be sought. The two most useful tests are the **viral markers** for HAV, HBV and HCV, with an ultrasound examination. Liver biochemistry confirms the jaundice and may help in the diagnosis.

An **ultrasound examination** should always be performed to exclude an extrahepatic obstruction, and to diagnose any features compatible with chronic liver disease. Ultrasound will demonstrate:

- the size of the bile ducts, which are dilated in extrahepatic obstruction (**Fig. 14.9**)

![Liver ultrasound. A. Dilated intrahepatic bile ducts (arrowed). B. Common bile duct (arrowed). The normal bile duct measures 6 mm at the porta hepatis.](image)

- the level of the obstruction
- the cause of the obstruction in virtually all patients with tumours and in 75% of patients with gallstones.

The pathological diagnosis of any mass lesion can be made by fine-needle aspiration cytology (sensitivity approximately 60%) or by needle biopsy (sensitivity approximately 90%).

A flow diagram for the general investigation of the jaundiced patient is shown in **Figure 14.10**.
Liver biochemistry

In hepatitis, serum AST and ALT tend to be high early in the disease, with only a small rise in serum ALP. Conversely, in extrahepatic obstruction, the ALP is high, with a smaller rise in aminotransferases. However, these findings alone cannot be relied upon to make a diagnosis in an individual case. The prothrombin time is often prolonged in longstanding liver disease, and the serum albumin is also low.

Haematological tests

In haemolytic jaundice, the bilirubin is raised and the other liver biochemistry is normal. A raised white cell count may indicate infection (e.g. cholangitis). A leucopenia often occurs in viral hepatitis, while abnormal mononuclear cells suggest infectious mononucleosis and a Monospot test should be performed.

Other blood tests

These include tests to confirm the presence of specific causes of acute or chronic liver disease, e.g. anti-mitochondrial antibody (AMA) for PBC. HIV status should be established.

Hepatitis
• **Acute parenchymal liver damage** can be caused by many agents ([Fig. 14.11](#)).

![Figure 14.11](image)

**FIGURE 14.11** Some causes of acute parenchymal damage.

• **Chronic hepatitis** is defined as any hepatitis lasting for 6 months or longer and is classified according to the aetiology ([Box 14.4](#)). Chronic viral hepatitis is the principal cause of chronic liver disease, cirrhosis and hepatocellular carcinoma worldwide.

### Box 14.4

**Causes of chronic hepatitis**

- Metabolic:
  – Non-alcoholic fatty liver disease
- Alcohol-induced
- Viral:
  – Hepatitis B ± hepatitis D
  – Hepatitis C
  – Hepatitis E (immunosuppressed)
- Drugs:
  – (e.g. Methyldopa, isoniazid, ketoconazole, nitrofurantoin)
- Autoimmune
- Hereditary:
  – Wilson's disease, haemochromatosis.

**Unusual causes** include infections (syphilis, tuberculosis, various tropical infections), infiltrative diseases, including amyloidosis and lymphoma, and ingestion of toxins.
Acute hepatitis

Pathology

Although some histological features are suggestive of the aetiological factor, most changes are non-specific. Hepatocytes show degenerative changes (swelling, cytoplasmic granularity, vacuolation) and undergo necrosis (becoming shrunken, containing eosinophilic Councilman bodies). The distribution of these changes may vary with aetiology, but necrosis is usually maximal in zone 3. The extent of the damage is very variable between individuals, even when they are affected by the same agent; at one end of the spectrum, single and small groups of hepatocytes die (spotty or focal necrosis), while at the other end, there is multiacinar necrosis involving a substantial part of the liver (massive hepatic necrosis), resulting in acute hepatic failure. Between these extremes, there is limited confluent necrosis with collapse of the reticulin framework, leading to linking (bridging) between the central veins, between the central veins and portal tracts, and between the portal tracts. The extent of the inflammatory infiltrate is also variable, but portal tracts and lobules are infiltrated mainly by lymphocytes. Other variable features include cholestasis in zone 3 and fatty change, the latter being prominent in hepatitis that is due to alcohol or certain drugs.

Chronic hepatitis

Pathology

The pathological features are often diagnostic. Chronic inflammatory cell infiltrates, comprising lymphocytes, plasma cells and sometimes lymphoid follicles, are usually present in the portal tracts. The amount of inflammation varies from mild to severe. In addition, there may be:

- loss of definition of the portal/periportal limiting plate – interface hepatitis (damage is due to apoptosis rather than necrosis)
- lobular change, focal lytic necrosis, apoptosis and focal inflammation
- confluent necrosis
- fibrosis, which may be mild, bridging (across portal tracts) or severe cirrhosis.

The overall severity of the hepatitis is judged by the degree of hepatitis and inflammation (grading), and the severity of fibrosis or cirrhosis (staging). In chronic viral hepatitis, there are various scoring systems. For example, the Knodell Scoring System (histological activity index) uses the sum of four factors (periportal or bridging necrosis, intralobular degeneration and focal necrosis, portal inflammation and fibrosis). The Ishak score stages fibrosis from 0 (none) to 6 (cirrhosis). The METAVIR system has four stages. Scoring systems are used for drug trials and for assessing progression of disease, but are not quantitative measures of
fibrosis and different systems may be used for different diseases (for example, the \textit{Brunt scoring system} is usually applied to NAFLD, and the METAVIR system is reserved for hepatitis C).

\section*{Viral hepatitis}

The differing features of the common forms of viral hepatitis are summarized in \textit{Box 14.5}. Two different patterns are recognized: acute hepatitis with rapid onset of infection and, usually, rapid resolution; and chronic viral hepatitis, which is asymptomatic and often detected on routine blood tests or during screening for infection. Hepatitis A always and E usually cause acute infections whilst hepatitis B, C and D may cause acute or chronic disease.

*Chronic hepatitis in immunosuppressed patients.

HBsAg, hepatitis B surface antigen.

---

**Hepatitis A**

**Epidemiology**

Hepatitis A is the most common acute viral hepatitis occurring worldwide, often in epidemics. The disease is commonly seen in the autumn and affects children and young adults. Spread of infection is mainly by the faeco-oral route and arises from the ingestion of contaminated food or water (e.g. shellfish). Overcrowding and poor sanitation facilitate spread. There is no carrier state. In the UK, it is a notifiable disease.
Hepatitis A virus (HAV)

Hepatitis A virus (HAV) is a picornavirus, having the structure shown in Figure 14.12. It has a single serotype, as only one epitope is immunodominant. It replicates in the liver, is excreted in bile, and then excreted in the faeces for about 2 weeks before the onset of clinical illness and for up to 7 days after. The disease is maximally infectious just before the onset of jaundice. HAV particles can be demonstrated in the faeces by electron microscopy.

**FIGURE 14.12** Hepatitis A. A. The hepatitis A (HAV) virion consists of four polypeptides (VP1–VP4), which form a tight protein shell, or capsid, containing the RNA. The major antigenic component is associated with VP1. B. Arrangement of the HAV genome.

**Clinical features**

The viraemia causes the patient to feel unwell, with non-specific symptoms that include nausea and anorexia. Many recover at this stage and remain anicteric. An anicteric infection is common in children and leads to lifetime immunity. In the developing world, improvements in hygiene have reduced early infection and, paradoxically, led to an increase in symptomatic
infection in exposed adults.

After 1 or 2 weeks, some patients become jaundiced and symptoms often improve. Persistence of nausea, vomiting or any mental confusion warrants assessment in hospital. As the jaundice deepens, the urine becomes dark and the stools pale, owing to intrahepatic cholestasis. The liver is moderately enlarged and the spleen is palpable in about 10% of patients. Occasionally, tender lymphadenopathy is seen, with a transient rash in some cases. Thereafter, the jaundice lessens and, in the majority of cases, the illness is over within 3–6 weeks. Extrahepatic complications are rare but include arthritis, vasculitis, myocarditis and acute kidney injury. A biphasic illness occasionally occurs, with the return of jaundice and, classically, a more severe ‘second phase’, which is cholestatic (cholestatic viral hepatitis) with an increase in the alkaline phosphatase rather than the aminotransferases; thus, it runs a prolonged course of 7–20 weeks. Rarely, the disease may be very severe with acute hepatitis, liver coma and death; this is more common in the elderly. The typical sequence of events after HAV exposure is shown in Figure 14.13.

![Figure 14.13](image)

**FIGURE 14.13**  Hepatitis A virus (HAV): sequence of events after exposure. ALT, alanine aminotransferase; Ig, immunoglobulin.

**Investigations**

**Liver biochemistry**

- **Prodromal stage**: The serum bilirubin is usually normal. However, there is bilirubinuria and increased urinary urobilinogen. A raised serum AST or ALT, which can sometimes be very high, precedes the jaundice.

- **Icteric stage**: The serum bilirubin reflects the level of jaundice. Serum AST reaches a
maximum 1–2 days after the appearance of jaundice, and may rise above 500 IU/L. Serum ALP is usually less than 300 IU/L.

After the jaundice has subsided, the aminotransferases may remain elevated for some weeks and occasionally for up to 6 months.

Haematological tests
There is leucopenia with a relative lymphocytosis. Very rarely, there is a Coombs'-positive haemolytic anaemia or an associated aplastic anaemia. The prothrombin time is prolonged in severe cases. The erythrocyte sedimentation rate (ESR) is raised.

Viral markers: antibodies to HAV
IgG antibodies are common in the general population over the age of 50 years, but an anti-HAV IgM means an acute infection. In areas of high prevalence, most children have antibodies by the age of 3 years following asymptomatic infection.

Other tests
Further tests are not necessary in the presence of an IgM antibody, but liver biochemistry must be followed to establish a return to normal levels.

Differential diagnosis
Differentiation must be made from all other causes of jaundice, but in particular from other types of viral and drug-induced hepatitis.

Prognosis
The prognosis is excellent, with most patients making a complete recovery. The mortality in young adults is 0.1% but increases with age. Death is due to acute hepatic necrosis. During convalescence, 5–15% of patients may suffer a relapse of the hepatitis but this settles spontaneously.

There is no reason to stop alcohol consumption, other than for the few weeks when the patient is ill. Patients may complain of debility for several months following resolution of the symptoms and biochemical parameters. This is known as the post-hepatitis syndrome and treatment is by reassurance. HAV hepatitis never progresses to chronic liver disease.

Management
There is no specific treatment, and rest and dietary measures are unhelpful. Corticosteroids have no benefit. Admission to hospital is not usually necessary.

Prevention
Control of hepatitis depends on good hygiene. The virus is resistant to chlorination but is killed by boiling water for 10 minutes.

**Active immunization**

A formaldehyde-inactivated HAV vaccine is given to people travelling frequently to endemic areas, patients with chronic liver disease, those with haemophilia, and workers in frequent contact with hepatitis cases (e.g. in residential institutions for patients with learning difficulties). Community outbreaks can be interrupted by vaccination. A single dose produces antibodies that persist for at least 1 year, with immunity lasting beyond 10 years. This obviates the need for a booster injection in healthy individuals.

**Passive immunization**

Normal human immunoglobulin (0.02 mL/kg i.m.) is used if exposure to HAV is <2 weeks. HAV vaccine should also be given.

---

**Hepatitis B**

**Epidemiology**

The hepatitis B virus (HBV) is present worldwide and there are an estimated 220 million carriers. The UK and the USA have a low carrier rate (0.5–2%), but this rises to 10–20% in parts of Africa and the Middle and Far East.

*Vertical transmission* from mother to child, *in utero*, during parturition or soon after birth, is the usual means of transmission worldwide, although in Africa transmission from other infected children is very common during the early childhood years. HBV is not transmitted by breast-feeding.

*Horizontal transmission* occurs, particularly in children, through minor abrasions or close contact with other children, and HBV can survive on household articles, such as toys or toothbrushes, for prolonged periods. Childhood chronic HBV is associated with very high levels of viral replication (up to $10^{10}$ IU/mL), ensuring that high levels of virus are present in minute amounts of blood and thus facilitating viral spread.

HBV spread also occurs by the intravenous route (e.g. by transfusion of infected blood or blood products, or by contaminated needles used by drug users, tattooists or acupuncturists) or by close personal contact, such as during sexual intercourse, particularly in men who have sex with men. The virus can be found in semen and saliva.

**Hepatitis B virus**

The complete infective virion or Dane particle is a 42 nm particle comprising an inner core or nucleocapsid (27 nm), surrounded by an outer envelope of surface protein (hepatitis B surface antigen, HBsAg). This surface coat is produced in excess by the infected hepatocytes and can exist separately from the whole virion in serum and body fluid as 22 nm particles or tubules.
The hepatitis B virus (HBV) genome is variable, and genetic sequencing can be used to define the different HBV genotypes, A to H. There is a strong correlation between genotypes and geographical areas. **Genotype A** is found in north-west Europe, North America and Central Africa; **B** in South-east Asia (including China, Taiwan and Japan); genotype **C** in South-east Asia; **D** in southern Europe, India and the Middle East; **E** in West Africa; **F** in South and Central America, in American Indians and in Polynesia; **G** in France and the USA; and **H** in Central and South America. These genotypes may influence the chance of responding to interferon treatment (A more than B; C more than D) but all genotypes respond equally well to nucleoside analogues.

The core or nucleocapsid is formed of core protein (HBcAg), containing incompletely double-stranded circular DNA and DNA polymerase/reverse transcriptase. One strand is almost a complete circle and contains overlapping genes that encode both structural proteins (pre-S, surface (S), core (C)) and replicative proteins (polymerase and X). The other strand is variable in length. DR1 and DR2 are direct repeats necessary for HBV synthesis during viral replication (**Fig. 14.14**).

**FIGURE 14.14** Hepatitis B virus (HBV) genome. The viral DNA is partially double-stranded (red incomplete circle and blue circle). The long strand (blue) encodes seven proteins from four overlapping reading frames (S, surface (Pre-S1, Pre-S2, S); c, core (Pre-C, C); P, polymerase (P); and X gene (X)). EcoRI restriction-enzyme-binding site is included as a reference point. DR, direct repeat; HBsAg, hepatitis B surface antigen.

HBeAg is a protein formed via specific self-cleavage of the pre-core/core gene product, which is secreted separately by the cell.

**Hepatitis B mutants**
Mutations occur in the various reading frames of the HBV genome (**Fig. 14.14**). These mutants
can emerge in patients with chronic HBV infection (escape mutants) or can be acquired by infection.

**HBsAg mutants** are produced by alterations in the ‘a’ antigenic determinants of the HbsAg proteins, usually with a substitution of glycine for arginine at position 145. This results in changes in the antibody-binding domain and may confer resistance to the vaccine.

In patients with some HBV genotypes (particularly genotype D), a mutation in the **pre-core region**, when a guanosine (G) to adenosine (A) change creates a stop codon (TAG), prevents the production of HBeAg (the secreted form of HbcAg), but the synthesis of HbcAg is unaffected. This mutation may be associated with HBeAg-negative disease but other mutations in the core promoter region of the virus also give rise to HBeAg-negative disease. To detect infectivity in HBeAg-negative disease, HBV DNA must always be measured, as no eAg will be present.

**DNA polymerase mutants** occur, particularly following treatment with the first generation of directly acting antiviral drugs, such as lamivudine.

#### Pathogenesis

**Pre-S\textsubscript{1} and pre-S\textsubscript{2} regions** are involved in attachment to the hepatocyte receptor, recently identified as the sodium taurocholate co-transporting polypeptide (NTCP). After penetration into the cell, the virus loses its coat and the virus core is transported to the nucleus without processing. The transcription of HBV into messenger RNA takes place when the HBV DNA is converted into a closed circular form (cccDNA), which acts as a template for RNA transcription.

**Translation into HBV proteins (Box 14.6)**, as well as replication of the genome, takes place in the endoplasmic reticulum; the proteins are then packaged together and exported from the cell. There is an excess production of non-infective HBsAg particles, which are extruded into the circulation.
The HBV is not usually directly cytopathic (although high replication levels in immunosuppressed individuals can lead to direct toxicity) and liver damage is produced by the host immune response.

HBV-specific cytotoxic CD8 T cells recognize the viral antigen via human leucocyte antigen (HLA) class I molecules on the infected hepatocytes. However, suppressor or regulatory T cells inhibit these cytotoxic cells, leading to viral persistence and chronic HBV infection. Th1 responses (IL-2, γ-interferon) are thought to be associated with viral clearance, and Th2 (IL-4, 5, 6, 10, 13) responses with the development of chronic infection and disease severity. Viral persistence in patients with a very poor cell-mediated response leads to an asymptomatic, inactive, chronic HBV infective state. However, a better response results in continuing hepatocellular damage, with the development of chronic hepatitis.

Chronic HBV infection progresses through a series of four distinct phases (Fig. 14.15).

- **Immunotolerant phase.** The natural history of childhood-acquired HBV is shown in the figure. In this first early phase, high-level viral replication, with HBeAg, is not associated with an immune response and hence there is no damage to hepatocytes. Management is not indicated but close follow-up is required. This phase matures into the next adolescent phase.

- **Immunoactive phase.** During adolescence, an immune response develops, leading to liver damage with fluctuating raised transferases (ALT) in the presence of high levels of HBeAg-positive infection. In some patients, this disease phase will progress to cirrhosis and therapy is therefore indicated to reduce the development of fibrosis. Management in this phase may lead to seroconversion from HBeAg-positive to HBeAg-negative.

- **Immunosurveillance phase.** In many, the immunoactive phase is followed by a period of immune control (the ‘inactive carrier’ phase), when host immune responses suppress viral replication, leading to low-level HBV DNA (<2000 IU/mL), absence of HBeAg and normal ALTs. In some patients, the virus is eventually cleared with the loss of HBsAg.

- **Immunoescape phase.** A proportion of patients with inactive HBV will reactivate their disease as they age, and this final phase of disease is characterized by high-level viral replication (HBV DNA $10^5/10^6$) but negative HBeAg and raised ALT. Note that, in this phase, fluctuating ALT levels may lead to a misdiagnosis and so the liver function tests and HBV DNA should be tested four times a year to establish the diagnosis in patients who are HBeAg-
FIGURE 14.15 Natural history of childhood-acquired hepatitis B virus (HBV). Immunotolerant phase: Early disease is characterized by high-level viraemia with HBeAg (the secreted form of HBCAg) and a minimal immune response, leading to no significant liver damage. Immunoactive phase: Fluctuating liver function tests (ALTs) and ongoing liver damage that may lead to cirrhosis. Treatment in this phase may lead to seroconversion. In many, the immunoactive phase is followed by a period of immune control (the ‘inactive carrier’ phase), when host immune responses suppress viral replication, leading to low-level HBV DNA (<2000 IU/mL), absence of HBeAg and normal ALTs. In some patients, the virus is eventually cleared, with the loss of HBsAg; in many, however, viral reactivation occurs with viral mutations, leading to HBeAg-negative disease with high levels of viral replication (HBV DNA $10^9$-$10^{10}$) and alanine aminotransferase (ALT) in the absence of HBeAg. Note that, in this phase, fluctuating ALTs may lead to misdiagnosis, and so the ALTs and HBV DNA should be tested four times a year to establish the diagnosis in patients who are HBeAg-negative.

This disease phase is often associated with viral mutations (see above). Therapy for HBeAg-negative disease is indicated to prevent disease progression.

Hepatocellular carcinoma (HCC) can develop in patients at all stages of disease but is more common in those with high levels of HBV DNA.

Immunosuppression, such as occurs during chemotherapy, aggravates all phases of HBV and a particular problem is seen in patients with HBeAg-negative, inactive disease, where the presence of normal liver biochemistry provides a false sense of security. HBV reactivation is common in such patients and has a high mortality. It is essential that all patients who are due to receive chemotherapy are screened for HBsAg, and those who have chronic HBV should receive prophylactic antiviral therapy, such as tenofovir or entecavir.

Clinical features of acute hepatitis B infection

The sequence of events following acute HBV infection is shown in Figure 14.16. However, in
many, the infection is subclinical. When HBV infection is acquired perinatally, an acute hepatitis does not usually occur and chronic infection develops. In adults, an acute infection is common and the virus is cleared in approximately 99% of patients. The clinical picture is the same as that found in HAV infection, although the illness may be more severe. In addition, a serum sickness-like immunological syndrome may be seen. This consists of rashes (e.g. urticaria or a maculopapular rash) and polyarthritis affecting small joints occurring in up to 25% of cases in the prodromal period. Fever is usual. Extrahepatic immune complex-mediated conditions, such as an arteritis or glomerulonephritis, are occasionally seen.

**Investigations**

These are generally the same as for hepatitis A.

**Specific tests**

The markers for HBV are shown in Box 14.7. HBsAg is looked for initially; if it is found, a full viral profile is then performed. In acute infection, as HBsAg may be cleared rapidly and anti-HBc IgM is diagnostic, patients must be tested for both HBsAg and anti-core antibodies if HBV is suspected. HBV DNA is the most sensitive index of viral replication.

**Box 14.7**

**Significance of viral markers in hepatitis B**
### Prognosis

The majority of patients recover completely, acute hepatic failure occurring in up to 1%. Some patients go on to develop chronic hepatitis and the outcome depends upon several factors, chiefly the age of the patient.

### Management of acute hepatitis

This is mainly symptomatic. However, patients should have their HBV markers monitored. Several experts suggest that entecavir or tenofovir should be given for the persistent presence of HbeAg beyond 12 weeks, and in some patients who are very ill.

### Prevention

Prevention depends on vaccination. In countries that do not vaccinate all citizens, prevention depends upon avoiding risk factors (see above). These include not sharing needles and having safe sex. Vertical transmission is discussed below. Infectivity is highest in those with the e antigen and/or HBV DNA in their blood.

### Immunization

Vaccination is obligatory in most developed countries (but not the UK), as well as countries with high endemicity. Vaccination has been shown to reduce mortality and morbidity. In countries that do not have a universal vaccination policy, groups at high risk are vaccinated. These include all healthcare personnel; members of emergency and rescue teams; morticians and embalmers; children in high-risk areas; people with haemophilia; patients in some

psychiatric units; patients with chronic kidney disease/on dialysis units; long-term travellers; men who have sex with men, bisexual men and sex workers; and intravenous drug users.

Active and passive (combined) prophylaxis with vaccination and immunoglobulin should be given to: healthcare staff with accidental needlestick injury; all newborn babies of HBsAg-positive mothers; and regular sexual partners of HBsAg-positive patients who have been found to be HBV-negative.

For adults, a dose of 500 IU of specific hepatitis B immunoglobulin (HBIG) (200 IU to newborns) is given; the vaccine (i.m.) is given at another site.

**Active immunization**
This is with a recombinant yeast vaccine, produced by insertion of a plasmid containing the gene of HBsAg into a yeast.

**Dosage regimen**
Three injections (at 0, 1 and 6 months) are given into the deltoid muscle; this gives short-term protection in over 90% of patients. People who are over 50 years of age or clinically ill and/or immunocompromised (including those with human immunodeficiency virus (HIV) infection or acquired immunodeficiency syndrome (AIDS)), have a poor antibody response; more frequent and larger doses are required. Antibody levels should be measured at 7–9 months after the initial dose in all at-risk groups. Antibody levels fall steadily after vaccination, and booster doses may be required after approximately 3–5 years. It is not cost-effective to check antibody levels prior to active immunization. There are few side-effects from the vaccine.

**Chronic hepatitis B virus infection**
Following an acute HBV infection, which may be subclinical, approximately 1–10% of patients will not clear the virus and will develop a chronic HBV infection. The features are described on pages 455–456.

**Investigations**
These may show a moderate rise in aminotransferases but infection with normal aminotransferases is common. The serum bilirubin is often normal. HBsAg and HBV DNA are found in the serum, sometimes with HBeAg.

**Histologically**, there is a full spectrum of changes, from near-normal with only a few lymphocytes and interface hepatitis to a full-blown cirrhosis. HBsAg may lend a ‘ground-glass’ appearance to the cytoplasm on haematoxylin and eosin staining, and this can be confirmed on orcein staining or, more specifically, with immunohistochemical staining. HBcAg can also be demonstrated in hepatocytes by appropriate immunohistochemical staining.

**Management of chronic hepatitis B**
**Indications** for therapy are similar for HBeAg-positive and negative patients with chronic hepatitis. **Three criteria** are used: serum HBV DNA levels, serum ALT levels and histological grade and stage:

- **Patients with moderate to severe active necroinflammation** and/or fibrosis in the liver biopsy, with HBV DNA above 2000 IU/mL (approximately 10 000 copies/mL) and/or ALT above the upper limit of normal are usually offered therapy. Age and co-morbidities also affect the decision to treat and the choice of agents.

- **If cirrhosis is present**, treatment should be given, independent of ALT or HBV DNA levels. Patients with decompensated cirrhosis can also be treated with oral antiviral agents, but liver transplantation may be required.

All patients, regardless of disease phase, need long-term follow-up, as transition to an active phase is common; the lifetime risk of malignancy is increased in all patients who are HBsAg-positive.

**Aim of therapy**
This is to prevent disease progression and, ideally, to eliminate HBsAg.

- **Interferon** is an immunostimulator that induces an immune response, leading to prolonged remission after discontinuation of therapy.

- **Oral nucleotides** suppress viral replication and are used for prolonged periods of time.

  In patients receiving long-term oral antiviral agents, liver fibrosis regresses. Even those patients with cirrhosis may recover, and the liver may remodel and lose all traces of fibrosis.

**Antiviral agents**

*Interferon, entecavir* and *tenofovir* are the most commonly used drugs.

*Pegylated interferon-alfa-2a* (180 µg once a week s.c.) is most often used in patients who are HBeAg-positive with active disease. Some patients (25–45%, depending on genotype – A and B respond best) lose HBeAg and move to the ‘inactive’ HBeAg-negative phase of disease. A proportion then goes on to lose HBsAg some years after treatment discontinuation. Patients with higher serum aminotransferase values (three times the upper limit of normal), who are younger, with viral loads <10^7 IU/mL, respond best to treatment. Patients with concomitant HIV respond poorly and those with cirrhosis should not receive interferon. Response can be assessed during therapy by measuring the serum levels of HBsAg: if these fall after 3 months, then a favourable outcome is likely, and most doctors stop therapy after 3 months if the HBsAg level remains unchanged. In patients with HBeAg-negative HBV, pegylated interferon-alfa-2a is increasingly used, as it offers a finite duration of therapy. A proportion of patients with active disease (high ALT, increased HBV DNA) convert to inactive disease, and response can be assessed by an early decline in HBsAg.

**Side-effects** of treatment include an acute influenza-like illness occurring 6–8 hours after the first injection. This usually disappears after subsequent injections but malaise, headaches and myalgia are common; depression, reversible hair loss and bone marrow depression and
infection may also occur.

Oral antiviral therapy for HBV (entecavir, tenofovir and lamivudine) is very effective and almost all compliant patients respond with a decrease in HBV DNA to undetectable levels and a reduction in liver inflammation (Box 14.8). Both HBeAg-positive and HBeAg-negative patients respond equally well. Long-term viral suppression has been shown to reverse fibrosis, and even patients with cirrhosis respond with reversion of fibrosis. Resistance is rarely seen with third-generation drugs, and older, more resistance-prone drugs, like lamivudine, are no longer recommended. A small proportion of patients develop an immune response leading to loss of HBeAg and, very rarely, loss of HBsAg. However, the majority of patients who commence oral antiviral agents will require very prolonged treatment, perhaps life-long. Studies to determine whether antiviral therapy can ever be safely discontinued are in progress. Entecavir and tenofovir are the drugs of choice for HBV, and both agents are associated with very few side-effects and an excellent response. Combination therapy has little benefit and a single drug should be used.

### Box 14.8

**Factors predictive of a sustained response to treatment in chronic hepatitis B**

#### Duration of disease
- Short

#### Liver biochemistry
- High serum aminotransferases

#### Histology
- Active liver disease (mild to moderate)

#### Viral levels
- Low HBV DNA levels

#### Other
- Absence of immunosuppression
- Female gender
- Adult-acquired
- Delta virus negative
- Rapidity of response to oral therapy

### Prognosis
The clinical course of hepatitis B is very variable; treatments have improved survival, stopped progression of fibrosis and enabled regression of fibrosis to occur. Established cirrhosis is associated with a poor prognosis. Hepatocellular carcinoma (HCC) is a frequent association and is one of the most common carcinomas in HBV-endemic areas such as the Far East. Surveillance for HCC must continue, even when HBV DNA is negative in patients who have HBsAg and are not treated, and also in these rendered negative by therapy. The incidence of HCC is being reduced by routine HBV vaccination of all children.

Hepatitis D

This is caused by the hepatitis D virus (HDV or delta virus), which is an incomplete RNA particle enclosed in a shell of HBsAg; it belongs to the Deltaviridae family. The virus is unable to replicate on its own but is activated by the presence of HBV. It is common in some parts of the world, including Eastern Europe (Romania, Bulgaria), North Africa and the Brazilian rainforest. Hepatitis D viral infection can occur either as a co-infection or as a superinfection.

• Co-infection of HDV and HBV is clinically indistinguishable from an acute icteric HBV infection, but a biphasic rise of serum aminotransferases may be seen. Diagnosis is confirmed by finding serum IgM anti-HDV in the presence of IgM anti-HBc. IgM anti-delta appears at 1 week and disappears by 5–6 weeks (occasionally 12 weeks), when serum IgG anti-delta is seen. The HDV RNA is an early marker of infection. The infection may be transient but the clinical course is variable.

• Superinfection results in an acute flare-up of previously quiescent chronic HBV infection. A rise in serum AST or ALT may be the only indication of infection. Diagnosis is made by finding HDV RNA or serum IgM anti-HDV at the same time as IgG anti-HBc. Active HBV DNA synthesis is reduced by delta superinfection and patients are usually negative for HBeAg with low HBV DNA.

Acute hepatic failure can follow both types of infection but is more common after co-infection. HDV RNA in the serum and liver can be measured and is found in acute and chronic HDV infection.

Chronic hepatitis D

This is a relatively infrequent chronic hepatitis, but spontaneous resolution is rare. Between 60% and 70% of patients will develop cirrhosis, and more rapidly than with HBV infection alone. In 15%, the disease is rapidly progressive, with development of cirrhosis in only a few years. The diagnosis is made by finding anti-delta antibody in a patient with chronic liver disease who is HBsAg-positive. It can be confirmed by finding HDV in the liver or HDV RNA in the serum by reverse transcription polymerase chain reaction (PCR).
Management

Treatment of patients with active liver disease (raised ALT levels and/or inflammation on biopsy) is with pegylated interferon-alfa-2a for 12 months, although response rates are very low.

Hepatitis C

Epidemiology

An estimated 240 million people are infected with this virus worldwide. The prevalence rate of infection ranges from 0.4% in Europe, 1–3% in Southern Europe (possibly linked to intramuscular injections of vaccines or other medicines) and 6% in Africa; in Egypt, the rates are as high as 19% owing to parenteral antimony treatment for schistosomiasis. The virus is transmitted by blood and blood products, and was common in people with haemophilia treated before screening of blood products was introduced. The incidence in intravenous drug users is high (50–60%). The low rate of hepatitis C virus infection in high-risk groups – such as men who have sex with men, sex workers and attendees at sexually transmitted infection clinics – suggests a limited role for sexual transmission. Vertical transmission from a healthy mother to child can occur but is rare (approximately 5%). Other routes of community-acquired infection (e.g. close contact) are extremely rare. In 20% of cases, the exact mode of transmission is unknown.

Hepatitis C virus (HCV)

Hepatitis C virus (HCV) is a single-stranded RNA virus of the Flaviviridae family. The RNA genome is approximately 10 kb in length, encoding a polyprotein product consisting of structural (capsid and envelope) and non-structural viral proteins (Fig. 14.17). Comparisons of subgenomic regions, such as E1, NS4 or NS5, have allowed variants to be classified into six genotypes, which have differing geographical distributions. Variability is distributed throughout the genome, with the non-structural gene of different genotypes showing 30–50% nucleotide sequence disparity. Genotypes 1a and 1b account for 70% of cases in the USA and 50% in Europe. There is a rapid change in envelope proteins, making it difficult to develop a vaccine. Antigens from the nucleocapsid regions have been used to develop enzyme-linked immunosorbent assays (ELISAs). The current assay, ELISA-3, incorporates antigens NS3, NS4 and NS5 regions.
Clinical features

Most acute infections are asymptomatic, about 10% of patients having a mild influenza-like illness with jaundice and a rise in serum aminotransferases. Most patients will not be diagnosed until they present, years later, with evidence of abnormal transferase values at health checks or with chronic liver disease.

Investigations

This is by evaluation of HCV, RNA and HCV antibodies; HCV RNA can be detected from 1 to 8 weeks after infection. Anti-HCV tests are usually positive 8 weeks from infection. Patients with acute HCV infection should be tested on several occasions, as many have fluctuating viraemia during the first few months of infection, with periods of undetectable HCV RNA followed by virological relapse. Viral clearance is confirmed by multiple tests for HCV RNA over a period of many months.

Management

In acute infection, most experts recommend a period of monitoring for a few weeks with serial assessments of HCV RNA. If the viral load is falling, treatment may not be required, but the patient should be observed for several months to confirm true viral clearance. If the HCV RNA level does not decline, then therapy with interferon (with or without ribavirin) is indicated. Needle-stick injuries must be followed and treated early, although the vast majority (>97%) do not go on to develop viraemia. For treatment of patients with co-infection with HIV, see p. 351.
Prognosis

Some 85–90% of asymptomatic patients develop chronic liver disease. A higher percentage of symptomatic patients ‘clear’ the virus, with only 48–75% going on to chronic liver disease (see pp. 447–448).

Chronic hepatitis C infection

Pathogenesis

As with hepatitis B infection, cytokines in the Th2 phenotypes are profibrotic and cause the development of chronic infection. A dominant CD4 Th2 response, with a weak CD8 interferon-gamma response, may lead to rapid fibrosis. Th1 cytokines are antifibrotic and thus a dominant CD4 Th1 and CD8 cytolytic response may cause less fibrosis.

Clinical features

Patients with chronic HCV infection are usually asymptomatic, the disease only being discovered following a routine biochemical test when mild elevations in the aminotransferases (usually ALT) are noticed (50%). The elevation in ALT may be minimal and fluctuating (Fig. 14.18), and some patients have a persistently normal ALT (25%), the disease being detected by checking HCV antibodies (e.g. in blood donors). Non-specific malaise and fatigue are common in chronic infection and often reverse following viral clearance. Extrahepatic manifestations are seen, including arthritis, cryoglobulinaemia with or without glomerulonephritis, and porphyria cutanea tarda. There is a higher incidence of diabetes, and associations with lichen planus, sicca syndrome and non-Hodgkin's lymphoma.
Chronic HCV infection causes slowly progressive fibrosis that leads, over decades, to cirrhosis. After 20 years of infection, 16% of patients have developed cirrhosis; the proportion that will ultimately develop cirrhosis after a lifetime of infection remains unknown but is likely to be higher than the proportions reported after short-term follow-up. Factors associated with rapid progression of HCV fibrosis include excess alcohol consumption, co-infection with HIV, obesity, diabetes and infection with genotype 3. Once cirrhosis has developed, some 3–4% per year will develop decompensated cirrhosis and approximately 1% will develop liver cancer. Unlike HBV infection, HCV does not cause liver cancer in the absence of cirrhosis. In most parts of the world, HCV was spread (either by injection drug use, or by poorly sterilized medical devices) in the 1970s. Given the slow development of cirrhosis, current mathematical models of disease burden predict a massive increase in HCV-related end-stage liver disease over the next decade.

**Investigations**

Diagnosis is made by finding HCV antibody in the serum using third-generation ELISA-3 tests. A small proportion of patients with spontaneous clearance will have undetectable HCV RNA in the serum (measured by PCR) but most individuals who are antibody-positive will be viraemic. The level of viraemia varies from a few thousand to many millions of viral copies per millilitre, although current practice is to present viral load measurements in international units (IU). Disease progression is not influenced by the viral load, but treatment outcome is modified in those with high levels of viraemia.

The HCV genotype should be characterized in patients who are to be given treatment (see below), and assessment of fibrosis (by either liver biopsy or non-invasive methods) is required in patients who would prefer to defer therapy. Cirrhosis should be excluded in all patients who have been infected for more than 20 years and a liver biopsy or non-invasive marker should be used.
Management

The aim of treatment is to eliminate the HCV RNA from the serum in order to:

• stop the progression of active liver disease
• prevent the development of HCC.

A clinical cure is determined by a sustained virological response (SVR), defined by a negative HCV RNA by PCR, 6 months after the end of therapy.

Antiviral agents

Treatment for HCV infection is undergoing a revolution, with treatments changing from interferon-based regimes to all-oral combination regimes using directly acting antiviral agents. The latter are expensive and currently are available and funded in a few countries only. However, new, less costly, all-oral regimes are expected and it is to be hoped that, in the near future, all patients can be cured without interferon, which is associated with numerous side-effects. Therapy for HCV is critically dependent upon the genotype of the infecting virus; current treatment algorithms are outlined below.

The direct-acting antiviral regimes for HCV target different viral replication enzymes, and inhibitors of the NS3 protease enzyme, the NS5A replication complex initiator and the NS5B polymerase are now available. NS5B polymerase can be inhibited by both nucleotide and non-nucleotidic inhibitors.

The optimal therapy for patients with genotype 1 infection is with a combination of direct-acting antiviral agents. Two regimes are available: one involves the nucleotide sofosbuvir, which, when combined with either a protease inhibitor (simeprevir) or an NS5A inhibitor (daclatasvir or ledipasvir), cures over 90% of patients. The preferred combination is likely to be an 8-week regime involving a combined tablet containing sofosbuvir plus ledipasvir, which showed SVR rates of 95% in clinical trials. Alternative regimes that do not involve a nucleotide usually require three agents; regimes involving a protease inhibitor, an NS5A inhibitor and a non-nucleotidic NS5B inhibitor have been shown to cure over 95% of patients following 12 weeks of treatment. Both regimes are effective in patients with cirrhosis and there is an on-going debate as to whether or not patients with cirrhosis should receive slightly longer durations of therapy.

Alternative interferon-based regimes for patients with genotype 1 HCV involve at least 24 weeks of a long-acting pegylated interferon (given by weekly injections), combined with the oral agent ribavirin and a protease inhibitor. Older protease inhibitors (telaprevir and boceprevir) are associated with high levels of anaemia but the newer protease inhibitors (such as simeprevir) are better tolerated.

For patients with genotype 2 HCV, 12 weeks' therapy with sofosbuvir plus ribavirin cures over 90% and compares favourably to 24 weeks' therapy with pegylated interferon and ribavirin, which leads to an SVR in no more than 80% of individuals.

For genotype 3-infected patients, 24 weeks of sofosbuvir plus ribavirin are required to achieve SVR rates of more than 80%; the cost of this regime has led many to suggest that
interferon and ribavirin for 24 weeks should be used, as the response rate, approaching 70–80%, is not too dissimilar. Combining sofosbuvir with an NS5A inhibitor (such as ledipasvir or daclatasvir) allows the duration of therapy to be shortened to 12 weeks, and response rates approaching 90% are to be expected in patients without cirrhosis.

Patients with **genotype 3 HCV and cirrhosis** respond less well to current therapies; pegylated interferon combined with ribavirin and sofosbuvir for 12 weeks may be preferred, as response rates approaching 90% have been reported in large-scale clinical trials. Interferon-free regimes – sofosbuvir plus daclatasvir or ledipasvir – are effective alternatives, but ribavirin should be included in the regimen and therapy may need to be extended to 24 weeks. In the future, new drugs that are active against genotype 3 HCV may change this approach and allow effective, all-oral combination therapy for patients with cirrhosis. Novel NS5A inhibitors (5816) and protease inhibitors (grazoprevir) are expected in the near future and results of phase III trials are awaited with interest.

**Side-effects** of interferon are described on page 458. Ribavirin is usually well tolerated but side-effects include a dose-related haemolysis, pruritus and nasal congestion. Telaprevir causes a rash and anaemia, and boceprevir causes dysgeusia and anaemia. Pregnancy must be avoided with antiviral therapy. The new all-oral regimes are almost free of side-effects; they have not yet been widely used, however, so their full side-effect profile has not been clearly defined.

### Hepatitis E

Hepatitis E virus (HEV) is an RNA virus (Hepeviridae virus; **Fig. 14.19**); it causes a hepatitis that is clinically very similar to hepatitis A. It is enterally transmitted, usually by contaminated water, with 30% of dogs, pigs and rodents carrying the virus. Epidemics have been seen in many developing countries and sporadically in developed countries, in patients who have had contact with farm animals or have travelled abroad. In some developing countries, zoonotic infection from contaminated pork has led to acute HEV infection becoming relatively common. It has a mortality from fulminant hepatic failure of 1–2%, which rises to 20% in pregnant women. There is no carrier state and infection does not progress to chronic liver disease, except in some immunosuppressed patients. An ELISA for IgG and IgM anti-HEV is available for diagnosis. HEV RNA can be detected in the serum or stools by PCR. Prevention and control depend on good sanitation and hygiene; a vaccine has been developed and used successfully in China.
Hepatitis non-A–E

Approximately 10–15% of acute viral hepatitides cannot be typed and are described as hepatitis non-A–E. GB agent (hepatitis G virus, HGV) and transfusion-transmitted virus (TTV) agents have not been documented as causing disease in humans.

Acute hepatitis due to other infectious agents

Abnormal liver biochemistry is frequently found in a number of acute infections. The abnormalities are usually mild and have no clinical significance.

Infectious mononucleosis

Infectious mononucleosis (see also p. 258) is due to the Epstein–Barr (EB) virus. Mild jaundice, associated with minor abnormalities of liver biochemistry, is extremely common but ‘clinical’ hepatitis is rare. Hepatic histological changes occur within 5 days of onset; the sinusoids and portal tracts are infiltrated with large mononuclear cells but the liver architecture is preserved. A Paul–Bunnell or Monospot test is usually positive, and atypical lymphocytes are present in the peripheral blood. Treatment is symptomatic.

Cytomegalovirus

Cytomegalovirus (CMV; see also pp. 258–259) can cause acute hepatitis, usually a ‘glandular
fever-type syndrome’, in healthy individuals, but is more severe in those with an impaired immune response. Only the latter need treatment with valganciclovir or ganciclovir (see pp. 258–259).

CMV DNA is positive in blood; CMV IgM is also positive, but there are false-positive reactions. Liver biopsy shows intranuclear inclusions and giant cells.

**Herpes simplex**

Very occasionally, the herpes simplex virus (see also pp. 247–249) causes a generalized acute infection, particularly in the immunosuppressed patient, and occasionally in pregnancy. Aminotransferases are usually massively elevated. Liver biopsy shows extensive necrosis. Aciclovir is used for treatment.

**Toxoplasmosis**

The clinical picture in toxoplasmosis (see also p. 305) is similar to that of infectious mononucleosis, with abnormal liver biochemistry, but the Paul–Bunnell test is negative.

**Yellow fever**

Yellow fever (see also pp. 265–266) is a viral infection carried by the mosquito *Aedes aegypti*; it can cause acute hepatic necrosis. There is no specific treatment.

**Further reading**

Acute Hepatic Failure

Acute liver failure is defined as acute liver injury with encephalopathy and dearranged coagulation (INR > 1.5) in a patient with a previously normal liver. The time intervals are variable. The development of jaundice to encephalopathy varies from 7 days (hyper-acute), 8–28 days (acute), and sub-acute (>21 and <26 weeks). Occasionally, patients may have previous liver damage: for example, D virus superinfection in a previous carrier of HBsAg, Budd–Chiari syndrome or Wilson's disease).

AHF is a rare but often life-threatening syndrome that is due to acute hepatitis from many causes (Box 14.9). These causes vary throughout the world; most cases are due to viral hepatitis, but paracetamol overdose is common in the UK (50% of cases). HCV does not usually cause acute hepatic failure, although exceptional cases have been reported from Japan and India.

Box 14.9

Causes of acute hepatic failure

Viruses

- HAV, HBV, (HDV), HEV; rarely, HCV
- Cytomegalovirus
- Haemorrhagic fever viruses
- Herpes simplex virus
- Paramyxovirus
- Epstein–Barr virus

Drugs (examples)

- Paracetamol (acetaminophen)
- Antibiotics (ampicillin-clavulanate, ciprofloxacin, doxycycline, erythromycin, isoniazid, nitrofurantoin, tetracycline)
• Antidepressants (amitriptyline, nortriptyline)
• Antiepileptics (phenytoin, valproate)
• Anaesthetic agents (halothane)
• Lipid-lowering medications (atorvastatin, lovastatin, simvastatin)
• Immunosuppressive agents (cyclophosphamide, methotrexate)
• NSAIDs
• Salicylates (as a result of Reye syndrome, p. 483)
• Disulfiram, flutamide, gold, propylthiouracil
• Illicit drugs (e.g. ‘ecstasy’ or cocaine)
• Herbal/alternative medicines (ginseng, pennyroyal oil, Teucrium polium chaparral or germander tea, kawa kawa)

**Toxins**

• *Amanita phalloides* mushroom toxin
• *Bacillus cereus* toxin
• Cyanobacteria toxin
• Organic solvents (e.g. carbon tetrachloride)
• Yellow phosphorus

**Hepatic failure in pregnancy**

• Acute fatty liver of pregnancy (AFLP)
• HELLP (haemolysis, elevated liver enzymes, low platelets)

**Vascular causes**

• Ischaemic hepatitis
• Budd–Chiari syndrome
• Hepatic sinusoidal obstruction syndrome
• Portal vein thrombosis
• Hepatic arterial thrombosis (consider post transplant)

**Metabolic causes**

• α₁-antitrypsin deficiency
• Fructose intolerance
• Galactosaemia
• Lecithin–cholesterol acyltransferase deficiency
• Reye syndrome
• Tyrosinaemia
• Wilson's disease
**Malignancies**
- Primary (usually HCC, rarely cholangiocarcinoma)
- Secondary (extensive hepatic metastases or infiltration)

**Miscellaneous**
- Adult-onset Still's disease
- Heatstroke
- Primary graft non-function in liver transplant
  - HAV/HBV/HCV/HDV/HEV, hepatitis A/B/C/D/E virus; HCC, hepatocellular carcinoma; NSAIDs, non-steroidal anti-inflammatory drugs.

Histologically, there is multiacinar necrosis involving a substantial part of the liver. Severe fatty change is seen in pregnancy (see p. 1304) and Reye's syndrome (p. 486), or following intravenous tetracycline administration.

**Clinical features**

Examination shows a jaundiced patient with a small liver and signs of hepatic encephalopathy. The mental state varies from slight drowsiness, confusion and disorientation (grades I and II) to unresponsive coma (grade IV) with convulsions. Fetal hepaticus is common, but ascites and splenomegaly are rare. Fever, vomiting, hypotension and hypoglycaemia occur. Neurological examination shows spasticity and hyper-reflexia; plantar responses remain flexor until late. Cerebral oedema develops in 80% of patients with AHF but is far less common with subacute failure and its consequences of intracranial hypertension and brain herniation account for about 25% of the causes of death. Other complications include bacterial and fungal infections, gastrointestinal bleeding, respiratory arrest, kidney injury (hepatorenal syndrome and acute tubular necrosis) and pancreatitis.

**Investigations**

- Routine tests (see pp. 443–447)
- There is hyperbilirubinaemia, high serum aminotransferases and low levels of coagulation factors, including prothrombin and factor V. Aminotransferases are not useful indicators of the course of the disease, as they tend to fall along with the albumin with progressive liver damage.
- An electroencephalogram (EEG) is sometimes helpful in grading the encephalopathy.
- Ultrasound will define liver size and may indicate underlying liver pathology.

**Management**
There is no specific treatment but patients should be managed in a specialized unit. Transfer criteria to such units are shown in **Box 14.10**. Supportive therapy as for hepatic encephalopathy is necessary (see p. 474). When signs of raised intracranial pressure (which is sometimes measured directly) are present, 20% mannitol (1 g/kg body weight) should be infused intravenously; this dose may need to be repeated. Dexamethasone is of no value. Hypoglycaemia, hypokalaemia, hypomagnesaemia, hypophosphataemia and hypocalcaemia should be anticipated and corrected with a 10% glucose infusion (checked by 2-hourly dipstick testing) and with potassium, calcium, phosphate and magnesium supplements. Hyponatraemia should be corrected with hypertonic saline (see p. 161). Coagulopathy is managed with intravenous vitamin K, platelets, blood or fresh frozen plasma. Haemorrhage may be a problem and patients are given a proton pump inhibitor (PPI) to prevent gastrointestinal bleeding. Prophylaxis against bacterial and fungal infection is routine, as infection is a frequent cause of death and may preclude liver transplantation. Suspected infection should be treated immediately with suitable antibiotics. Renal and respiratory failure should be treated as necessary. Liver transplantation has been a major advance for patients with AHF. It is difficult to judge the timing or the necessity for transplantation, but there are guidelines based on validated prognostic indices of survival (see below).

**Box 14.10**

**Transfer criteria to specialized units for patients with acute liver injury**

- INR >3.0
- Presence of hepatic encephalopathy
- Hypotension after resuscitation with fluid
- Metabolic acidosis
- Prothrombin time (seconds) > interval (hours) from overdose (paracetamol cases)

INR, International Normalized Ratio.

**Prognosis**

In mild cases (grades I and II encephalopathy with drowsiness and confusion), two-thirds of the patients will survive. The outcome of severe cases (grades III and IV encephalopathy with stupor or deep coma) is related to the aetiology. In special units, 70% of patients with paracetamol overdose and grade IV coma survive, as do 30–40% patients with HAV or HBV hepatitis. Poor prognostic variables indicating a need to transplant the liver are shown in **Box 14.11**.

**Further reading**
### Box 14.11

**Poor prognostic variables in acute hepatic failure indicating liver transplantation**

**Non-paracetamol (acetaminophen) causes**

Three of following five:
- Drug or non-A, non-B hepatitis
- Age <10 and >40 years
- Interval from onset of jaundice to encephalopathy >7 days
- Serum bilirubin >300 µmol/L
- Prothrombin time >50 s (or >100 s in isolation)

**Paracetamol overdose**

- Arterial pH <7.3 (after resuscitation, 7.25 on acetylcysteine)
  
  or

- Serum creatinine >300 µmol/L *and*
- Prothrombin time >100 s *and*
- Grade III–IV encephalopathy

---

**Autoimmune Hepatitis**

Autoimmune hepatitis (AIH) is a progressive inflammatory liver condition with a 75% female preponderance. Approximately 40% of AIH patients have a family history of autoimmune disease (e.g. pernicious anaemia, thyroiditis or coeliac disease), and at least 20% have concomitant autoimmune diseases or develop them during follow-up.

**Pathogenesis**

The pathogenesis of AIH is incompletely understood, although increasingly evidence demonstrates that genetic susceptibility, molecular mimicry and impaired immunoregulatory networks contribute to the initiation and perpetuation of the autoimmune attack. Liver damage is thought to be mediated primarily by T cell-mediated events (CD4+ T cells) against liver antigens, producing a progressive necroinflammatory process that leads to fibrosis and cirrhosis. However, no clear trigger mechanism has been found.

**Clinical features**
There are two peaks in presentation. In the peri- and postmenopausal group, patients may be asymptomatic, or present with fatigue and abnormalities in liver biochemistry or the presence of chronic liver disease on examination. In the teens and early twenties, the disease (often type II) presents as an acute hepatitis with jaundice and very high aminotransferases, which do not improve with time. This age group often has clinical features of cirrhosis and patients who are ill may also have features of an autoimmune disease, such as fever, migratory polyarthritis, glomerulonephritis, pleurisy, pulmonary infiltration or lung fibrosis.

There are rare overlap syndromes with primary biliary cholangitis and primary sclerosing cholangitis, existing concomitantly or developing consecutively.

**Investigations**

**Liver biochemistry**

The serum aminotransferases are high, with lesser elevations in the ALP and bilirubin. The serum γ-globulins are high: frequently twice normal, particularly the IgG. The biochemical pattern is similar in both types.

**Haematology**

A mild normochromic normocytic anaemia with thrombocytopenia and leucopenia is present, even before portal hypertension and splenomegaly. The prothrombin time is often high.

**Autoantibodies**

Two types of autoimmune hepatitis have been recognized:

- **Type I with antibodies** (titres >1:80):
  - anti-nuclear (ANA)
  - anti-smooth muscle (anti-actin).

- **Type II with antibodies**: anti-liver/kidney microsomal (anti-LKM1). The main target is cytochrome P4502D6 (CYP2D6) on liver cell plasma membranes.

- A third type of AIH (AIH-3) was proposed, positive for anti-soluble liver antigen (SLA) and negative for conventional autoantibodies. However, subsequent studies showed that anti-SLA is also present in typical cases of AIH-1 and AIH-2. Patients positive for anti-SLA only, and therefore having *bona fide* AIH-3, are rare.

  Approximately 13% of patients lack the autoantibodies listed above.

**Liver biopsy**

Since transferases and IgG levels do not reflect disease activity, liver biopsy is mandatory to confirm the diagnosis and evaluate disease severity. The biopsy *(Fig. 14.20)* commonly shows chronic active hepatitis with inflammation and interface hepatitis. This reflects the changes of chronic hepatitis described on page 452. The amount of interface hepatitis is variable, but
tends to be high in untreated patients. Lymphoid follicles are less often seen than in hepatitis C, and plasma cell infiltration is frequent. Fibrosis is present in all but the mildest forms of the disease and approximately one-third of patients have cirrhosis at presentation.

**Management**

Prednisolone 30 mg is given daily for at least 2 weeks, followed by slow reduction to a maintenance dose of 5–15 mg daily. Azathioprine should be added, 1–2 mg/kg daily, as a steroid-sparing agent and, in some, as sole long-term maintenance therapy. Levels of thiopurine methyltransferase (TPMT) should be obtained before treatment is started (see p. 411). Other agents that have been used in resistant cases include budesonide (in non-cirrhotic patients), mycophenolate, ciclosporin and tacrolimus.

**Prognosis**

Steroid and azathioprine therapy induce remission in over 80%; indeed, this response forms part of the diagnostic criteria. Treatment is life-long in most, although withdrawal may be considered after 2–3 years of biochemical remission. Those with initial cirrhosis are more likely to relapse following withdrawal and require indefinite therapy. Liver transplantation is performed if treatment fails, although the disease may recur. HCC occurs less frequently than with viral-induced cirrhosis. The risk of malignancy associated with chronic low-dose azathioprine therapy has been reported to be 1.4 times normal.

Liberal R, Grant CR, Mieli-Vergani G et al. Autoimmune hepatitis: a comprehensive
Drug-Induced Chronic Hepatitis

Several drugs can cause a chronic hepatitis similar to autoimmune hepatitis (see Box 14.23). Patients are often female, present with jaundice and hepatomegaly, and have raised serum aminotransferases and globulin levels. Improvement follows drug withdrawal but exacerbations can occur with re-introduction. Isoniazid, amiodarone and methotrexate can cause chronic histological changes. With rare exceptions, patients with pre-existing chronic liver disease are not more susceptible to drug injury.

Chronic Hepatitis of Unknown Cause

As increasing numbers undergo routine blood tests, mild elevations in serum aminotransferases and γ-GT are commonly found. Many will have no symptoms or signs of liver disease. All known aetiological agents should be excluded, risk factors for NAFLD evaluated, and tests carried out to exclude liver diseases. Liver biopsy should be performed if the elevation in aminotransferases (>100 IU/L) persists for over a year, but often only non-specific changes are found.

Non-Alcoholic Fatty Liver Disease

Non-alcoholic fatty liver disease (NAFLD) is now the most common cause of chronic liver disease in many developed countries. It is often detected on routine abdominal ultrasound examination, and steatosis is found in up to one-third of these patients. Traditionally, it was considered that the 10–30% of patients with non-alcoholic steatohepatitis (NASH) were considerably more likely than those with simple steatosis to develop cirrhosis, but a recent large study demonstrated no difference in liver-related adverse events between definite NASH and severe steatosis. However, patients with advanced fibrosis at presentation were much more likely to progress than those without. In this cohort, complications of cirrhosis were the third most common cause of death, following cardiovascular events and non-hepatic malignancies.

Risk factors for NAFLD are obesity, hypertension, type 2 diabetes and hyperlipidaemia, such that NAFLD is considered to be the liver component of the metabolic syndrome (see p. 209). Most patients are asymptomatic; hepatomegaly may be present. Mild increases in serum aminotransferases and/or γ-GT (with ALT greater than AST) are frequently the sole liver biochemical abnormality.

Pathogenesis

Histological changes follow a spectrum similar to those of alcohol-induced hepatic injury, and range from simple fatty change to fat and inflammation (NASH), fibrosis and cirrhosis.
Oxidative stress injury and other factors lead to lipid peroxidation in the presence of fatty infiltration and inflammation. Fibrosis may then occur, enhanced by insulin resistance, which induces connective tissue growth factor.

**Investigations**

- **Diagnosis** is usually by *ultrasound* demonstration of steatosis in the absence of other injurious causes, such as alcohol.
- **Liver biopsy** allows staging of the disease. Although no definitive guidelines exist, many clinicians perform a biopsy if a diagnosis of NASH or advanced fibrosis is considered likely.
- **Elastography** (see p. 446) is used to evaluate the degree of fibrosis but may not be technically possible in the morbidly obese.

**Management**

- All NAFLD patients require *lifestyle advice* aimed at weight loss, increased physical activity, and attention to cardiovascular risk factors. Calorie restriction is recommended, aimed at losing 0.5–1 kg per week until target weight is achieved. A reduction of more than 7–9% in body weight has been associated with reduced steatosis, hepatocellular injury and hepatic inflammation.
- **Orlistat**, an enteric lipase inhibitor causing malabsorption of dietary fat, is used with a low-fat diet as an adjunct in subjects with a body mass index (BMI) of more than 30 kg/m². Only those achieving a loss of body weight of more than 5% in 3 months should continue orlistat, and then for only 1 year, as fat-soluble vitamin deficiency may occur.
- **Pioglitazone** or vitamin E may be used for those with biopsy-proven NASH, in whom lifestyle intervention has failed. Meta-analysis data demonstrated that pioglitazone significantly improved liver steatosis, inflammation and, to a lesser degree, fibrosis. However, it is associated with weight gain and reports of congestive cardiac failure, bladder cancer and reduced bone density. Conversely, pioglitazone reduces death, myocardial infarction and stroke in diabetes patients. The risks and benefits to each patient should be evaluated accordingly.
- **Vitamin E** (800 IU/day) is an antioxidant that improves steatohepatitis. However, a meta-analysis showed an increase in all-cause mortality at doses over 400 IU/day, and an increased risk of haemorrhagic stroke and prostate cancer has also been reported.
- Weight loss following **bariatric surgery** leads to reduced steatosis, steatohepatitis and fibrosis. The optimum technique is unknown and long-term data are lacking, although initial concerns about worsening fibrosis do not appear to have been borne out. Bariatric surgery should be avoided in those with advanced cirrhosis and portal hypertension, but gastric bypass and sleeve gastrectomy (pp. 210–211) have been shown to achieve weight loss and improve obesity-related co-morbidities in Child–Pugh A cirrhotic patients.
Hepatocellular carcinoma
The yearly cumulative incidence of HCC is 2.6% in patients with NASH cirrhosis, and ultrasound surveillance should therefore be performed 6-monthly. Hyperinsulinaemia and obesity are risk factors for many malignancies. Metformin and statin treatment may reduce the risk of HCC in patients with type 2 diabetes.

Liver transplantation
NASH cirrhosis is now the third most common indication for liver transplantation in the USA. Survival is comparable to that in other indications, and although recurrence occurs post transplant (4–25%), it does not appear to have an impact on graft survival. Patients frequently have multiple cardiovascular risk factors that should be managed aggressively. UK guidelines suggest that bariatric surgery could be considered at transplantation for the morbidly obese.
Cirrhosis

In cirrhosis, the liver architecture is diffusely abnormal and interferes with liver blood flow and function; this leads to the clinical manifestations of portal hypertension and liver failure.

Aetiology

Causes of cirrhosis are shown in Box 14.12. Alcohol is currently the most common cause in the West, but likely to be superseded by NAFLD; viral infection the most common worldwide. Young patients with cirrhosis must be investigated to exclude treatable causes (e.g. Wilson's disease).

Box 14.12

Causes of cirrhosis

Common

• Alcohol
• Hepatitis B ± D
• Hepatitis C
• Non-alcoholic fatty liver disease (NAFLD)

Others

• Primary biliary cholangitis
• Secondary biliary cirrhosis
• Autoimmune hepatitis
• Hereditary haemochromatosis
• Hepatic venous congestion
• Budd–Chiari syndrome
• Wilson's disease
Pathogenesis

Although the liver has a remarkable capacity to adapt to injury through tissue repair, chronic injury results in inflammation, matrix deposition, necrosis and angiogenesis, all of which lead to fibrosis (Fig. 14.21). Liver injury causes necrosis and apoptosis, releasing cell contents and reactive oxygen species (ROS). This activates hepatic stellate cells and tissue macrophages through the CC-chemokine ligand 2–CC-chemokine receptor 2 (CCL2–CCR2) axis (see p. 440). These cells phagocytose necrotic and apoptotic cells and secrete pro-inflammatory mediators, including transforming growth factor-beta (TGF-β); this leads to transdifferentiation of stellate cells to myofibroblasts and platelet-derived growth factor (PDGF), which stimulates myofibroblast proliferation. Macrophages degrade scar matrix by secretion of matrix metalloproteinases (MMPs), but this is inhibited by concurrent myofibroblast and macrophage production of tissue inhibitors of metalloproteinases (TIMPs). This results in progressive matrix deposition and scar accumulation. Increased gut permeability and hepatic lipopolysaccharide–Toll-like receptor 4 (LPS–TLR4) signalling also promotes fibrogenesis. Repetitive or chronic injury and inflammation perpetuate this process.
If the cause of fibrosis is eliminated (e.g. treatment of viral hepatitis), resolution (complete reversal to near-normal liver architecture) of early fibrosis can occur. In cirrhosis, regression (improvement, not reversal) occurs, which improves clinical outcomes. Antifibrotic therapies are emerging (including stem cell transplant strategies) but currently liver transplantation is the only available treatment for liver failure.

Pathology

The characteristic features of cirrhosis are regenerating nodules separated by fibrous septa, and loss of lobular architecture within the nodules (*Fig. 14.22A–C*). Two types are described:

- **Micronodular cirrhosis.** Regenerating nodules are usually <3 mm in size with uniform involvement of the liver; often caused by alcohol or biliary tract disease.
- **Macronodular cirrhosis.** The nodules are of variable size and normal acini may be seen within larger nodules; often caused by chronic viral hepatitis.
A mixed picture with small and large nodules occurs occasionally. Symptoms and signs are described on pages 447–448.

**Investigations**

Investigations aim to assess the severity and type of liver disease.

**Severity**

- **Liver function.** Serum albumin and prothrombin time are the best indicators of liver function; the outlook is poor if the albumin level is <28 g/L. The degree to which the prothrombin time is prolonged is commensurate with disease severity.

- **Liver biochemistry.** This may be normal, depending on the severity of disease. In most cases, there is a slight elevation in the serum ALP and serum aminotransferases. In decompensated cirrhosis, all biochemistry is deranged.

- **Serum electrolytes.** A low sodium indicates severe liver disease due to a defect in free water clearance or excess diuretic therapy.

- **Serum creatinine.** An elevated concentration >130 µmol/L is a marker of poor prognosis.

- **Biomarkers.** In the Enhanced Liver Fibrosis (ELF™) test, which assesses fibrosis, a value of <7.7 indicates none to mild, 7.7–9.8 moderate, and ≥9.8 severe.

  In addition, a serum α-fetoprotein of >200 ng/mL is strongly suggestive of HCC.
Type
This can be determined by:
• viral markers
• serum autoantibodies
• serum immunoglobulins
• iron indices and ferritin
• copper and caeruloplasmin (see p. 479)
• α₁-antitrypsin (see pp. 479–480).
• genetic markers.

Serum copper and serum α₁-antitrypsin should always be measured in young cirrhotics. Total iron-binding capacity (TIBC) and ferritin should be measured to exclude hereditary haemochromatosis; genetic markers are also available (see pp. 477–479).

Imaging
• Ultrasound examination can demonstrate changes in the size and shape of the liver. Fatty change and fibrosis produce a diffusely increased echogenicity. In established cirrhosis, there may be marginal nodularity of the liver surface and distortion of the arterial vascular architecture. The patency of the portal and hepatic veins can be evaluated. Ultrasound is useful for detecting HCC.
• Transient elastography is increasingly used to avoid liver biopsy (see p. 446). Technical limitations preclude its use in patients with ascites or morbid obesity, but it is suitable for most.
• CT scanning (see p. 446) is also helpful. Figure 14.22D–E show hepatosplenomegaly and the dilated collaterals seen in chronic liver disease. Arterial phase-contrast-enhanced scans are useful for detecting of HCC.
• Endoscopy is performed for the detection and treatment of varices and portal hypertensive gastropathy. Colonoscopy is occasionally carried out for colopathy.
• MRI scanning is useful in the diagnosis of both malignant and benign tumours such as haemangiomas. MR angiography can demonstrate the vascular anatomy, and MR cholangiography the biliary tree.

Liver biopsy
This remains the ‘gold standard’ for confirming the type and severity of liver disease. Adequate samples, in terms of length and number of complete portal tracts, are necessary for diagnosis and staging/grading of chronic viral hepatitis; in macronodular cirrhosis, the core of liver may fragment, causing sampling errors. Immunocytochemical stains can identify viruses, bile ducts, angiogenic structures and oncogenic markers. Chemical measurement of iron and copper is necessary to confirm a diagnosis of iron overload or Wilson's disease. Digital image
analysis of Picrosirius red staining can be used to quantitate collagen in biopsy specimens (*Fig. 14.22C*).

### Management

Management is that of the complications of decompensated cirrhosis. Patients should undergo 6-monthly ultrasound to screen for the early development of HCC (see p. 485), as all therapeutic strategies work best with small, single tumours. Treatment of the underlying cause may arrest or reverse cirrhosis. Patients with compensated cirrhosis should lead a normal life. Those at risk should receive hepatitis A and B vaccination. The only dietary restriction is to reduce salt intake (≤2 g sodium per day). Alcohol should be avoided, as should aspirin and non-steroidal anti-inflammatory drugs (NSAIDs), which may precipitate gastrointestinal bleeding or renal impairment.

### Prognosis

Prognosis is extremely variable. In general, the 5-year survival rate is approximately 50%, depending on the stage at which diagnosis is made. Poor prognostic indicators are shown in *Box 14.13*. Development of any complication usually worsens the prognosis.

**Blood tests**
- Low albumin (<28 g/L)
- Low serum sodium (<125 mmol/L)
- Prolonged prothrombin time >6 s above normal value
- Raised creatinine >130 µmol/L

**Clinical**
- Persistent jaundice
- Failure of response to therapy
- Ascites
- Haemorrhage from varices, particularly with poor liver function
- Neuropsychiatric complications developing with progressive liver failure
- Small liver
- Persistent hypotension
- Aetiology (e.g. alcoholic cirrhosis, if the patient continues drinking)
There are a number of prognostic classifications based on modifications of Child's grading (A, B and C; Box 14.14) and the Model for End-stage Liver Disease (MELD; Box 14.15), based on serum bilirubin, creatinine and INR, which is widely used as a predictor of mortality in patients awaiting liver transplantation. Modifications of the MELD score (e.g. UKELD) are used in some countries.

**Acute-on-chronic liver failure**

Acute-on-chronic liver failure (ACLF) refers to the condition of patients hospitalized for an
acute complication of cirrhosis accompanied by organ failure(s); it has a high short-term mortality. ACLF is believed to be distinct from traditional decompensated cirrhosis, based not only on the presence of organ failure(s) and high mortality rate, but also on younger age, alcohol aetiology, higher prevalence of certain precipitating events (e.g. bacterial infections or active alcohol excess), and a higher level of systemic inflammation. It is estimated to occur in 31% of patients hospitalized with an acute complication of cirrhosis.

Liver assist devices
As the liver has great potential to regenerate, extracorporeal liver support devices may allow patients with liver failure to be bridged to recovery or even liver transplantation. Current approaches include the use of biological devices that contain hepatocytes and those that function as detoxification devices, and artificial liver support systems. However, no device is currently available routinely.

Gut–liver axis
The liver is exposed to gut-derived bacterial components that have little consequence in health, as an effective gut barrier limits the amount of bacterial components transported to the liver. In advanced liver disease, the intestinal barrier function is compromised due to changes in gut motility, an increase in intestinal permeability, and suppression of gut immunological functions. This leads to bacteria and components entering the portal circulation and being transported to the liver, activating Toll-like receptors and producing an inflammatory response. This cross-talk between the intestinal microbiota and the liver is referred to as the gut–liver axis; it is seen as a key pathophysiological mechanism in the progression of liver disease and development of the complications of cirrhosis. Antibiotics and non-selective β-blockers intercept the gut–liver axis by blocking bacterial translocation, which is likely to account for their beneficial effects in reducing portal pressure, variceal haemorrhage and spontaneous bacterial peritonitis. However, absorbable antibiotics will lead to the selection of resistant bacteria. Rifaximin, a poorly absorbed antibiotic used for encephalopathy, specifically affects the gut flora and has a low risk for inducing resistance; it may therefore have a role in this indication.

**Further reading**

Liver transplantation

This is the only established treatment for advanced liver disease. Shortage of donors is a major problem in all developed countries and in some, such as Japan or South Korea, living related donors form the majority.

Indications

These include:

• **Acute liver disease**: acute hepatic failure of any cause (see p. 463).
• **Chronic liver disease**: usually for complications of cirrhosis that are no longer responsive to therapy.

The timing of transplantation depends on donor availability. All patients with end-stage cirrhosis (Child's grade C; MELD score ≥20; UKELD score ≥49) and those with debilitating symptoms should be referred to a transplant centre. In addition, specific extrahepatic complications of cirrhosis, even with preserved liver function, such as hepatopulmonary syndrome and porto-pulmonary hypertension, can be reversed by transplantation.

• **Primary biliary cholangitis**. Patients should be transplanted when their serum bilirubin is persistently >100 µmol/L or when they have symptoms such as intractable pruritus.
• **Chronic hepatitis B if HBV DNA-negative** or levels are falling with therapy. Following transplantation, recurrence of hepatitis is prevented by hepatitis B immunoglobulin and nucleoside analogues in combination (see pp. 243–244).
• **Chronic hepatitis C**. This is the most common indication. Universal HCV re-infection occurs with varying severity and cirrhosis occurs in 10–20% at 5 years. The new antiviral drugs are highly likely to improve these figures greatly.
• **Autoimmune hepatitis**. In patients who have failed to respond to medical treatment, the disease can recur.
• **Alcoholic liver disease**. Well-motivated patients who have stopped drinking without improvement of liver disease are offered a transplant, with frequent counselling. It has been shown that transplantation may represent life-saving treatment in patients with severe alcoholic hepatitis who are not responding to medical therapy. However, further studies are awaited.
• **Primary metabolic disorders**. Examples are Wilson's disease, hereditary haemochromatosis and α₁-antitrypsin deficiency.
• **NASH cirrhosis**. Now one of the most common causes of chronic liver disease in developed countries, this is likely to become the most frequent indication for transplantation.
• **Other conditions**, such as primary sclerosing cholangitis (PSC), polycystic liver disease, and metabolic diseases such as primary oxaluria.

Contraindications
Absolute contraindications include active sepsis outside the hepatobiliary tree, malignancy outside the liver, liver metastases (except neuroendocrine), and a lack of psychological commitment on the part of the patient.

Relative contraindications are mainly anatomical considerations that make surgery more difficult, such as extensive splanchnic venous thrombosis. With exceptions, patients aged 70 years or over are not usually given a transplant. In HCC, the recurrence rate is high, unless there are fewer than three small (<3 cm) lesions or a solitary nodule of <5 cm (Milan criteria).

Preparation for surgery
Pre-transplant work-up includes confirmation of the diagnosis, ultrasound and cross-sectional imaging, and radiological demonstration of the hepatic arterial and biliary trees, as well as assessment of cardiorespiratory and renal status. In view of the ethical and financial implications of transplantation, regular psychosocial, and possibly psychiatric, support is vital.

The donor should be ABO-compatible (HLA matching is not necessary) and have no evidence of active sepsis, malignancy, or HIV, HBV or HCV infection. Younger donors (<50 years) experience better graft function. The donor liver is cooled and stored on ice; its preservation time may be up to 20 hours. The recipient operation takes approximately 8 hours and rarely requires a large blood transfusion. Cadaveric donor livers (from heart-beating or non-heart-beating donors) may consist of whole graft, split grafts (for two recipients) or reduced grafts. Live donors may be healthy individuals or patients with, for example, familial amyloid polyneuropathy, whose livers can be transplanted into others (domino transplant). The mortality of right lobe donors is between 1 in 200 and 1 in 400.

The operative mortality is low and most postoperative deaths occur in the first 3 months. Sepsis and haemorrhage can be serious complications. Opportunistic infections occur owing to immunosuppression. Various immunosuppressive agents have been used, but tacrolimus – alone or in combination with azathioprine or mycophenolate mofetil, steroids, sirolimus and microemulsified ciclosporin are the most common.

Rejection
• **Acute or cellular rejection** usually occurs 5–10 days post transplant; it can be asymptomatic or there may be a fever. On biopsy, a pleomorphic portal infiltrate is seen with prominent eosinophils, bile duct damage and endothelialitis of the blood vessels. This responds well to immunosuppressive therapy.

• **Chronic ductopenic rejection** is seen between 6 weeks and 9 months post transplant, with disappearing bile ducts (vanishing bile duct syndrome, VBDS), and an arteriopathy with narrowing and occlusion of the arteries. Early ductopenic rejection is rarely reversed by immunosuppression and often requires retransplantation.

• **Graft-versus-host disease** is extremely rare.

Prognosis
Elective liver transplantation in low-risk patients has a 90% 1-year survival and a 70–85% 5-
year survival. Patients require life-long immunosuppression, although doses can be reduced over time without significant problems. Future strategies to reduce immunosuppression requirements after transplant may include infusion of autologous regulatory T cells. HCV cirrhosis, PSC and HCC are conditions in which long-term survival after transplantation is compromised by disease recurrence.

### Complications and effects of cirrhosis

These are shown in *Box 14.16*.

#### Box 14.16

**Complications and effects of cirrhosis**

- Portal hypertension and gastrointestinal haemorrhage
- Ascites
- Portosystemic encephalopathy
- Hepatocellular carcinoma
- Bacteraemias, infections
- Renal failure
- Hepatopulmonary syndrome

#### Portal hypertension

The portal vein is formed by the union of the superior mesenteric and splenic veins. Normal pressure is 5–8 mmHg with only a small gradient across the liver to the hepatic vein, in which blood is returned to the heart via the inferior vena cava. Portal hypertension is classified according to the site of obstruction:

- **Prehepatic** – blockage of the portal vein before the liver
- **Intrahepatic** – distortion of the liver architecture, either pre-sinusoidal (e.g. schistosomiasis) or post-sinusoidal (e.g. cirrhosis)
- **Post-hepatic** – venous blockage outside the liver (rare).

As portal pressure rises above 10–12 mmHg, the compliant venous system dilates and collaterals form within the systemic venous system. The main sites of collaterals are the gastro-oesophageal junction, rectum, left renal vein, diaphragm, retroperitoneum and the
anterior abdominal wall via the umbilical vein.

The collaterals at the gastro-oesophageal junction (varices) are superficial and tend to rupture. Portosystemic anastomoses at other sites rarely cause symptoms. Rectal varices are found frequently (30%) if looked for and can be differentiated from haemorrhoids, which are lower in the anal canal. The microvasculature of the gut becomes congested, giving rise to portal hypertensive gastropathy and colopathy, in which there is punctate erythema and erosions, which can bleed.

**Pathophysiology**

Following liver injury and fibrogenesis, the contraction of activated myofibroblasts (mediated by endothelin, nitric oxide and prostaglandins) contributes to increased resistance to blood flow. This increased resistance leads to portal hypertension and opening of portosystemic anastomoses in both pre-cirrhotic and cirrhotic livers. Neoangiogenesis also occurs. The hyperdynamic circulation of cirrhosis (caused by nitric oxide, cannabinoids and glucagon) leads to peripheral and splanchnic vasodilatation. This, combined with plasma volume expansion due to sodium retention (see ‘Ascites’, pp. 472–473), has a significant effect in maintaining portal hypertension.

**Aetiology**

The most common cause is cirrhosis (*Box 14.17*). Others are described below.

---

**Box 14.17**

**Causes of portal hypertension**

**Prehepatic**
- Portal vein thrombosis

**Intrahepatic**
- *Pre-sinusoidal*
  - Schistosomiasis; sarcoidosis
  - Primary biliary cholangitis
- *Sinusoidal*
  - Cirrhosis (e.g. alcoholic)
  - Partial nodular transformation
  - Congenital hepatic fibrosis
- *Post-sinusoidal*
  - Veno-occlusive disease
  - Budd–Chiari syndrome
**Post-hepatic**

- Right heart failure (rare)
- Constrictive pericarditis
- Inferior vena cava obstruction

**Prehepatic causes**

Extrahepatic blockage due to portal vein thrombosis can be caused by congenital portal venous abnormalities, neonatal sepsis of the umbilical vein, or inherited prothrombotic conditions, such as factor V Leiden or primary myeloproliferative disorders with or without JAK2 mutations (see p. 97).

Patients present with gastrointestinal bleeding, often at a young age. They have normal liver function, and prognosis following bleeding is therefore excellent.

The portal vein blockage can be identified by ultrasound with Doppler imaging; CT and MR angiography are also used.

Treatment for variceal bleeding is usually repeated endoscopic therapy or non-selective beta-blockade. Splenectomy is only performed if there is isolated splenic vein thrombosis. Anticoagulation prevents further thrombosis and intestinal infarction, and does not increase the risk of bleeding.

**Intrahepatic causes**

Cirrhosis is by far the most common cause but others include:

- **Non-cirrhotic portal hypertension** is characterized by mild portal tract fibrosis on liver histology. The aetiology is unknown, but arsenic, vinyl chloride, antiretroviral therapy and other toxins have been implicated. A similar disease is frequently found in India. The liver lesion does not progress and prognosis is good.

- **Schistosomiasis** with extensive pipe-stem fibrosis in endemic areas such as Egypt and Brazil. Often, there is concomitant liver disease, such as HCV infection, which was transmitted by non-sterile equipment.

- **Other causes** include congenital hepatic fibrosis, and nodular regenerative hyperplasia and partial nodular transformation.

**Post-hepatic causes**

Prolonged severe heart failure with tricuspid incompetence or constrictive pericarditis can cause portal hypertension. The Budd–Chiari syndrome is described on page 482.

**Clinical features**

Patients are often asymptomatic, the only clinical evidence being splenomegaly, although features of chronic liver disease may exist (see pp. 447–448).
Variceal haemorrhage

Approximately 90% of patients with cirrhosis will develop gastro-oesophageal varices over 10 years, but only one-third of these will bleed. Bleeding is likely to occur with large varices, or those with red signs at endoscopy, and in severe liver disease.

Management

Management can be divided into:

• the active bleeding episode
• prevention of rebleeding
• prophylactic measures to prevent the first haemorrhage.

Despite the therapeutic techniques available, prognosis ultimately depends on the severity of the underlying liver disease; overall 6-week mortality from variceal haemorrhage is 15–25%, reaching 50% in Child's grade C.

Initial management of acute variceal bleeding

See Figure 14.23, and also the general management of gastrointestinal haemorrhage on page 385.

Resuscitation
• **Assess** the patient: pulse, blood pressure and conscious state.

• Insert a **large-bore intravenous line** and obtain **blood** for group and crossmatching, haemoglobin, prothrombin time/INR, urea, electrolytes, creatinine, liver biochemistry and blood cultures.

• **Restore blood volume** with plasma expanders or, if possible, blood transfusion. See the treatment of shock for more detail (pp. 1156–1161). Prompt correction, but not over-correction, of hypovolaemia is necessary in cirrhosis patients, as their baroreceptor reflexes are diminished. A target haemoglobin of 80 g/L is sufficient and this lessens the likelihood of early rebleeding.

• Carry out an **ascitic tap**.

• **Monitor for alcohol withdrawal.** Give intravenous thiamine.

• Start **prophylactic antibiotics**. These treat and prevent infection, and reduce early rebleeding and mortality.

**Urgent endoscopy**

Endoscopy (**Fig. 14.24**) should be performed to confirm the diagnosis and to exclude bleeding from other sites (e.g. gastric ulceration) and portal hypertensive gastropathy/gastric antral vascular ectasia (GAVE). The latter describes chronic gastric congestion, punctate erythema and gastric erosions, which may contribute to chronic anaemia. Portal hypertensive gastropathy and GAVE are distinct entities; management of portal hypertensive gastropathy is centred on reduction in portal pressures with β-blockers, whereas treatment of GAVE is endoscopic and uses various ablative techniques.
Variceal banding or injection sclerotherapy

Banding of oesophageal varices is performed by mounting a band on the tip of the endoscope, sucking the varix into the end of the scope, and dislodging the band over the varix using a trip-wire mechanism.

Between 15% and 20% of bleeding comes from gastric varices, which are associated with a greater mortality (up to 40%); endoscopic injection of cyanoacrylate is the best treatment.

Overall, haemostasis is achieved in 80–90% of patients. Best practice is to perform the endoscopy with the patient under general anaesthetic and to provide appropriate airway support.

Injection sclerotherapy is now rarely performed for oesophageal varices.

Other measures

Vasoconstrictor therapy

This is used to restrict portal inflow by splanchnic arterial constriction and has shown benefit when used in combination with endoscopic techniques.

• Terlipressin. This is the only vasoconstrictor proven to reduce mortality. The dose is 2 mg 6-hourly, reducing to 1 mg 4-hourly after 48 h if a prolonged regimen is required (up to 5 days). Terlipressin should not be given to patients with ischaemic heart disease. The patient may complain of abdominal colic, and may defecate and have facial pallor owing to generalized
vasoconstriction. If haemostasis has been achieved at endoscopy, there is probably little added benefit with this therapy and treatment should be tapered accordingly.

- **Somatostatin.** This has few side-effects. An infusion of 250–500 µg/h reduces bleeding and is reserved for patients with contraindications to terlipressin. A recent prospective, multicentre study showed that haemostatic effects and safety at day 5 of treatment did not differ significantly between terlipressin, somatostatin and octreotide when utilized as adjuvants to endoscopic treatment.

**Balloon tamponade**

Balloon tamponade is used if endoscopic therapy has failed or if there is exsanguinating haemorrhage. The usual balloon tube is a four-lumen Sengstaken–Blakemore, which should be left in place for no more than 12 hours and removed in the endoscopy room prior to endoscopy. The tube is passed into the stomach and the gastric balloon inflated with air and pulled back. It should be positioned in close apposition to the gastro-oesophageal junction to prevent the cephalad variceal blood flow to the bleeding point. The oesophageal balloon should only be inflated if bleeding is not controlled by the gastric balloon alone.

Haemostasis is achieved in up to 90%. However, the balloon may cause serious complications, such as aspiration pneumonia, oesophageal rupture and mucosal ulceration. The procedure is also very unpleasant for the patient.

A self-expanding covered metal stent (Danis), which has a wire loop to enable removal, and is introduced orally or endoscopically, can be placed over the varices. This is effective and has the advantages that it does not impair swallowing, cannot be removed by uncooperative patients, and allows post-endoscopic investigation. The stent is removed 7 days after insertion. It is currently only used in specialist centres but early results are encouraging.

**Additional management of the acute episode**

- **Measures to prevent encephalopathy.** Portosystemic encephalopathy (PSE) can be precipitated by a large bleed (blood contains protein). Management is as outlined on page 474.

- **Nursing.** Patients require high-dependency/intensive care nursing. They should remain nil by mouth until bleeding has stopped.

- **Reduction in acid secretion.** Ranitidine may be preferable to PPIs, as it lessens the risk of *Clostridium difficile* infection; PPIs are widely used, however. Sucralfate 1 g four times daily can reduce oesophageal ulceration following endoscopic therapy.

**Management of an acute rebleed**

Rebleeding occurs in about 15–20% within 5 days. The source should be established by endoscopy and is sometimes due to ulceration or slippage of a ligation band. Endoscopy should be performed once only to control rebleeding. If haemostasis cannot be achieved, then transjugular intrahepatic portocaval shunting will be necessary.
**Transjugular intrahepatic portocaval shunt**

Transjugular intrahepatic portocaval shunt (TIPS) is used when bleeding cannot be controlled either acutely or following a rebleed. Under X-ray guidance, a guidewire is passed from the jugular vein into the liver and the portal vein. After balloon expansion of the tract between the hepatic and portal veins, an expandable, covered metal shunt is placed over the wire to form a channel between the systemic and portal venous systems. It reduces the hepatic sinusoidal and portal vein pressure by creating a total shunt. There is an increased risk of portal systemic encephalopathy. Stent stenosis or thrombosis is far less frequent with ‘covered’, compared to ‘bare’, stents. Collaterals arising from the splenic or portal veins can be selectively embolized. These reduce rebleeding rates compared to endoscopic techniques, but do not improve survival and increase encephalopathy.

**Emergency surgery**

This is performed rarely when other measures fail or if TIPS is not available. Oesophageal transection and ligation of the feeding vessels to the bleeding varices is most commonly performed; an alternative is acute portosystemic shunt surgery.

**Prevention of recurrent variceal bleeding (secondary prophylaxis)**

The risk of bleeding recurring without prophylaxis is 60–80% over a 2-year period, with an approximate mortality of 20% per episode.

**Prophylactic long-term measures**

**Non-selective beta-blockade**

Oral propranolol or carvedilol to reduce the resting pulse rate by 25% decreases portal pressure. Portal inflow is reduced by a decrease in cardiac output ($\beta_1$) and by blockade of $\beta_2$ vasodilator receptors on the splanchnic arteries, leaving an unopposed vasoconstrictor effect. Significant reduction of hepatic venous pressure gradient (HVPG; measured by hepatic vein catheterization) is associated with very low rates of rebleeding, particularly if <12 mmHg. Data have emerged demonstrating that additional $\alpha_1$-adrenergic blockade, causing vasodilatation with carvedilol, may increase the number of patients with a reduction in hepatic venous pressure gradient compared to propranolol.

**Endoscopic treatment**

Repeated courses of banding at 2-weekly intervals lead to obliteration of varices. This markedly reduces rebleeding, most instances occurring before the varices have been fully obliterated. Between 30% and 40% of varices return per year, so follow-up endoscopy should be performed at 1–3 months after obliteration and then every 6–12 months. Complications of banding include oesophageal ulceration, mediastinitis and, rarely, strictures.

Combination therapy reduces overall bleeding compared to endoscopic therapy alone but with no overall improvement in mortality. A pragmatic approach is therefore to give
combination therapy to those who can tolerate beta-blockade, and band ligation alone to those who cannot.

**Surgery**

- **Surgical portosystemic shunting** is associated with an extremely low risk of rebleeding and is used if TIPS is not available. Hepatic encephalopathy is a significant complication. The ‘shunts’ are usually an end-to-side portocaval anastomosis or a selective distal splenorenal shunt (Warren shunt).

- **Devascularization procedures**, including oesophageal transection, do not produce encephalopathy, and can be used when there is splanchnic venous thrombosis.

- **Liver transplantation** (see pp. 468–469) is the best option when there is poor liver function.

**Prophylactic measures (primary prophylaxis)**

Patients with cirrhosis and significant varices that have not bled should be prescribed non-selective β-blockers. This reduces the chances of upper gastrointestinal bleeding by approximately 50%, may increase survival, and is cost-effective. If there are contraindications, variceal banding is an option.

---

**Ascites**

Ascites, fluid within the peritoneal cavity, is a common complication of cirrhosis. Several factors underlie its pathogenesis:

- **Sodium and water retention** results from peripheral arterial vasodilatation (secondary to nitric oxide, atrial natriuretic peptide and prostaglandins), which causes a reduction in the effective blood volume. This reduction activates the sympathetic nervous system and the renin–angiotensin system, promoting salt and water retention (see Fig. 9.3).

- **Portal hypertension** exerts a local hydrostatic pressure, leading to increased hepatic and splanchnic production of lymph, and transudation of fluid into the peritoneal cavity.

- **Low serum albumin** (due to poor liver function) may further contribute by reducing plasma oncotic pressure.

  In patients with ascites, urine sodium excretion rarely exceeds 5 mmol in 24 hours. Loss of sodium from extrarenal sites accounts for approximately 30 mmol in 24 hours. Under these circumstances, a normal daily sodium intake of 120–200 mmol results in a positive sodium balance of approximately 90–170 mmol in 24 hours (equivalent to 600–1300 mL of fluid retained).

**Clinical features**

Abdominal swelling may develop over days or several weeks. Precipitating factors include a high-sodium diet or development of an HCC or splanchnic vein thrombosis. Mild abdominal
pain and discomfort are common but, if more severe, should raise the suspicion of spontaneous bacterial peritonitis (see below). Respiratory distress and difficulty eating accompany tense ascites.

The presence of fluid is confirmed clinically by demonstrating shifting dullness. Many patients also have peripheral oedema. A pleural effusion (usually right-sided) may infrequently be found and arises from the passage of ascites through congenital diaphragmatic defects.

### Investigations

A diagnostic aspiration of 10–20 mL of fluid should be obtained for:

- **Cell count.** A neutrophil count >250 cells/mm$^3$ is indicative of an underlying (usually spontaneous) bacterial peritonitis.

- **Gram stain and culture.**

- **Protein measurement.** A high serum–ascites albumin gradient of >11 g/L suggests portal hypertension, and a low gradient <11 g/L is associated with non-liver disease-related abnormalities of the peritoneum, such as neoplasia (*Box 14.18*).

---

#### Box 14.18

**The serum–ascites albumin gradient**

**High serum–ascites albumin gradient (>11 g/L)**

- Portal hypertension, e.g. hepatic cirrhosis
- Hepatic outflow obstruction
- Budd–Chiari syndrome
- Hepatic veno-occlusive disease
- Tricuspid regurgitation
- Constrictive pericarditis
- Right-sided heart failure

**Low serum–ascites albumin gradient (<11 g/L)**

- Peritoneal carcinomatosis
- Peritoneal tuberculosis
- Pancreatitis
- Nephrotic syndrome

• **Cytology.** A search should be made for malignant cells.
• **Amylase** Pancreatic ascites should be excluded.

The differential diagnosis of ascites is listed in **Box 14.19.**

---

### Box 14.19

**Causes of ascites according to type of ascitic fluid**

#### Straw-coloured

- Malignancy (most common cause)
- Cirrhosis
- Infective:
  - Tuberculosis
  - Following intra-abdominal perforation – any bacterium may be found (e.g. *Escherichia coli*)
  - Spontaneous in cirrhosis
- Hepatic vein obstruction (Budd–Chiari syndrome) – protein level high in fluid
- Chronic pancreatitis
- Congestive cardiac failure
- Constrictive pericarditis
- Meigs syndrome (ovarian tumour)
- Hypoproteinaemia (e.g. nephrotic syndrome)

#### Chylous

- Obstruction of main lymphatic duct (e.g. by carcinoma) – chylomicrons are present
- Cirrhosis

#### Haemorrhagic

- Malignancy
- Ruptured ectopic pregnancy
- Abdominal trauma
- Acute pancreatitis

---

### Management

The aim is both to reduce sodium intake and to increase renal sodium excretion, producing a net reabsorption of fluid from the ascites into the circulating volume. The maximum rate at which ascites can be mobilized is 500–700 mL in 24 hours (see below).
• *Serum electrolytes, creatinine and estimated glomerular filtration rate (eGFR).* Check on alternate days; weigh the patient and measure urinary output daily.

• **Bed rest.** This will cause a diuresis by improving renal perfusion, but is rarely helpful.

• **Dietary sodium restriction.** It is possible to reduce sodium intake to 40 mmol in 24 h and still maintain an adequate protein and calorie intake with a palatable diet.

• **Drugs.** Many contain significant amounts of sodium (up to 50 mmol daily). Examples include antacids and antibiotics (particularly penicillins and cephalosporins). Sodium-retaining drugs (NSAIDs, corticosteroids) should be avoided.

• **Fluid restriction.** This is unnecessary unless the serum sodium is <128 mmol/L (see below).

• **Diuretics.** The diuretic of choice is the aldosterone antagonist, spironolactone, starting at 100 mg daily. Chronic administration produces gynaecomastia. Eplerenone 25 mg once daily does not cause gynaecomastia.

  The aim of diuretic therapy should be to produce a net loss of fluid approaching 700 mL in 24 hours (0.7 kg weight loss, or 1.0 kg if peripheral oedema is present). Although 60% of patients respond on this regimen, the spironolactone can be increased gradually to 400 mg daily if necessary, providing there is no hyperkalaemia. A loop diuretic, such as furosemide 20–40 mg or bumetanide 0.5 mg or 1 mg daily, is added if response is poor. These loop diuretics have several potential disadvantages, including hyponatraemia, hypokalaemia and volume depletion.

  Diuretics should be temporarily discontinued if a rise in serum creatinine occurs, representing over-diuresis and hypovolaemia, or if there is hyperkalaemia or worsening encephalopathy. Hyponatraemia almost always represents haemodilution secondary to a failure to clear free water (usually a marker of reduced renal perfusion), and diuretics should be stopped if the sodium falls below 128 mmol/L. Vaptans (see p. 164), vasopressin V₂-receptor antagonists that increase free water clearance, have a small beneficial effect on hyponatraemia and ascites but do not affect mortality, complications of cirrhosis or renal failure; routine use in cirrhosis cannot be recommended.

**Paracentesis**

This is used to relieve symptomatic tense ascites or when diuretic therapy is insufficient to control accumulation of fluid. The main complications are hypovolaemia and renal dysfunction (post-paracentesis circulatory dysfunction), predominantly due to an accentuation of the arteriolar vasodilatation already present in these patients; this is more likely with >5 L removal and worse liver function. In patients with normal renal function and without hyponatraemia, this is overcome by infusing albumin (8 g/L of ascitic fluid removed). In practice, up to 20 L can be removed over 4–6 hours, with albumin infusion.

**Shunts**

A TIPS may be inserted to treat resistant ascites, providing there is no spontaneous portosystemic encephalopathy and there is minimal disturbance of renal function. Frequency of
paracentesis and diuretic use is reduced and nutrition is enhanced. Survival may also improve.

A peritoneo-bladder conduit, by means of an implantable, rechargeable, battery-powered pump, has been developed for use in patients with advanced cirrhosis and resistant ascites (alfapump®). This removes ascites from the peritoneal cavity into the urinary bladder, to be eliminated through urination. Early studies have shown a reduction in the need for large-volume paracentesis but several complications, including pain and infection, occur.

### Spontaneous bacterial peritonitis

Spontaneous bacterial peritonitis (SBP) represents a serious complication that is an indication for referral for transplant assessment; it occurs in up to 18% of patients with ascites who have undergone a decompensation. The infecting organisms gain access to the peritoneum by haematogenous spread; most are *Escherichia coli, Klebsiella* or enterococci. The condition should be suspected in any patient with ascites who deteriorates, as pain and pyrexia are frequently absent. Diagnostic aspiration should always be performed. A raised neutrophil count in ascites is sufficient evidence alone to start immediate treatment. A broad-spectrum antibiotic is used, with subsequent alteration according to culture results *in combination with infusions of human albumin solution*. Evidence has emerged that non-selective β-blockers should be stopped following diagnosis of SBP, as prescription increases the risk of renal impairment. Mortality is 10–15%. Recurrence is common (70% within a year) and secondary prevention – for example, with norfloxacin 400 mg daily – prolongs survival. Primary prophylaxis of SBP in patients with ascites protein <10 g/L or severe liver disease may prevent hepatorenal syndrome and improve survival.

### Portosystemic encephalopathy

Portosystemic encephalopathy (PSE) is a chronic neuropsychiatric syndrome that is secondary to cirrhosis. Acute encephalopathy can occur in acute hepatic failure (see p. 462). PSE can arise in portal hypertensive patients due to spontaneous ‘shunting’, or in those with surgical or TIPS shunts.

### Pathogenesis

In cirrhosis, the portal blood bypasses the liver via collaterals, and ‘toxic’ metabolites pass directly to the brain to produce encephalopathy. Ammonia-induced alteration of brain neurotransmitter balance, especially at the astrocyte–neurone interface, is considered to be the leading pathophysiological mechanism. Ammonia is produced by the breakdown of protein by intestinal bacteria. Other implicated substances are free fatty acids and mercaptans; accumulation of false neurotransmitters (octopamine) or activation of the γ-aminobutyric acid (GABA) inhibitory neurotransmitter system may also be responsible. Increased blood levels of aromatic amino acids (tyrosine and phenylalanine) and reduced branched-chain amino acids (valine, leucine and isoleucine) also occur. The factors precipitating PSE are shown in **Box**
Factors precipitating portosystemic encephalopathy

- High dietary protein
- Gastrointestinal haemorrhage
- Constipation
- Infection, including spontaneous bacterial peritonitis
- Fluid and electrolyte disturbance due to diuretic therapy or paracentesis
- Drugs (e.g. any central nervous system depressant)
- Portosystemic shunt operations, TIPS
- Any surgical procedure
- Progressive liver damage
- Development of hepatocellular carcinoma

TIPS, transjugular intrahepatic portocaval shunt.

Clinical features

An acute onset often has a precipitating factor (Box 14.20). The patient becomes increasingly drowsy and comatose.

Chronically, there is a disorder of personality, mood and intellect, with a reversal of normal sleep rhythm. These changes may fluctuate and a collateral history should be obtained. The patient is irritable, confused and disorientated, and has slow, slurred speech. General features include nausea, vomiting and weakness. There is hyper-reflexia and increased tone. Coma occurs as the encephalopathy becomes more marked. Convulsions are very rare, but if they do occur, other causes must be considered.

Signs include:
- fetor hepaticus (a sweet smell to the breath)
- a coarse flapping tremor seen when the hands are outstretched and wrists hyperextended (asterixis)
- constructional apraxia, with the patient being unable to write or draw a five-pointed star, for example
- decreased mental function, which can be assessed by using the serial sevens test or a trail-making (or connection) test.

Investigations
**Diagnosis** is clinical.

**Additional investigations**
- **EEG** shows a decrease in the frequency of the normal α-waves (8–13 Hz) to 1.5–3 Hz. These changes occur before coma supervenes.
- **Visual evoked responses** (see p. 823) also detect subclinical encephalopathy.
- **Arterial blood ammonia** can be useful for the differential diagnosis of coma and for following a patient with PSE, but is not always available.

**Management**
- **Identify and remove the possible precipitating cause**, such as cerebral depressant drugs, constipation or electrolyte imbalance due to over-diuresis.
- **Give purgation and enemas** to empty the bowels of nitrogenous substances. Lactulose (10–30 mL three times daily) is an osmotic purgative that reduces the colonic pH and limits ammonia absorption. Lactilol (β-galactoside sorbitol 30 g daily) is metabolized by colonic bacteria and is comparable in efficacy.
- **Maintain nutrition**, if necessary via a fine-bore nasogastric tube, and do not restrict protein for more than 48 h.
- **Give antibiotics**. Rifaximin is a poorly absorbed semisynthetic antibiotic based on rifamycin that has a beneficial effect on secondary prevention of PSE. Metronidazole (200 mg four times daily) may be effective acutely. Neomycin should be avoided.
- **Stop or reduce diuretic therapy**.
- **Give intravenous fluids** as necessary (beware too much sodium).
- **Treat infection**.
- **Increase protein** in the diet to the limit of tolerance as encephalopathy improves.

**Prognosis**
Acute encephalopathy in acute hepatic failure has a very poor prognosis associated with that of the disease itself. In cirrhosis, chronic PSE adversely affects prognosis but the course is very variable. Very rarely with chronic portosystemic shunting, an organic syndrome with cerebellar signs or choreoathetosis develops, as well as myelopathy leading to a spastic paraparesis due to demyelination. These patients require referral to a liver transplant centre.

**Renal failure (hepatorenal syndrome)**
The hepatorenal syndrome typically occurs in patients with advanced cirrhosis, portal hypertension, jaundice and ascites. The urine output is low with a low urinary sodium concentration, a maintained capacity to concentrate urine (i.e. intact tubular function) and
almost normal renal histology. The renal failure is therefore described as ‘functional’. It is often precipitated by over-vigorous diuretic therapy, NSAIDs, diarrhoea, paracentesis and infection, particularly spontaneous bacterial peritonitis.

The mechanism is similar to that of ascites, with extreme peripheral vasodilatation leading to decreased effective blood volume and consequent hypotension (see pp. 472–473). This causes increased plasma renin, aldosterone, noradrenaline (norepinephrine) and vasopressin, leading to renal vasoconstriction. There is an increased pre-glomerular vascular resistance that causes blood to be directed away from the renal cortex. This leads to a reduced glomerular filtration rate and plasma renin remains high. Salt and water retention occurs, with reabsorption of sodium from the renal tubules.

Eicosanoids have been incriminated in the pathogenesis, supported by precipitation of the syndrome by inhibitors of prostaglandin synthase, such as NSAIDs.

Diuretic therapy should be stopped and intravascular hypovolaemia corrected, preferably with albumin. Terlipressin or noradrenaline with intravenous albumin improves renal function in approximately 50%. Liver transplantation is the best option. In patients who are candidates for transplantation, haemodialysis can be used as a bridging option but is frequently difficult to perform, and survival is generally limited by the severity of the hepatic failure.

**Hepatopulmonary syndrome**

This is hypoxaemia in patients with advanced liver disease due to intrapulmonary vascular dilatation with no evidence of primary pulmonary disease. The patients have features of cirrhosis with spider naevi and clubbing, as well as cyanosis. Most are asymptomatic, but with more severe disease, patients are breathless on standing. Transthoracic echocardiography shows intrapulmonary shunting, and arterial blood gases confirm hypoxaemia. These changes are improved with liver transplantation.

**Porto-pulmonary hypertension**

This occurs in 1–2% of patients with cirrhosis and portal hypertension. It may respond to medical therapy (e.g. intravenous epoprostenol, or oral bosentan and sildenafil). Severe pulmonary hypertension is a contraindication to liver transplantation.

**Primary hepatocellular carcinoma**

This is discussed on page 485.

**Further reading**

Types of cirrhosis

**Alcoholic cirrhosis**

This is discussed in the section on alcoholic liver disease (see pp. 480–482).

**Primary biliary cholangitis**

Primary biliary cholangitis (PBC; Fig. 14.25) is a chronic disorder with progressive destruction of small bile ducts, leading to cirrhosis. Women aged 40–50 years constitute 90% of patients. PBC is diagnosed increasingly frequently in its milder forms. The prevalence is approximately 7.5 per 100 000, with a 1–6% increase in first-degree relatives. PBC has been called ‘chronic non-suppurative destructive cholangitis’, a term more descriptive of the early lesion, which emphasizes the fact that true cirrhosis occurs only in the later stages.

![Figure 14.25](image)

**Aetiology**

The aetiology is unknown but an immunological basis is well described. Serum anti-mitochondrial antibodies (AMA) are found in almost all patients. The mitochondrial antigen M2 is specific to PBC and five M2-specific antigens have been identified. The presence of AMA in high titre is unrelated to the clinical or histological picture and its role in pathogenesis...
is unclear. Antibodies against nuclear antigens, e.g. anti-gp210, are present in 50% of patients and correlate with progression towards liver failure.

It seems likely that an environmental factor acts on a genetically predisposed host via molecular mimicry, initiating autoimmunity. *E. coli* and *Novosphingobium aromaticivorans* antibodies are present in high titre.

Synthesis of IgM is increased, thought to be due to failure of the switch from IgM to IgG antibody synthesis. No specific associated class II major histocompatibility complex (MHC) loci have been found.

### Clinical features

Asymptomatic patients are discovered on routine examination or screening and may have hepatomegaly, a raised serum alkaline phosphatase or autoantibodies.

Pruritus is often the earliest symptom. Fatigue, which is frequently disabling, may accompany the pruritus, particularly in progressive cases. When jaundice appears, hepatomegaly is usually present. Pigmented xanthelasma on eyelids or deposits of cholesterol in the creases of the hands may be seen.

### Associated disorders

Autoimmune disorders (e.g. Sjögren syndrome, scleroderma, thyroid disease) occur with increased frequency. Keratoconjunctivitis sicca (dry eyes and mouth) is seen in 70% of cases. Renal tubular acidosis, membranous glomerulonephritis, coeliac disease and interstitial pneumonitis are also associations.

### Investigations

- **Mitochondrial antibodies** – measured routinely by ELISA (in titres >1:160) – are present in over 95% of patients; M2 antibody is 98% specific. Other non-specific antibodies (e.g. anti-nuclear factor and smooth muscle) may also be present.

- **High serum alkaline phosphatase** is often the only liver biochemistry abnormality.

- **Serum cholesterol** is raised.

- **Serum IgM** may be very high.

- **Ultrasound** can show a diffuse alteration in liver architecture.

- **Liver biopsy** shows characteristic histological features of a portal tract infiltrate, mainly of lymphocytes and plasma cells; approximately 40% have granulomas. Most of the early changes are in zone 1. Later, there is damage to and loss of small bile ducts with ductular proliferation. Portal tract fibrosis and, eventually, cirrhosis are seen.

  **Hepatic granulomas** are also seen in sarcoidosis, tuberculosis, schistosomiasis, drug reactions, brucellosis and parasitic infestation (e.g. strongyloidiasis).
Differential diagnosis

The classical picture presents little difficulty with diagnosis (and can be confirmed by biopsy, although this is only necessary in doubtful cases). A group of patients with the histological changes of PBC but the serology of autoimmune hepatitis are termed as having autoimmune cholangitis and respond to steroids and azathioprine.

In the jaundiced patient, extrahepatic biliary obstruction should be excluded by ultrasound or MRCP.

Management

- **Ursodeoxycholic acid** (10–15 mg/kg) improves bilirubin and aminotransferase levels. It should be given early in the asymptomatic phase, as these patients benefit, whereas no benefit is achieved in advanced disease.

- **Steroids** improve biochemical and histological disease but cause osteoporosis and other side-effects, and so should not be used.

- **Malabsorption** of fat-soluble vitamins (A, D and K) occurs and supplementation is required.

- **Bisphosphonates** are required for osteoporosis. Despite raised serum lipid concentrations, PBC is not associated with an increased cardiovascular disease risk and strategies for prevention of vascular events should be tailored to the individual.

- **Pruritus** is difficult to control; *colestyramine* is helpful, although unpalatable. *Rifampicin*, and *naloxone* and *naltrexone* (opioid antagonists) have been shown to be of benefit. Intractable pruritus can be relieved by plasmapheresis or a molecular absorbent recirculating system (MARS).

- The lack of effective medical therapy has made PBC a major indication for liver transplantation (see p. 468).

- **Fatigue** is common and can be severely debilitating; there is no proven therapy and transplantation does not improve symptoms. Modafinil, used for narcolepsy, has shown promise but has yet to be evaluated in randomized studies; it may cause significant side-effects and has addictive potential.

Complications

The complications are those of cirrhosis. In addition, osteoporosis and, rarely, osteomalacia and a polyneuropathy occur.

Prognosis

Prognosis is very variable. Asymptomatic patients and those presenting with pruritus only will survive for more than 20 years. Symptomatic patients with jaundice have a more rapidly
progressive course and may die of liver failure or bleeding varices within 5 years. Liver transplantation should therefore be offered when the serum bilirubin is persistently above 100 µmol/L.

### Primary sclerosing cholangitis

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease characterized by fibrosing inflammatory destruction of both the intra- and extrahepatic bile ducts. In 75% of patients, PSC is associated with inflammatory bowel disease (usually ulcerative colitis); it is not unusual for PSC to predate the onset of inflammatory bowel disease. The causes are unknown but genetic susceptibility to PSC is associated with the HLA-A1-B8-DR3 haplotype. The autoantibody pANCA (anti-neutrophil cytoplasmic antibody) is found in the serum of 60% of cases. Seventy per cent of patients are men and the average age of onset is approximately 40 years. Secondary PSC is seen in patients with HIV and cryptosporidium (see p. 350) and may follow ketamine misuse.

### Clinical features

With increasing screening of patients with inflammatory bowel disease, PSC is detected at an asymptomatic phase with abnormal liver biochemistry, usually a raised serum alkaline phosphatase. Symptomatic presentation is usually with fluctuating pruritus, jaundice and cholangitis.

### Diagnosis

The typical biliary changes associated with PSC may be identified by MRCP. The cholangiogram characteristically shows irregularity of calibre of both intra- and extrahepatic ducts, although either may be involved alone (Fig. 14.26).
Primary sclerosing cholangitis. An endoscopic cholangiogram showing the typical features of primary sclerosing cholangitis. There are calibre irregularities of the intrahepatic ducts (IHD). There is also minor stricturing of the extrahepatic ducts at the confluence between the common bile duct (CBD) and the common hepatic duct (CHD).

Pathology

Histology can be contributory; it shows inflammation of the intrahepatic biliary radicles with associated scar tissue, classically described as have the appearance of ‘onion skin’. These changes range from minor inflammatory infiltrates to the level of established cirrhosis.

Management

PSC is a slowly progressive lesion (symptoms and biochemical tests may fluctuate), which ultimately leads to liver cirrhosis and associated decompensation. Recurrent cholangitis may be a feature before the onset of cirrhosis. Cholangiocarcinoma occurs in up to 15% of patients (see pp. 485–486 and 498).

The only proven treatment is liver transplantation. The bile acid, ursodeoxycholic acid, has been evaluated extensively but there is no evidence of benefit. High-dose therapy (30 mg/kg) may be deleterious. In a small minority, the dominant lesion is sited in the extrahepatic ducts (Fig. 14.26). Such lesions may be amenable to endoscopic biliary intervention with balloon dilatation and temporary stent placement (see p. 497).

Secondary biliary cirrhosis
Cirrhosis can result from prolonged (for months) large duct biliary obstruction. Causes include bile duct strictures, gallstones and sclerosing cholangitis. An ultrasound examination and MRCP, sometimes followed by ERCP or percutaneous transhepatic cholangiography (where the ducts are cannulated under ultrasound guidance through the skin) if cannulation is difficult, is performed to outline the ducts, and any remedial cause is treated.

### Hereditary haemochromatosis

Hereditary haemochromatosis (HH; see also p. 445) is an inherited disease characterized by excess iron deposition in various organs, leading to eventual fibrosis and functional organ failure. There are four main types of inherited disorders:

- **type 1** HFE: the *HFE* gene (mutation C282Y) is the most common and is on chromosome 6
- **type 2A**: juvenile *HJV* gene (mutation G320V)
  - type 2B: juvenile *HAMP* gene (mutation 93delG)
- **type 3** Tfr2: the *TfR2* gene (mutation Y250X)
- **type 4** ferroportin: the *SLC40A1* gene (mutation V162del).

  - All are transmitted by an autosomal recessive gene, apart from the ferroportin iron overload, which is dominantly transmitted.
  - HH has a prevalence in Caucasians (homozygotes) of 1 in 400, but very variable phenotypic expression and a heterozygote (carrier) frequency of 1 in 10. It is the most common single-gene disorder in Caucasians.

### Aetiology

Between 85% and 90% of patients with overt HH are homozygous for the Cys 282 Tyr (C282Y mutation): that is, type 1 *HFE*. A second mutation (His 63 Asp, H63D) occurs in about 25% of the population and is in complete linkage disequilibrium with Cys 282 Tyr.

Another form of haemochromatosis (type 3) occurs in southern Europe and is associated with Tfr2, a transferrin receptor isoform. The other types, ferroportin-related (type 4) and juvenile forms (types 2A and 2B), are much rarer.

Dietary intakes of iron and chelating agents (ascorbic acid) may be relevant. Iron overload may be present in alcoholics; alcohol excess *per se* does not cause HH, although there is a history of excess alcohol intake in 25% of patients.

### Mechanism of damage

The *HFE* gene protein interacts with the transferrin receptor 1, which is a mediator in intestinal iron absorption (see Fig. 16.8). Iron is taken up by the mucosal cells inappropriately, exceeding the binding capacity of transferrin.

Hepcidin, a protein synthesized in the liver (Fig. 14.27), is central to the control of iron absorption; it is increased in iron deficiency states and decreased with iron overload. The
mutations described above disrupt hepcidin expression, thereby internalizing ferroportin and leading to uninhibited iron overload.

**FIGURE 14.27** The circulation of iron from the duodenal enterocyte to and from the liver, red cells and reticuloendothelial macrophages. Some 1–2 g of iron is absorbed from the intestine (see Fig. 16.8) and circulates bound to transferrin. The reticuloendothelial cells clear old erythrocytes and release iron to circulate and be stored as ferritin in the liver. The liver is the major site of production of the peptide hormone, hepcidin. Hepcidin blocks release of iron from the erythrocytes and macrophages by degrading the iron exporter transferrin. Fe, iron. (Modified from Fleming RE, Ponka P. Iron overload in human disease. N Engl J Med 2012; 366:348–359, with permission.)

Hepatic expression of the hepcidin gene is decreased in HFE haemochromatosis, facilitating liver iron overload. Excess iron is then gradually taken up by the liver and other tissues over a long period. It seems likely that it is the iron itself that precipitates fibrosis.

**Pathology**

In symptomatic patients, the total body iron content is 20–40 g, compared with 3–4 g in a normal person. The iron content is particularly increased in the liver (Fig. 14.28) and pancreas (50–100 times normal) but is also increased in other organs (e.g. the endocrine glands, heart and skin).
In established cases, the liver shows extensive iron deposition and fibrosis. Early in the disease, iron is deposited in the periportal hepatocytes (in pericanalicular lysosomes). Later, it is distributed widely throughout all acinar zones, biliary duct epithelium, Kupffer cells and connective tissue. Cirrhosis is a late feature.

**Clinical features**

The course of the disease depends on a number of factors, including gender, dietary iron intake, presence of associated hepatotoxins (especially alcohol) and genotypes. Overt clinical manifestations occur more frequently in men; the reduced incidence in women is probably explained by physiological blood loss and a smaller dietary intake of iron. Most affected individuals present in the fifth decade. The classic triad of bronze skin pigmentation (due to melanin deposition), hepatomegaly and diabetes mellitus is present only in cases of gross iron overload.

Hypogonadism secondary to pituitary dysfunction is the most common endocrine feature. Deficiency of other pituitary hormones is also found, but symptomatic endocrine deficiencies, such as loss of libido, are very rare. Cardiac manifestations, particularly heart failure and arrhythmias, are common, especially in younger patients. Calcium pyrophosphate is deposited asymmetrically in both large and small joints (chondrocalcinosis), leading to an arthropathy. The exact relationship of chondrocalcinosis to iron deposition is uncertain.

**Complications**

Some 30% of people with cirrhosis will develop primary hepatocellular carcinoma (HCC; *Fig. 14.29*). HCC has been described only very rarely in non-cirrhotic patients in whom the excess iron stores have been removed. Early diagnosis is vital.
**Investigations**

**Homozygotes**

• **Serum iron** is elevated (>30 µmol/L) in 90% with a reduction in the TIBC and a transferrin saturation of >45%.
• **Serum ferritin** is elevated (usually >500 µg/L or 240 nmol/L).
• **Liver biochemistry** is often normal, even with established cirrhosis.

**Heterozygotes**

Heterozygotes may have normal biochemical tests or modest increases in serum iron transferrin saturation (>45%) or serum ferritin (usually >400 µg/L).

**Genetic testing**

If iron studies are abnormal, genetic testing is performed.

**Liver biopsy**

This is not required for diagnosis, but is useful to establish the extent of tissue damage, assess tissue iron, and measure the hepatic iron concentration (>180 µmol/g dry weight of liver indicates haemochromatosis).

Mild degrees of parenchymal iron deposition in patients with other forms of cirrhosis, particularly if due to alcohol, can often cause confusion with true homozygous HH.

**Magnetic resonance imaging**

MRI shows a dramatic reduction in the signal intensity of the liver and pancreas owing to the paramagnetic effect of ferritin and haemosiderin. A highly T2-weighted, gradient recalled echo (GRE) technique detects all clinically relevant liver iron overload (>60 µmol/g of liver). In secondary iron overload (haemosiderosis), which involves the reticuloendothelial cells, the
pancreas is spared, enabling distinction between these two conditions.

## Management

### Venesection

This prolongs life and may reverse tissue damage; the risk of malignancy still remains if cirrhosis is present. All patients should have excess iron removed as rapidly as possible. This is achieved using venesection of 500 mL performed twice weekly for up to 2 years, i.e. 160 units with 250 mg of iron per unit, which equals 40 g removed. During venesection, serum iron and ferritin and the mean corpuscular volume (MCV) should be monitored. These fall only when available iron is depleted. Three or four venesections per year are required to prevent re-accumulation of iron. Serum ferritin should remain within the normal range.

Manifestations of the disease usually improve or disappear, except for diabetes, testicular atrophy and chondrocalcinosis. The requirements for insulin often diminish in diabetic patients. Testosterone replacement is often helpful.

In the rare patient who cannot tolerate venesection (because of severe cardiac disease or anaemia), chelation therapy with desferrioxamine, either intermittently or continuously by infusion, has been successful in removing iron.

## Screening

In all cases of HH, all first-degree family members must be screened to detect early and asymptomatic disease. HFE mutation analysis is performed with measurement of transferrin saturation and serum ferritin.

In the general population, serum iron and transferrin saturation are the best and cheapest tests available.

### Wilson's disease (progressive hepatolenticular degeneration)

Dietary copper is normally absorbed from the stomach and upper small intestine. Copper is transported to the liver loosely bound to albumin; in the liver, it is incorporated into apoceruloplasmin, forming caeruloplasmin, a glycoprotein synthesized in the liver, and secreted into the blood. The remaining copper is normally excreted in the bile and excreted in faeces.

Wilson's disease is a very rare inborn error of copper metabolism that results in copper deposition in various organs, including the liver, the basal ganglia of the brain and the cornea. It is potentially treatable and all young patients with liver disease must be screened for this condition.

## Aetiology

Wilson's disease is an autosomal recessive disorder with a molecular defect within a copper-
transporting ATPase encoded by a gene (designated ATP7B) located on chromosome 13. It affects between 1 in 30,000 and 1 in 100,000 individuals. Over 300 mutations have been identified, the most frequent being His 1069 Gly (H1069Q), found in approximately 50% of Caucasian patients; compound heterozygotes are common. This mutation is rare in India and Asia. Wilson's disease occurs worldwide, particularly in countries where consanguinity is common. There is a failure of both incorporation of copper into procaeruloplasmin, which leads to low serum caeruloplasmin, and biliary excretion of copper. There is a low serum caeruloplasmin in over 80% of patients but this is not the cause of the copper deposition. The precise mechanism for the failure of copper excretion is not known.

Pathology

The liver histology is not diagnostic and varies from that of chronic hepatitis to macronodular cirrhosis. Stains for copper show a periportal distribution but this can be unreliable (see below). The basal ganglia are damaged and show cavitation, the kidneys show tubular degeneration, and erosions are seen in bones.

Clinical features

Children usually present with hepatic problems, whereas young adults have more neurological problems, such as tremor, dysarthria, involuntary movements and eventually dementia. The liver disease varies from episodes of acute hepatitis, especially in children (which can go on to acute hepatic failure), to chronic hepatitis or cirrhosis. Typical signs are those of chronic liver disease with neurological signs of basal ganglia involvement (see p. 855). A specific sign is the Kayser–Fleischer ring, caused by copper deposition in Descemet's membrane in the cornea. It appears as a greenish-brown pigment at the corneoscleral junction and frequently requires slit-lamp examination for identification. It may be absent in young children.

Investigations

- **Serum copper and caeruloplasmin** are usually reduced but can be normal.
- **Urinary copper** is usually increased to 100–1000 μg in 24 h (1.6–16 μmol); normal levels <40 μg (0.6 μmol).
- **Liver biopsy** aids diagnosis, which depends on measurement of the amount of copper in the liver (>250 μg/g dry weight), although high levels of copper are also found in the liver in chronic cholestasis.
- **Haemolysis and anaemia** may be present.
- **Genetic analysis** is limited but selected exons are screened according to population groups.

Management
• Lifetime treatment with **penicillamine**, 1–1.5 g daily, is effective in chelating copper. If treatment is started early, clinical and biochemical improvement can occur. Urinary copper levels should be monitored and the drug dose adjusted downwards after 2–3 years. Serious side-effects of the drug occur in 10% and include skin rashes, leucopenia, skin changes and renal damage.

• **Trientine** (1.2–1.8 g/day) and **zinc acetate** (150 mg/day) are used as maintenance therapy and for asymptomatic cases. All siblings and children of patients should be screened (*ATP7B* mutation analysis is useful) and treatment with zinc is given, even in the asymptomatic if there is evidence of copper accumulation. A diet low in copper (i.e. excluding chocolate and peanuts) is advised.

### Prognosis

Early diagnosis and effective treatment have improved the outlook. Neurological damage is, however, permanent. Acute hepatic failure or decompensated cirrhosis should be treated by liver transplantation.

### Alpha₁-antitrypsin deficiency

A deficiency of alpha₁-antitrypsin (α₁-AT; see also p. 1081) is sometimes associated with liver disease and pulmonary emphysema (particularly in smokers). Part of a family of serine protease inhibitors, or serpin superfamily, α₁-AT is a glycoprotein. Deficiency of α₁-AT is a genetic disorder and 1 in 10 northern Europeans carries an abnormal gene.

The protein is a 394-amino acid 52 kDa acute phase protein that is synthesized in the liver and constitutes 90% of the serum α₁-globulin seen on electrophoresis. Its main role is to inhibit the proteolytic enzyme, neutrophil elastase.

The gene is located on chromosome 14. The genetic variants of α₁-AT are characterized by their electrophoretic mobilities as medium (M), slow (S) or very slow (Z). The normal genotype is protease inhibitor MM (PiMM), the homozygote for Z is PiZZ, and the heterozygotes are PiMZ and PiSZ. S and Z variants are due to a single amino acid replacement of glutamic acid at positions 264 and 342 of the polypeptide, respectively. This results in decreased synthesis and secretion of the protein by the liver as protein–protein interactions occur between the reactive centre loop of one molecule and the β-pleated sheet of a second (loop sheet polymerization).

How this causes liver disease is uncertain. It is postulated that failure of secretion of the abnormal protein leads to an accumulation in the liver, causing liver damage.

### Clinical features

The majority of patients with clinical disease are homozygotes with a PiZZ phenotype. Some may present in childhood and a few require transplantation. Approximately 10–15% of adult
patients will develop cirrhosis, usually over the age of 50 years, and 75% will have respiratory problems. Approximately 5% of patients die of their liver disease. Heterozygotes (e.g. PiSZ or PiMZ) may develop liver disease but the risk is small.

**Investigations**

- **Serum α₁-antitrypsin** is low, at 10% of the normal level in the PiZZ phenotypes, and 60% of normal in the S variant.

  **Histologically**, periodic acid–Schiff (PAS)-positive, diastase-resistant globules that contain α₁-AT are seen in periportal hepatocytes. Fibrosis and cirrhosis can be present.

**Management**

There is no treatment, apart from dealing with the complications of liver disease. Patients with hepatic decompensation should be assessed for liver transplantation, and should stop smoking (see p. 1081).

**Further reading**

**Alcoholic Liver Disease**

This section describes the pathology and clinical features of alcoholic liver disease. The amounts needed to produce liver damage, alcohol metabolism, and other clinical effects of alcohol are described on pages 217–218.

Ethanol is metabolized in the liver by two pathways, resulting in an increase in the NADH/NAD ratio. The altered redox potential causes increased hepatic fatty acid synthesis with decreased fatty acid oxidation; both events lead to hepatic accumulation of fatty acid, which is then esterified to glycerides.

The changes in oxidation–reduction also impair carbohydrate and protein metabolism and are the cause of the centrilobular necrosis of the hepatic acinus that is typical of alcohol
damage. TNF-α release from Kupffer cells causes the release of reactive oxygen species, leading, in turn, to tissue injury and fibrosis.

Acetaldehyde is formed by the oxidation of ethanol, and its effect on hepatic proteins may well be a factor in producing liver cell damage. The exact mechanism of alcoholic hepatitis and cirrhosis is unknown, but since only 10–20% of people who drink heavily will develop cirrhosis, a genetic predisposition is recognized. Immunological mechanisms have also been proposed, with the release of cytokines, particularly IL-8, which is a neutrophil chemoattractant; infiltration with neutrophils is a feature of alcoholic hepatitis.

Alcohol can enhance the effects of the toxic metabolites of drugs (e.g. paracetamol) on the liver, as it induces microsomal metabolism via the microsomal ethanol oxidizing system (MEOS; see p. 217).

**Pathology**

Alcohol can produce a wide spectrum of liver disease from fatty change to hepatitis and cirrhosis.

**Fatty liver**

The metabolism of alcohol invariably produces fat in the liver (*Fig. 14.30*), mainly in zone 3. This is minimal with small amounts of alcohol, but with larger amounts the cells become swollen with fat (steatosis). There is no liver cell damage. The fat disappears on stopping alcohol. Steatosis is also seen in non-alcoholic fatty liver disease (NAFLD) (see p. 465).

![Liver steatosis (x10)](image)

In some cases, collagen is laid down around the central hepatic veins (perivenular fibrosis) and this can sometimes progress to cirrhosis without a preceding hepatitis. Alcohol directly affects stellate cells, transforming them into collagen-producing myofibroblast cells (see p. 440).
Alcoholic hepatitis

In addition to fatty change, there is infiltration by polymorphonuclear leucocytes and hepatocyte necrosis, mainly in zone 3. Dense cytoplasmic inclusions called Mallory bodies are sometimes seen in hepatocytes and giant mitochondria are also a feature. Mallory bodies are suggestive of, but not specific for, alcoholic damage, as they can be found in other liver disease, such as Wilson's disease and primary biliary cholangitis. If alcohol consumption continues, alcoholic hepatitis may progress to cirrhosis.

Alcoholic cirrhosis

This is classically of the micronodular type but a mixed pattern is also seen accompanying fatty change, and evidence of pre-existing alcoholic hepatitis may be present.

Clinical features

Fatty liver

There are often no symptoms or signs. Vague abdominal symptoms of nausea, vomiting and diarrhoea are due to the more general effects of alcohol on the gastrointestinal tract. Hepatomegaly, sometimes huge, can occur, together with other features of chronic liver disease.

Alcoholic hepatitis

The clinical features vary in degree:

• The patient may be well, with few symptoms, the hepatitis only being apparent on the liver biopsy in addition to fatty change.

• Mild to moderate symptoms of ill-health, occasionally with mild jaundice, may occur. Signs include all the features of chronic liver disease. Liver biochemistry is deranged and the diagnosis is made on liver histology.

• In the severe case, often superimposed on alcoholic cirrhosis, the patient is ill, with jaundice and ascites. Abdominal pain is frequently present, and a high fever is associated with the liver necrosis. On examination, there is deep jaundice, hepatomegaly, sometimes splenomegaly, and ascites with ankle oedema. The signs of chronic liver disease are also present.

Alcoholic cirrhosis

This represents the final stage of liver disease from alcohol use. Nevertheless, patients can be very well with few symptoms. On examination, there are usually signs of chronic liver disease (p. 448). The diagnosis is confirmed by liver biopsy.

The patient usually presents with one of the complications of cirrhosis. In many cases, there are features of alcohol dependency (see pp. 921–922), as well as evidence of involvement of other systems, such as polyneuropathy.
Investigations

Fatty liver
An elevated MCV often indicates heavy drinking. Liver biochemistry shows mild abnormalities with elevation of both serum aminotransferase enzymes. The γ-GT level is a useful test for determining whether the patient is taking alcohol. With severe fatty infiltration, marked changes in all liver biochemical parameters can occur. Ultrasound or CT will demonstrate fatty infiltration, as will liver histology. Elastography (p. 446) can be used to estimate the degree of fibrosis.

Alcoholic hepatitis
Investigations show a leucocytosis with markedly deranged liver biochemistry and elevated:
- serum bilirubin
- serum AST and ALT
- serum alkaline phosphatase
- prothrombin time.

A low serum albumin may also be found. Rarely, hyperlipidaemia with haemolysis (Zieve syndrome) may occur.

Liver biopsy, if required, is performed by the transjugular route because of the prolonged prothrombin time.

Alcoholic cirrhosis
Investigations are as for cirrhosis in general.

Management and prognosis

General management
All patients should stop drinking alcohol. Delirium tremens (a withdrawal symptom) is treated with diazepam. Intravenous thiamine should be given empirically to prevent Wernicke–Korsakoff encephalopathy. Bed rest is necessary, along with a diet high in protein and vitamin supplements. Dietary protein sometimes needs to be limited because of encephalopathy. Patients must be advised to participate in alcohol cessation programmes. The likelihood of abstention is dependent on many factors, particularly social and family ones.

Fatty liver
The patient is advised to stop drinking alcohol; the fat will disappear and the liver biochemistry usually returns to normal. Small amounts of alcohol can be drunk subsequently, as long as patients are aware of the problems and can control their consumption.
Alcoholic hepatitis

In severe cases, the patient requires admission to hospital. Nutrition must be maintained with enteral feeding, if necessary, and vitamin supplementation given. Steroid therapy has been widely used in patients with a discriminant function score of >32 but a recent multicentre UK study, which included over 1000 patients, suggested that there was no survival benefit.

**Discriminant function (DF)**

\[
DF = [4.6 \times \text{prothrombin time above control in seconds}] \\
+ \text{bilirubin (mg/dL)}
\]

\[
\text{Bilirubin mmol/L ÷ 17 to convert to mg/dL.}
\]

Severe = >32.

The response to steroid therapy can also be evaluated by the Lille score (>0.45 indicates poor response to steroids, which can therefore be stopped) and the Glasgow score (Boxes 14.21 and 14.22). A Glasgow score of >9 indicates that steroids are necessary because at >9 the 28-day mortality is 75%, while at <9 it is 50%. The MELD score (see p. 467) is also used but does not indicate which patients need steroid therapy.

### Box 14.21

**Lille score for alcoholic hepatitis**

*(Calculator at http://www.lillemodel.com)*

\[ R = 3.19 - (0.101 \times \text{age in years}) + (0.147 \times \text{albumin on admission in g/L}) + (0.0165 \times \text{change in bilirubin level from day 0 to day 7 in µmol/L}) - (0.206 \times \text{renal insufficiency [0 if absent, 1 if present]}^a) - (0.0065 \times \text{bilirubin day 0 in µmol/L}) - (0.0096 \times \text{INR}) \]

A score of <0.16 indicates a 96% chance of survival at 28 days; ≥0.56 indicates a 55% chance of survival at 28 days.

Score = EXP(−R)/(1+EXP(−R)]

*aCreatinine >115 µmol/L.

Poor prognosis = total score >9.

INR, International Normalized Ratio.

Infection must be excluded or concomitantly treated. Treatment for encephalopathy and ascites is commenced. Antifungal prophylaxis should also be used.

Patients are advised to stop drinking for life, as this is undoubtedly a pre-cirrhotic condition. The prognosis is variable and, despite abstinence, the liver disease is progressive in many patients. Granulocyte-colony stimulating factor (G-CSF) for 5 days improves 90-day survival in preliminary studies.

In severe cases, the mortality is at least 50%; with a prothrombin time twice normal, progressive encephalopathy and acute kidney injury, the mortality approaches 90%. Early transplantation for patients with severe alcoholic hepatitis has a survival rate of 78%, compared with 32% of those not transplanted. Unfortunately, many return to drinking.

**Alcoholic cirrhosis**

The management of cirrhosis is described on page 467. Again, all patients are advised to stop drinking for life. Abstinence from alcohol results in an improvement in prognosis, with a 5-year survival of 90%, but with continued drinking this falls to 60%. In advanced disease (i.e. jaundice, ascites and haematemesis) the 5-year survival rate falls to 35%, most of the deaths occurring in the first year. Liver transplantation results in good survival; recurrence of cirrhosis due to recidivism is rare. Patients often sign a contract with their clinicians regarding their abstinence, both before and after transplantation.

A trial of abstention to establish whether liver disease can improve is mandatory, but transplantation should not be denied if the patient continues to deteriorate. Specific follow-up regarding alcohol use is recommended.

HCC is a complication, particularly in men.

**Further reading**

**Budd–Chiari Syndrome**

In this condition, there is obstruction to the venous outflow of the liver owing to occlusion of
the hepatic vein. In one-third of patients the cause is unknown, but specific causes include hypercoagulability states (e.g. paroxysmal nocturnal haemoglobinuria, polycythaemia vera) or thrombophilia (see p. 575), taking the contraceptive pill, or leukaemia. Other causes include occlusion of the hepatic vein owing to posterior abdominal wall sarcomas, renal or adrenal tumours, hepatocellular carcinoma, hepatic infections (e.g. hydatid cyst), congenital venous webs, radiotherapy or trauma to the liver.

Clinical features

The acute form presents with abdominal pain, nausea, vomiting, tender hepatomegaly and ascites (a fulminant form occurs particularly in pregnant women). In the chronic form, there is enlargement of the liver (particularly the caudate lobe), mild jaundice, ascites, a negative hepatojugular reflux, and splenomegaly with portal hypertension.

Investigations

Investigations show a high protein content in the ascitic fluid and characteristic liver histology with centrilobular congestion, haemorrhage, fibrosis and cirrhosis. Ultrasound, CT or MRI will demonstrate hepatic vein occlusion with diffuse abnormal parenchyma on contrast enhancement. The caudate lobe is spared because of its independent blood supply and venous drainage. There may be compression of the inferior vena cava. Pulsed Doppler sonography or colour Doppler is useful, as it shows abnormalities of flow in the hepatic vein. Thrombophilia screening is mandatory. Multiple defects of coagulation occur. Thrombosis of the portal vein is present in 2% of patients.

Differential diagnosis

A similar clinical picture can be produced by inferior vena caval obstruction, right-sided cardiac failure or constrictive pericarditis, and appropriate investigations should be performed.

Management

In the acute situation, thrombolytic therapy can be given. Ascites should be treated, as should any underlying cause (e.g. polycythaemia). Congenital webs should be treated radiologically or resected surgically. A TIPS is the treatment of choice, as caval compression does not prejudice the efficacy of TIPS. Surgical portocaval shunts are reserved for those who fail this treatment, providing there is no caval obstruction or severe caval compression when a caval stent can be inserted. Liver transplantation is the first-choice treatment for chronic Budd–Chiari syndrome and for the fulminant form. Life-long anticoagulation is mandatory following TIPS and transplantation.
**Prognosis**

The prognosis depends on the aetiology but some patients can survive for several years.

**Further reading**

**Hepatic Sinusoidal Obstruction Syndrome**

Hepatic sinusoidal obstruction syndrome (SOS; previously known as veno-occlusive disease) is due to injury of the hepatic veins and presents clinically like the Budd–Chiari syndrome. It was originally described in Jamaica, where the ingestion of toxic pyrrolizidine alkaloids in bush tea (made from plants of the genera *Senecio*, *Heliotropium* and *Crotalaria*) caused damage to the hepatic veins. It can be seen in other parts of the world. It also occurs as a complication of chemotherapy and total body irradiation, used before allogeneic bone marrow transplantation. The development of SOS after bone marrow transplantation carries a high mortality. Treatment is supportive, with control of ascites and hepatocellular failure. TIPS has been used in a few cases. Defibrotide is recommended for prophylactic use before bone marrow transplantation in children and adults with a high risk of SOS (e.g. pre-existing hepatic disease or prior treatment with gemtuzumab ozogamicin).

**Fibropolycystic Diseases**

These diseases are usually inherited and lead to the presence of cysts or fibrosis in the liver, kidney and occasionally the pancreas, and other organs.

**Polycystic disease of the liver**

Multiple cysts can occur in the liver as part of autosomal dominant polycystic disease of the kidney (see pp. 789–790). These cysts are usually asymptomatic but occasionally cause abdominal pain and distension. Liver function is normal and complications such as oesophageal varices are very rare. The prognosis is excellent and depends on the kidney disease.

**Solitary cysts**

These are usually found by chance during imaging and are mainly asymptomatic.

**Congenital hepatic fibrosis**
In this rare condition, the liver architecture is normal but there are broad collagenous fibrous bands extending from the portal tracts. Congenital hepatic fibrosis is often inherited as an autosomal recessive condition but can also occur sporadically. It usually presents in childhood with hepatosplenomegaly, and portal hypertension is common. It may present later in life and can be misdiagnosed as cirrhosis.

A wedge biopsy of the liver may be required to confirm the diagnosis. The outlook is good and the condition should be distinguished from cirrhosis. Patients who bleed do well after endoscopic therapy of varices (or a portocaval anastomosis) because of their good liver function.

### Congenital intrahepatic biliary dilatation (Carolli's disease)

In this rare, non-familial disease there are saccular dilatations of the intrahepatic or extrahepatic ducts. It can present at any age (although it usually does so in childhood) with fever, abdominal pain and recurrent attacks of cholangitis with Gram-negative septicaemia. Jaundice and portal hypertension are absent. Diagnosis is by ultrasound, percutaneous transhepatic cholangiography and MRCP. There is an increased risk of biliary malignancy.

### Liver Abscess

#### Pyogenic abscess

Pyogenic abscesses are uncommon; they may be single or multiple. The most common used to be a portal pyaemia from intra-abdominal sepsis (e.g. appendicitis or perforations), but now the aetiology is not known in many cases. In the elderly, biliary sepsis is a common cause. Other causes include trauma, bacteraemia and direct extension from, for example, a perinephric abscess.

The organism found most commonly is *E. coli*. *Streptococcus milleri* and anaerobic organisms such as *Bacteroides* are often seen. Other organisms include *Enterococcus faecalis*, *Proteus vulgaris* and *Staphylococcus aureus*. Often the infection is mixed.

#### Clinical features

Some patients are not acutely ill and present with malaise lasting several days or even months. Others can present with fever, rigors, anorexia, vomiting, weight loss and abdominal pain. In these patients, a Gram-negative septicaemia with shock can occur. On examination, there may be little to find. Alternatively, the patient may be toxic, febrile and jaundiced. In such patients, the liver is tender and enlarged, and there may be signs of a pleural effusion or a pleural rub in the right lower chest.
Investigations

Patients who are not acutely ill are often investigated as a case of ‘pyrexia of unknown origin’ (PUO) and most investigations will be normal. Often, the only clue to the diagnosis is a raised serum alkaline phosphatase.

- **Serum bilirubin** is raised in 25% of cases.
- **Normochromic normocytic anaemia** may occur, usually accompanied by a polymorphonuclear leucocytosis.
- **Serum alkaline phosphatase, ESR and CRP** are often raised.
- **Serum vitamin B<sub>12</sub>** is very high, as it is stored in and subsequently released from the liver.
- **Blood cultures** are positive in only 30% of cases.

Imaging

Ultrasound is useful for detecting abscesses. A CT scan may be of value in complex and multiple lesions (*Fig. 14.31*). A chest X-ray will show elevation of the right hemidiaphragm with a pleural effusion in the severe case. Depending on age, imaging of the colon may be necessary to find the source of the infection.

![CT scan showing liver abscesses. Abscesses are shown in the right lobe of the liver (arrowed), secondary to partial biliary obstruction.](image)

Management

Aspiration of the abscess should be attempted under ultrasound control. Antibiotics should initially cover Gram-positive, Gram-negative and anaerobic organisms until the causative organism is identified.

Further drainage via a large-bore needle under ultrasound control or surgically may be necessary if resolution is difficult or slow. Any underlying cause must also be treated.

Prognosis
The overall mortality depends on the nature of the underlying pathology but has been reduced to approximately 16% with needle aspiration and antibiotics. A unilocular abscess in the right lobe has the best prognosis. Scattered multiple abscesses have a very high mortality, with only 1 in 5 patients surviving.

### Amoebic abscess

This condition occurs worldwide and must be considered in patients travelling from endemic areas. *Entamoeba histolytica* (see pp. 305–306) can be carried from the bowel to the liver in the portal venous system, leading to portal inflammation, with the development of multiple microabscesses and, eventually, single or multiple large abscesses.

Clinically, the onset is usually gradual but may be sudden. There is fever, anorexia, weight loss and malaise. There is often no history of dysentery. On examination, the patient looks ill and has tender hepatomegaly and signs of an effusion or consolidation in the base of the right side of the chest. Jaundice is unusual.

### Investigations

These are as for pyogenic abscess, plus:

- **Serological tests for amoeba** (e.g. haemagglutination, amoebic complement fixation test, ELISA). These are always positive, particularly if there are bowel symptoms; they remain positive after a clinical cure and therefore do not indicate current disease. A repeat negative test, however, is good evidence against an amoebic abscess.

- **Diagnostic aspiration of fluid** looking like anchovy sauce.

### Management

Metronidazole 800 mg three times daily is given for 10 days. Aspiration is used in patients failing to respond, in those with multiple and sometimes large abscesses, and in those with abscesses in the left lobe of the liver or impending rupture.

### Complications

Complications include rupture, secondary infection and septicaemia.

### Other Infections of the Liver

#### Schistosomiasis

*Schistosoma mansoni* and *S. japonicum* affect the liver, but *S. haematobium* rarely does so (see also pp. 312–314). During their life cycle, the ova reach the liver via the venous system and obstruct the portal branches, producing granulomas, fibrosis and inflammation, but not
clinically, there is hepatosplenomegaly and portal hypertension, which is particularly severe with *S. mansoni*. In Egypt, there is frequently concomitant chronic hepatitis C infection.

Investigations show a raised serum alkaline phosphatase, and ova can be found in the stools (centrifuged deposits) and in rectal and liver biopsies. Skin tests and other immunological tests often give false results and may also be positive because of past infection.

**Management**

Treatment is with praziquantel, but fibrosis still remains with a potential risk of portal hypertension, characteristically pre-sinusoidal due to intense portal fibrosis.

**Hydatid disease**

Cysts caused by *Echinococcus granulosus* are single or multiple. They usually occur in the lower part of the right lobe. The cyst has three layers: an outside layer derived from the host, an intermediate laminated layer, and an inner germinal layer that buds off brood capsules to form daughter cysts (see also pp. 315–316).

**Clinical features and investigations**

Clinically, there may be no symptoms or there may be a dull ache and swelling in the right hypochondrium.

Investigations show a peripheral eosinophilia in 30% of cases and usually a positive hydatid complement fixation test or haemagglutination (85%). Plain abdominal X-ray may show calcification of the outer coat of the cyst. Ultrasound and CT scan demonstrate cysts and may show diagnostic daughter cysts within the parent cyst (*Fig. 14.32*).
**Management**

Medical treatment (e.g. with albendazole 10 mg/kg, which penetrates into large cysts) results in cysts becoming smaller. Puncture, aspiration, injection, re-aspiration (PAIR) has been used since the 1980s. Fine-needle aspiration is undertaken under ultrasound control with chemotherapeutic cover. Surgery can be performed with removal of the cyst intact, if possible, after first sterilizing the cyst with alcohol, saline or cetrimide. Chronic calcified cysts can be left; there have been no well-designed clinical trials for any therapy.

**Complications and prognosis**

These include rupture into the biliary tree or other organs, or intraperitoneally, with spread of infection. The prognosis without any complications is good, although there is always a risk of rupture. _Preventative measures_ include deworming of pet dogs and preventing pets from eating infected carcasses, as well as veterinary control programmes.

_Echinococcus multilocularis_ causes alveolar echinococcosis and is almost exclusively a hepatic disease, with a high mortality if not treated. Early diagnosis enables radical surgery and then continued chemosuppression.

**Acquired immunodeficiency syndrome**

The liver is often involved in AIDS and is a significant cause of morbidity or mortality. HIV (see also pp. 331–355) itself is not the cause of the liver abnormalities. Clinical hepatomegaly is common (60% of patients). The following are seen, although less frequently in areas where anti-retroviral therapy (ART) is available:

- _Pre-existing/coincidentual viral hepatitis_. The hepatitis (HBV, HCV, HDV) progresses more
rapidly and is a leading cause of death.

- **Neoplasia.** Kaposi’s sarcoma and non-Hodgkin's lymphoma may be seen, and there is an increased risk of HCC.

- **Opportunistic infection** (e.g. *Mycobacterium tuberculosis*, *M. avium-intracellulare*, *Cryptococcus*, *Candida albicans*, toxoplasmosis).

- **Drug hepatotoxicity.**

- **Secondary sclerosing cholangitis** (see p. 350).

- **Non-cirrhotic portal hypertension** associated with anti-retroviral therapy.

---

**Liver Disease in Pregnancy**

See pages 1303–1304.

**Liver Tumours**

**Secondary liver tumours**

The most common liver tumour is a secondary (metastatic) tumour, particularly from the gastrointestinal tract (from the distribution of the portal blood supply), breast or bronchus. Secondary liver tumours are usually multiple.

---

**Clinical features**

These are variable but usually include weight loss, malaise, upper abdominal pain and hepatomegaly, with or without jaundice.

---

**Diagnosis**

Ultrasound is the primary investigation, with CT or MRI to define metastases and look for a primary. The serum alkaline phosphatase is almost invariably raised.

---

**Management**

This will depend on the site of the primary and the burden of liver metastases. The best results are obtained in colorectal cancer in patients with few hepatic metastases. If the primary tumour is removed and hepatic resection is performed, reasonable survival rates are possible. Chemotherapy is used, particularly with breast cancer (see p. 634). Radiofrequency ablation of
the metastases is an alternative to surgery. Thermal therapy and cryotherapy are also used.

**Primary malignant tumours**

Primary liver tumours may be benign or malignant, but the most common are malignant.

**Hepatocellular carcinoma**

Hepatocellular carcinoma (HCC) is the fifth most common cancer worldwide.

**Aetiology**

Carriers of HBV and HCV have an extremely high risk of developing HCC. In areas where HBV is prevalent, 90% of patients with this cancer are positive for HBV. Cirrhosis is present in approximately 80% of these patients. The development of HCC is related to the integration of viral HBV DNA into the genome of the host hepatocyte (see p. 456), and to the degree of viral replication (>10,000 copies/mL). The risk of HCC in HCV is higher than in HBV (even higher with both HBV and HCV), despite no viral integration. Unlike HBV infection, cirrhosis is always present in HIV. Primary liver cancer is also associated with other forms of cirrhosis, such as alcoholic cirrhosis, non-alcoholic fatty liver disease (NAFLD)-associated cirrhosis, and haemochromatosis. Males are affected more than females. Other aetiological factors are aflatoxin (a metabolite of a fungus found in groundnuts) and androgenic steroids, and there is a weak association with the contraceptive pill.

**Pathology**

The tumour either is single or occurs as multiple nodules throughout the liver. Histologically, it consists of cells resembling hepatocytes. It can metastasize via the hepatic or portal veins to the lymph nodes, bones and lungs.

**Clinical features**

The clinical features include weight loss, anorexia, fever, an ache in the right hypochondrium and ascites. The rapid development of these features in a cirrhotic patient is suggestive of HCC. On examination, an enlarged, irregular, tender liver may be felt. Increasingly, due to surveillance, HCC is found without symptoms in patients with cirrhosis.

**Investigations**

- Routine liver biochemistry, full blood count, urea and electrolytes.
- **Serum α-fetoprotein** may be raised, but is normal in at least a third of patients.
- **Ultrasound** scans show filling defects in 90% of cases.
• **Enhanced CT scans** (*Fig. 14.33*) identify HCC but it is difficult to confirm the diagnosis in lesions smaller than 1 cm. An MRI can help to delineate lesions further.

![CT scan of liver with arrow pointing to lesion](image)

**FIGURE 14.33** Hepatocellular carcinoma. A. CT showing cirrhosis with a hepatocellular carcinoma (arrowed). B. T2-weighted MRI of the liver following gadolinium contrast showing a hepatocellular carcinoma.

• **Tumour biopsy** (see *Fig. 14.29*), particularly under ultrasonic guidance, is now used less frequently for diagnosis as imaging techniques show characteristic appearances (hypervascularity of the nodule and lack of portal vein washout) and because seeding along the biopsy tract can occur.
Management and prognosis
See page 638.

Prevention
Persistent HBV infection, usually acquired after perinatal infection, is a high risk factor for HCC in many parts of the world, such as South-east Asia. Widespread vaccination against HBV is being used and this has reduced the annual incidence of HCC in Taiwan.

Cholangiocarcinoma
Cholangiocarcinomas are increasing in incidence and can be extrahepatic (see p. 498) or intrahepatic (see p. 638). Intrahepatic adenocarcinomas arising from the bile ducts account for approximately 10% of primary tumours of the liver and biliary tract. They are not associated with cirrhosis or hepatitis B. In the Far East, they may be associated with infestation with *Clonorchis sinensis* or *Opisthorchis viverrini*. The clinical features are similar to those of primary HCC, except that jaundice is frequent with hilar tumours, and cholangitis is more common. There is an increased association with inflammatory bowel disease and primary sclerosing cholangitis (see pp. 476–477).

Surgical resection is rarely possible and patients usually die within 6 months. Transplantation is contraindicated, outside of specialized protocols.

Benign tumours
The most common benign tumour is a haemangioma. It is usually small and single but can be multiple and large. Haemangiomas are usually found incidentally on ultrasound, CT or MRI, and have characteristic appearances. They require no treatment.

Hepatic adenomas are associated with oral contraceptives. They can present with abdominal pain or intraperitoneal bleeding. Resection is required only for symptomatic patients, those with tumours >5 cm in diameter, and in those in whom discontinuation of oral contraception does not result in shrinkage of the tumour. Immunohistochemical characteristics are helpful in indicating malignant potential, which is far more common in men.

Miscellaneous Conditions of the Liver
**Hepatic mitochondrial injury syndromes**

These syndromes – in which there is mitochondrial damage with inhibition of β-oxidation of fatty acids – can be categorized as having the following causes:

- **Genetic**, with abnormalities that include medium-chain acyl-coenzyme A dehydrogenase deficiency, leading to microsteatosis.

- **Toxins** leading to liver failure, which include aflatoxin and cerulide (produced by *Bacillus cereus*); the latter causes food poisoning (see p. 277).

- **Drugs** (e.g. i.v. tetracycline, valproic acid and nucleoside reverse-transcriptase inhibitors), which can produce a fatal microsteatosis.

- **Idiopathic**, the best known being fatty liver of pregnancy (see p. 1304) and Reye syndrome. The latter, caused by inhibition of β-oxidation and uncoupling of oxidative phosphorylation in mitochondria, leads in children to an acute encephalopathy and diffuse microvesicular fatty infiltration of the liver. Aspirin ingestion and viral infections have been implicated as precipitating agents. Mortality is about 50%, usually due to cerebral oedema.

**Idiopathic adult ductopenia**

This unexplained condition is characterized by pruritus and cholestatic jaundice. Histology of the liver shows a decrease in intrahepatic bile ducts in at least 50% of the portal tracts, together with the features of cholestasis and marked fibrosis or cirrhosis. In most, the disease is progressive and the only treatment is liver transplantation.

**Indian childhood cirrhosis**

This condition of children is seen in the Indian subcontinent. The cause is unknown. Eventually, there is development of a micronodular cirrhosis with excess copper in the liver.

**Hepatic porphyrias**

These are dealt with on page 1290.

**Cystic fibrosis**

Cystic fibrosis (see also pp. 1088–1089) mainly affects the lung and pancreas, but patients can develop fatty liver, cholestasis and cirrhosis. The aetiology of the liver involvement is unclear.

**Coeliac disease**

Abnormal liver biochemical tests are common in coeliac disease (see also p. 396) and return to normal with a gluten-free diet. A tissue transglutaminase test should be performed if hepatic
causes are not found when investigating abnormal liver biochemistry.

**Drugs and the Liver**

**Drug metabolism**

The liver is the major site of drug metabolism. Drugs are converted from fat-soluble to water-soluble substances that can be excreted in the urine or bile. This metabolism of drugs is mediated by a group of mixed-function enzymes (see p. 19).

**Drug hepatotoxicity**

Many drugs impair liver function. When abnormal liver biochemical tests are found, drugs should always be considered as a cause, particularly when other causes have been excluded. Damage to the liver by drugs is usually classified as being either predictable (or dose-related) or non-predictable (not dose-related) (see p. 22). However, there is considerable overlap and at least **six mechanisms may be involved in the production of damage**:  
1. disruption of intracellular calcium homeostasis  
2. disruption of bile canalicular transport mechanisms  
3. formation of non-functioning adducts (enzyme–drug), which may then lead to  
4. presentation on the surface of the hepatocyte as new immunogens (attacked by T cells)  
5. induction of apoptosis  
6. inhibition of mitochondrial function, which prevents fatty acid metabolism and accumulation of both lactate and reactive oxygen species.

The predominant mechanism or combination of mechanisms determines the type of liver injury: that is, hepatitic, cholestatic or immunological (skin rashes, fever and arthralgia, i.e. serum-sickness syndrome). Eosinophilia and circulating immune complexes and antibodies are occasionally detected.

When a small amount of hepatotoxic drug whose effect is dose-dependent (e.g. paracetamol) is ingested, a large proportion of it undergoes conjugation with glucuronide and sulphate, while the remainder is metabolized by microsomal enzymes to produce toxic derivatives that are immediately detoxified by conjugation with glutathione. If larger doses are ingested, the former pathway becomes saturated and the toxic derivative is produced at a faster rate. Once the hepatic glutathione is depleted, large amounts of the toxic metabolite accumulate and produce damage (see p. 79).

The ‘predictability’ of drugs to produce damage can, however, be affected by metabolic events preceding their ingestion. For example, chronic alcohol users may become more susceptible to liver damage because of the enzyme-inducing effects of alcohol, or ill or starving patients may become susceptible because of the depletion of hepatic glutathione produced by starvation. Many other factors, such as environmental or genetic effects, may be involved in determining the ‘susceptibility’ of certain patients to certain drugs.

The incidence of drug hepatotoxicity is 14 per 100 000 population with a 6% mortality. It is
the most common cause of acute liver failure in the USA. Liver transplantation is used.

**Hepatitic damage**

The type of damage produced by various drugs is shown in *Box 14.23*. Most reactions occur within 3 months of starting the drug. Monitoring liver biochemistry in patients on long-term treatment, such as anti-tuberculosis therapy, is *mandatory*. If a drug is suspected of causing hepatic damage, it should be stopped immediately. Liver biopsy is of limited help in confirming the diagnosis, but occasionally, hepatic eosinophilia or granulomas may be seen. Diagnostic challenge with subtherapeutic doses of the drug is sometimes required after the liver biochemistry has returned to normal, to confirm the diagnosis.

NSAID, non-steroidal anti-inflammatory drug. Note: Anti-HIV drugs, e.g. maraviroc, cause hepatic dysfunction.
Individual drugs

**Paracetamol**
In high doses, paracetamol produces liver cell necrosis (see above). The toxic metabolite binds irreversibly to liver cell membranes. Overdosage is discussed on pages 79–80.

**Volatile liquid anaesthetics**
Halothane, which was the first available drug in this class, is now not used in the UK because it produced hepatitis in patients with repeated exposures. Both sevoflurane and isoflurane also cause hepatotoxicity in those patients sensitized to halogenated anaesthetics; however, the risk is smaller than with halothane and remote with desflurane.

**Steroid compounds**
Cholestasis is caused by natural and synthetic oestrogens, as well as methyltestosterone. These agents interfere with canalicular biliary flow by blocking MRP2 and MDR3 (see Fig. 14.4) and cause a pure cholestasis.

Cholestasis is rare with the contraceptive pill because of the low dosage used. However, the contraceptive pill is associated with an increased incidence of gallstones, hepatic adenomas (rarely, HCCs), the Budd–Chiari syndrome and peliosis hepatis. The latter condition, which also occurs with anabolic steroids, consists of dilatation of the hepatic sinusoids to form blood-filled lakes.

**Phenothiazines**
Phenothiazines (e.g. chlorpromazine) can produce a cholestatic picture owing to a hypersensitivity reaction. This occurs in 1% of patients, usually within 4 weeks of starting the drug. Typically, it is associated with a fever and eosinophilia. Recovery occurs on stopping the drug.

**Anti-tuberculous chemotherapy**
Isoniazid produces elevated aminotransferases in 10–20% of patients. Hepatic necrosis with jaundice occurs in a smaller percentage. The hepatotoxicity of isoniazid is related to its metabolites and is dependent on acetylator status. Rifampicin produces hepatitis, usually within 3 weeks of starting the drug, particularly in patients on high doses. Pyrazinamide produces abnormal liver biochemical tests and, rarely, liver cell necrosis.

**Amiodarone**
This leads to a steatohepatitis histologically, and liver failure if the drug is not stopped in time.

**Sodium valproate**
This causes mitochondrial injury with microvesicular steatosis. Intravenous carnitine should be used as an antidote.
Drug prescribing for patients with liver disease

The metabolism of drugs is impaired in severe liver disease (with jaundice and ascites), as the removal of many drugs depends on liver blood flow and the integrity of the hepatocyte. In general, therefore, the effect of drugs is prolonged by liver disease and also by cholestasis. This is further accentuated by portosystemic shunting, which diminishes the first-pass extraction of drugs. With hypoproteinaemia, there is decreased protein binding of some drugs, and bilirubin competes with many drugs for the binding sites on serum albumin. In patients with portosystemic encephalopathy, care must be taken in prescribing drugs with a central depressant action, such as narcotics, including codeine and anxiolytics. Other common drugs to be avoided in cirrhosis include angiotensin-converting enzyme (ACE) inhibitors (which cause hepatorenal failure) and NSAIDs (which cause bleeding).

Bibliography

Introduction

Biliary and pancreatic disease are a major burden on healthcare systems worldwide. In the West, acute pancreatitis and gallstone disease are the two most common gastrointestinal causes of urgent hospital admission. Pancreatic and biliary tree neoplasms carry a poor prognosis, pose significant diagnostic challenges and are increasing in incidence.

Current ultrasound, computed tomography (CT) and magnetic resonance imaging (MRI) technology enable the biliary tree and pancreas to be visualized with increasing resolution. Widespread use of such improved imaging has led to improved diagnosis but also to a burgeoning need to characterize and manage incidental, small, often asymptomatic lesions, particularly in the pancreas.

Endoscopic diagnosis of pancreatobiliary disease has been enhanced by improvements in endoscopic ultrasound technology, and the re-emergence of direct cholangioscopy for visualization of the bile duct. Therapeutic endoscopy and laparoscopic surgery are now widely available and permit a minimally invasive approach to the management of almost all gallstone disease, and to the resection or palliation of pancreatobiliary cancer.
The Gall Bladder and Biliary System

The structure and function of the biliary system and the formation of bile are discussed on pages 441–443.

Gallstones

Gallstone disease represents a major cause of patient morbidity, particularly in the Western world, and has a major impact on healthcare economics. Gallstones may be present at any age but are unusual before the third decade. The prevalence of gallstones is strongly influenced by both age and gender. There is a progressive increase in the presence of gallstones with age but the prevalence is 2–3 times higher in women than in men, although this difference is less marked in the sixth and seventh decades. At this age, the prevalence ranges between 20% and 30%. The increase in life expectancy is reflected in an increased burden of symptomatic gallstone disease. There are considerable racial differences, gallstones being more common in Scandinavians, South Americans and Native North Americans but less common in Asian and African groups. These racial differences may reflect both genetic and dietary factors. Some of these differences are being eroded by the adoption of Western diets containing high cholesterol in countries with emerging economies.

Pathogenesis

Types of gallstones

The large majority of gallstones are of two types: cholesterol stones (containing >50% of the sterol) and, less frequently, ‘pigment stones’, predominantly composed of calcium bilirubinate or polymer-like complexes with calcium, copper and some cholesterol.

Cholesterol gallstones

This type of stone accounts for 85% of gallstones in the Western world. The formation of cholesterol stones is the consequence of cholesterol crystallization from gall bladder bile. This is dependent on three factors:

• cholesterol supersaturation of bile
• crystallization-promoting factors within bile
• motility of the gall bladder.

The majority of cholesterol is derived from hepatic uptake from dietary sources. However, hepatic biosynthesis may account for up to 20%. The rate-limiting step in cholesterol synthesis is β-hydroxy-β methyl glutaryl CoA (HMG-CoA) reductase, which catalyses the first step: that is, the conversion of acetate to mevalonate.

• The cholesterol formed is co-secreted with phospholipids into the biliary canaliculus as unilamellar vesicles.
Cholesterol will only crystallize into stones when the bile is supersaturated with cholesterol relative to the bile salt and phospholipid content. This can occur as a consequence of excess cholesterol secretion into bile, which, in some instances, has been shown to be due to an increase in HMG-CoA reductase activity.

Increased secretion of cholesterol into bile has also been associated with the insulin resistance associated with the metabolic syndrome.

A high-cholesterol diet increases biliary cholesterol secretion and decreases bile salt synthesis and the bile salt pool in cholesterol gallstone subjects but not in controls.

These findings suggest that increased intestinal uptake of the sterol could play a role in gallstone pathogenesis. In support of this observation, pharmacological inhibition of cholesterol absorption prevents gallstone formation in a mouse model. Ezetimibe is a highly selective intestinal cholesterol absorption inhibitor, suppressing the uptake of dietary and biliary cholesterol across the brush border membrane of the enterocyte. This may offer a potential therapy for the management/prevention of gallstone formation in patients.

While cholesterol supersaturation of bile is essential for cholesterol stone formation, many individuals in whom such supersaturation occurs will never develop stones. It is the balance between cholesterol crystallizing and solubilizing factors that determines whether cholesterol will crystallize out of solution. A number of lipoproteins have been reported as putative crystallizing factors.

Statins are effective in the treatment of hypercholesterolaemia by competitively inhibiting HMG-CoA reductase. There is emerging evidence that statins reduce cholesterol secretion into bile and, by doing so, promote gallstone dissolution. The prevalence of gallstone disease in patient groups taking statins for the management of hypercholesterolaemia appears to be reduced.

Leptin (see p. 206) has been shown to increase cholesterol secretion into bile. Elevated levels of leptin during rapid weight loss may account for the increased incidence of cholesterol gallstones.

An alternative mechanism of supersaturation is a decreased bile salt content, which may occur as a consequence of bile salt loss (e.g. terminal ileal resection or ileal involvement with Crohn's disease).

The composition of the bile salt pool may also influence the ability to maintain cholesterol in solution. There is evidence that an increased proportion of the secondary hydrophobic bile acid (deoxycholic acid) in the bile acid pool may predispose to cholesterol stone formation. This has been linked with slow colonic transit, during which the primary bile acid, cholic acid, may undergo microbial enzyme metabolism, yielding deoxycholic acid, which is then absorbed back into the bile salt pool (see Fig. 14.4).

Evidence from epidemiological, family and twin studies points to the role of genetic factors in gallstone formation. A number of lithogenic genes have been identified, which may interact with environmental factors. The process of bile formation is maintained by a network of adenosine triphosphate-binding cassette (ABC) transporters in the hepatocyte canalicular membrane, which enables biliary secretion of cholesterol, bile salts and phospholipids. This
process is regulated by the nuclear receptors farnesoid x receptor (FXR) and liver x receptor (LXR). Loss-of-function mutations in specific ABC transporter genes have been associated with cholesterol gallstones secondary to bile salt and phospholipid deficiencies within the nascent bile (Fig. 15.1). However, monogenic susceptibility appears uncommon. There are rare cases in which a single missense mutation of the multidrug-resistant (MDR3) gene has been associated with extensive intra- and extrahepatic cholelithiasis at an early age (<40 years).

**FIGURE 15.1** Nascent bile formation at the hepatocytic canalicular membrane, biliary cholesterol solubilization and gallstone formation. (a) ABCG5/G8 transports cholesterol into bile (regulated by nuclear receptor LXR). (b) ABCB11 and ABCB4 transport bile salts and phosphatidylcholine into bile (regulated by nuclear receptor FXR). (c) Bile cholesterol is solubilized in mixed micelles or contained in cholesterol– phospholipid vesicles. (d) Most gallstones are caused by excess biliary cholesterol secretion and subsequent crystallization from supersaturated vesicles (continuous lines). (e) Low phospholipid-associated cholelithiasis (LPAC) occurs if there is deficient phospholipid in bile due to function mutations in gene ABCB4. (f) Benign recurrent intrahepatic cholestasis (BRIC) type 2 is characterized by deficient bile salts in bile due to function mutations in gene ABCB11. (g) In both LPAC and BRIC type 2, there is an increased risk of gallstone formation.

**Gall bladder motility** represents a further factor that may influence the cholesterol crystallization from supersaturated bile. There is evidence from animal models that gall bladder stasis leads to cholesterol crystallization mediated by hypersecretion of mucin. Abnormalities of gall bladder motility have been suggested as factors in such circumstances as pregnancy, multiparity and diabetes, as well as octreotide-related gall bladder stones (see p.
Recognized risk factors for cholesterol gallstones are shown in Box 15.1.

**Bile pigment stones**

The pathogenesis of pigment stones is entirely independent of cholesterol gallstones. There are two main types of pigment gallstones: black and brown.

*Black pigment gallstones* are composed of calcium bilirubinate and a network of mucin glycoproteins that interlace with salts, such as calcium carbonate and/or calcium phosphate. These stones range in colour from deep black to very dark brown and have a glass-like cross-sectional surface on fracturing. Because hyperbilirubinemia is the critical risk factor, black stones are associated with all major haemolytic anaemias, such as spherocytosis, sickle cell disease and thalassaemia, and also with subclinical haemolysis from prosthetic valve replacements, malaria, hypersplenism from hepatic cirrhosis, and foot trauma in long-distance runners. An increased prevalence of black pigment gallstones is also seen in Gilbert syndrome (see p. 448), which is associated with enhanced biliary secretion of monoglucuronosyl bilirubin.

There is evidence that bile salt loss into the colon (consequent on ileal resection or ileal disease) promotes solubilization and colonic reabsorption of bilirubin. This enhances the enterohepatic circulation and biliary secretion of bilirubin with the formation of gallstones. Pigment stones have also been linked with bacterial colonization of the biliary tree. Some
pigment stones have been shown to contain bacteria, many of which produce glucuronidase and phospholipase, factors that are known to facilitate stone formation. It is speculated that this subclinical bacterial colonization of the bile duct is responsible for pigment stone formation.

**Brown pigment stones** are usually of a muddy hue and, on cross-section, seem to have alternating brown and tan layers. These stones are composed of calcium salts of fatty acids, as well as calcium bilirubinate. They are almost always found in the presence of bile stasis and/or biliary infection. Brown stones can form in any part of the biliary tree secondary to chronic stasis and the presence of anaerobic bacterial infection.

The **Oriental hepatolithiasis syndrome (recurrent pyogenic cholangitis)** is the most serious manifestation of pigment stone disease. Biliary strictures are formed, possibly due to nematode or fluke infestation within the extrahepatic and intrahepatic bile ducts. *Ascaris lumbricoides, Clonorchis sinensis* and *Opisthorchis viverrini* are the parasites most commonly recognized with this condition. The evidence for causation is unclear, as is the role of bacterial infection. Brown stones may also be the cause of recurrent bile duct stones following cholecystectomy, and are also found in the intrahepatic bile ducts in stenosing biliary disease such as Caroli syndrome and primary sclerosing cholangitis.

### Clinical features

The majority of gallstones are asymptomatic and remain so during a person's lifetime. Gallstones are increasingly detected as an incidental finding at the time of either abdominal radiography or ultrasound scanning (**Fig. 15.2**). Over a 10–15-year period, approximately 20% of these stones will be the cause of symptoms and 10% will involve severe complications. Once gallstones have become symptomatic, there is a strong trend towards recurrent complications, often of increasing severity. Gallstones do not cause dyspepsia, fat intolerance, flatulence or other vague upper abdominal symptoms.
The clinical syndromes associated with gallstones are shown in Figure 15.3.

**Biliary or gallstone colic**

Biliary colic is the term used for the pain associated with the temporary obstruction of the cystic or common bile duct by a stone usually migrating from the gall bladder. Despite the term ‘colic’, the pain of stone-induced ductular obstruction is of sudden onset, severe but constant (not like a ‘colic’), and has a crescendo characteristic. Some patients relate the symptoms to
over-indulgence with food, particularly when this has a high fat content. The most common
time of day for such an episode is in the mid-evening, lasting until the early hours of the
morning.

The initial site of pain is usually in the epigastrium but there may be a right upper quadrant
component. Radiation may occur over the right shoulder and right subscapular region.

Nausea and vomiting frequently accompany the more severe attacks. The attack may be
terminated spontaneously after a number of hours or by the administration of opiate analgesia.
More protracted pain, particularly when associated with fevers and rigors, suggests secondary
complications such as cholecystitis, cholangitis or gallstone-related pancreatitis (see below).

**Acute cholecystitis**

The initial event in acute cholecystitis is the obstruction of gall bladder emptying. In 95% of
cases, a gall bladder stone can be identified as the cause *(Fig. 15.4)*. Such obstruction results
in an increase of gall bladder glandular secretion, leading to progressive distension that, in
turn, may compromise the vascular supply to the gall bladder.

![Ultrasound scan in a patient with acute cholecystitis. There is a stone (casting an acoustic
shadow; thin arrow) impacted in the gall bladder neck, with a distended gall bladder (thick arrow) and
thickening and oedema of the gall bladder wall (dashed arrow).]

There is also an inflammatory response secondary to retained bile within the gall bladder.
Infection is a secondary phenomenon following the above vascular and inflammatory events.

The initial clinical features of an episode of cholecystitis are similar to those of biliary
colic described above. However, over a number of hours, there is progression with severe
localized right upper quadrant abdominal pain corresponding to parietal peritoneal
involvement in the inflammatory process. The pain is associated with tenderness and muscle
guarding or rigidity. This is frequently manifest by Murphy's sign, consisting of pain on taking a
deep breath when the examiner's fingers are on the approximate location of the gall bladder.
Occasionally, the gall bladder can become distended by pus (an empyema) and, rarely, an acute gangrenous cholecystitis develops, which can perforate, with generalized peritonitis.

Investigations

Biliary colic as a consequence of a stone in the neck of the gall bladder or cystic duct is unlikely to be associated with significant abnormality of laboratory tests. *Abdominal ultrasound scan* is the single most useful investigation for the diagnosis of gallstone-related disease (see *Fig. 15.2*).

Acute cholecystitis is usually associated with:

- a moderate leucocytosis
- raised inflammatory markers (e.g. C-reactive protein, CRP).
- *Serum bilirubin, alkaline phosphatase and aminotransferase levels* may be marginally elevated in the presence of cholecystitis alone, even in the absence of bile duct obstruction. More significant elevation of the bilirubin and alkaline phosphatase is in keeping with bile duct obstruction.

- *Abdominal ultrasound* has a positive predictive value of 92% and a negative predictive value of 95% in patients with a clinical history of acute cholecystitis and Murphy’s sign. Look for:
  - **Gallstones** within the gall bladder, particularly when these are obstructing the gall bladder neck or cystic duct.
  - **Focal tenderness** over the underlying gall bladder.
  - **Thickening of the gall bladder wall.** This may also be seen with hypoalbuminaemia, portal hypertension and acute viral hepatitis.

Gallstones are a common finding in an ageing population, and in the absence of specific symptoms, great care should be taken when determining whether the gallstones are responsible for the symptoms.

Differential diagnosis

Typical cases of biliary colic are usually suspected on the clinical history. The differential diagnosis includes the irritable bowel syndrome (spasm of the hepatic flexure), carcinoma of the right side of the colon, atypical peptic ulcer disease, renal colic and pancreatitis.

The differential diagnosis of acute cholecystitis includes a number of other conditions marked by severe right upper quadrant pain and fever: for example, acute episodes of pancreatitis, perforated peptic ulceration or an intrahepatic abscess. Conditions above the right diaphragm, such as basal pneumonia, as well as myocardial infarction, may mimic the clinical picture on occasion.

Management
**Cholecystectomy**

Cholecystectomy is the treatment of choice for virtually all patients with symptomatic gall bladder stones. In patients admitted with specific gallstone-related complications (see below), cholecystectomy should be carried out during the period of that admission to prevent the risk of recurrence. For those presenting with pain alone, an elective procedure can be planned but the waiting time should be minimized to avoid the high risk of recurrent symptoms (approximately 30% over 4 months) and the need for another hospital admission.

Cholecystectomy should not be performed in the absence of typical symptoms just because stones are found on investigation. There is an ongoing debate as to whether prophylactic cholecystectomy is justified in young patients found to have small stones. Such patients have a long period over which they may develop symptomatic disease and small stones are an independent risk factor for the potentially serious complication of gallstone pancreatitis. The most recent guidance available does not recommend prophylactic surgery.

The laparotomy approach to cholecystectomy has now been replaced by the laparoscopic technique. Postoperative pain is minimized with only a short period of ileus and the early ability to mobilize the patient. Laparoscopic cholecystectomy can be safely carried out on a day-care basis in an elective setting in otherwise fit patients. This has considerable cost benefits over open cholecystectomy, which is now reserved for a small proportion of patients with contraindications, such as extensive previous upper abdominal surgery, ongoing bile duct obstruction or portal hypertension.

In approximately 5% of cases, a laparoscopic cholecystectomy is converted to an open operation because of technical difficulties: in particular, adhesions in the right upper quadrant or difficulty in identifying the biliary anatomy.

**Acute cholecystitis**

The initial management is conservative, consisting of nil by mouth, intravenous fluids, opiate analgesia and intravenous antibiotics. Bacteria that are commonly associated with cholecystitis include *Escherichia coli, Bacteroides fragilis, Klebsiella, Enterococcus* and *Pseudomonas* species. Antibiotic selection is dictated by local policy and is guided by the severity of any associated sepsis. Options include extended-spectrum cephalosporins (e.g. ceftriaxone) in combination with metronidazole, piperacillin/tazobactam or imipenem/meropenem.

Cholecystectomy is usually delayed for a few days to allow the symptoms to settle but can then be carried out quite safely in the majority of cases.

When the clinical situation fails to respond to this conservative management, particularly if there is increasing pain and fever, an empyema or gangrene of the gall bladder may have occurred. In this circumstance, urgent imaging (transabdominal ultrasound or CT scan) is required to define the pathology. Surgical intervention is usually required, although a radiologically placed gall bladder drain can be used as a temporizing measure for the management of an empyema. The placement of a drain is the best option in patients who are considered unfit for early surgery (because of ongoing sepsis or significant co-morbidity).
Specific complications of cholecystectomy

These include a biliary leak, either from the cystic duct or from the gall bladder bed. Injury to the bile duct itself occurs in up to 0.5% of laparoscopic operations and may have serious long-term sequelae in the form of a bile duct stricture and secondary biliary liver injury. Injuries to the extrahepatic biliary tree are more likely with variant duct anatomy, such as a low cystic duct insertion or draining of the cystic duct into the right posterior ducts rather than the common bile duct. There is an overall mortality of 0.2% associated with cholecystectomy.

Stone dissolution and shock wave lithotripsy

These non-surgical techniques for the management of gall bladder stones are used infrequently but still have a role in a few highly selected patients who may not be fit for cholecystectomy or have declined the surgical option.

Stone dissolution

Pure or near-pure cholesterol stones can be solubilized by increasing the bile salt content of bile. Most experience is with oral ursodeoxycholic acid. The approach requires long-term therapy and the recurrence rate of gallstones is high when therapy is stopped. Additional pharmacological tools for treating cholesterol gallstones include cholesterol-lowering agents that inhibit hepatic cholesterol synthesis (statins) or intestinal cholesterol absorption (ezetimibe), or drugs acting on specific nuclear receptors involved in cholesterol and bile acid homeostasis (see p. 442).

Extracorporeal shock wave lithotripsy

A shock wave can be directed either radiologically or by ultrasound on to gall bladder stones. This technique was highly successful but only in a restricted patient population. The cystic duct requires patency for stone fragments to pass. Recurrence rates are high but may be reduced by the pharmacological approaches discussed above.

The post-cholecystectomy syndrome

This refers to right upper quadrant pain, often biliary in type, which occurs a few months after the cholecystectomy but may be delayed for a number of years. The patients often comment that the pain is identical to that for which the original operation was carried out. In many cases, this syndrome is related to a functional large bowel disorder with colonic spasm at the hepatic flexure (hepatic flexure syndrome). It may be speculated that a functional gut disorder may have been responsible for the original pain that led to the cholecystectomy. In a small proportion of patients, the pain is the result of a retained common bile duct stone; in a further subsection of patients, sphincter of Oddi dysfunction is a potential cause.

Sphincter of Oddi dysfunction (SOD)

This is a clinical syndrome of biliary or pancreatic pain and is caused by either:

- sphincter of Oddi stenosis, e.g. following prior instrumentation or passage of stones
sphincter of Oddi hypertension.

A full history of the type of pain, as well as an assessment of serum liver biochemistry and amylase during, and between, episodes of pain is performed.

**Biliary SOD**

In *type I* disease, patients have biliary-type pain with *both* raised serum bilirubin, alkaline phosphatase or aminotransferases during episodes *and* a distended common bile duct on imaging.

In *type II* disease, patients have biliary-type pain and *either* abnormal liver biochemistry during episodes *or* a distended common bile duct. In those with suspected type II SOD, sphincter of Oddi manometric studies can confirm the diagnosis and inform the decision as to whether to perform endoscopic sphincterotomy.

In *type III* disease, there is recurrent biliary-type pain but no abnormality in the liver biochemistry and a normal-calibre common bile duct.

**Management** is as follows:

- Type I SOD usually responds to endoscopic sphincterotomy.
- Type II SOD with demonstrable sphincter hypertension usually responds to endoscopic sphincterotomy.
- Type III SOD does not respond to endoscopic sphincterotomy and therefore this should not be performed.

**Pancreatic SOD**

In *type I* disease, patients have recurrent pancreatic pain, a raised serum amylase and a dilated pancreatic duct.

In *type II* disease, patients have recurrent pancreatic pain with *either* transient hyperamylasaemia *or* a dilated pancreatic duct.

In *type III* disease, patients have pain but neither an elevated amylase nor a dilated pancreatic duct.

**Management** is as follows:

- Types I and II SOD may respond to endoscopic sphincterotomy.
- Type III SOD with pain only does not respond to endoscopic sphincterotomy.

**Common bile duct stones**

The classical features of common bile duct (CBD) stones are biliary colic, fever and jaundice (acute cholangitis). This triad is present only in a minority of patients. Abdominal pain is the most common symptom and has the typical features of biliary colic (see above). Jaundice is a variable accompaniment and is almost always preceded by abdominal pain. A patient with bile duct stones may experience sequential episodes of pain, only some of which are accompanied by jaundice. In contrast to malignant bile duct obstruction, the level of jaundice associated with
CBD stones characteristically tends to fluctuate. In the elderly or immunocompromised patient, cholangitis may present with very non-specific symptoms, and only associated abnormal liver biochemistry may point to the diagnosis.

Fever is present only in a minority of cases but indicates biliary sepsis and sometimes associated septicaemia. The presence of such biliary sepsis is a significant adverse prognostic factor.

A minority of patients with bile duct stones are discovered incidentally during imaging for gall bladder disease or other intra-abdominal pathology. Some 15% of patients undergoing cholecystectomy will have stones within the bile duct that are detected only at the time of operative cholangiography. The frequency of asymptomatic bile duct stones resulting in complications is not well documented. It is likely that many such stones will pass into the duodenum without causing symptoms. However, the potential for serious complication is well recognized; in most circumstances, incidentally identified bile duct stones are removed (see below).

Examination

If the patient is examined between episodes, there may be no abnormal physical finding. During a symptomatic episode, the patient may be jaundiced with a fever and associated tachycardia. There is tenderness in the right upper quadrant, varying from mild to extremely severe.

More widespread abdominal tenderness extending from the epigastrium to the left upper quadrant, associated with distension, may indicate associated stone-related pancreatitis (see below).

Investigations

Laboratory tests

- **Full blood count** is usually normal in the presence of uncomplicated bile duct stones.
- **An elevated neutrophil count** and raised inflammatory markers (erythrocyte sedimentation rate (ESR) and CRP) are frequent accompaniments of cholangitis.
- **The raised serum bilirubin** tends to be mild and often transient. Very high concentrations of bilirubin (>200 µmol/L) almost always reflect complete bile duct obstruction.
- **Serum alkaline phosphatase and γ-glutamyl transpeptidase** are similarly elevated in proportion to the degree of hyperbilirubinaemia.
- **Aminotransferase levels** are usually mildly elevated, but with complete bile duct obstruction there may be very marked rises to 10–15 times the normal value. The alanine aminotransferase is characteristically higher than the aspartate aminotransferase. These high levels may lead to an initial misdiagnosis of a hepatic process.
- **Serum amylase levels** are often mildly elevated in the presence of bile duct obstruction but
are markedly so if stone-related pancreatitis has occurred.

• **Prothrombin time** may be prolonged if bile duct obstruction has occurred and is sustained over several days; this reflects decreased absorption of vitamin K.

**Imaging**

• **Transabdominal ultrasound** is the initial imaging technique of choice. **Bile duct obstruction** is characterized by dilatation of intrahepatic biliary radicles, which are usually readily detected by the ultrasound scan. It may, however, not be possible to identify the cause of obstruction. Stones situated in the distal CBD are poorly visualized by transabdominal ultrasound and up to 50% are missed. The detection of stones within the gall bladder is poorly predictive of the cause of bile duct obstruction. Asymptomatic gallstones are common (up to 15%) in patients who are 65 years and older. Conversely, in 5–10% of patients with bile duct stones, no calculi can be seen within the gall bladder.

• **Magnetic resonance cholangiography (MRC)** delineates the fluid column within the biliary tree and is a sensitive technique for the detection of CBD stones in the presence of a dilated duct. The technique may be less accurate in the absence of duct dilatation (see the role of endoscopic ultrasound, below) ([Fig. 15.5](#)).
• **CT scanning** is an alternative way to detect bile duct dilatation. Opaque stones are more readily identifiable within the bile duct than radiolucent cholesterol stones. CT scanning also provides a means of excluding other causes of bile duct obstruction, such as carcinoma of the head of the pancreas.

• **Endoscopic ultrasound scanning (Fig. 15.6)** has enabled high-resolution imaging of the CBD, gall bladder and pancreas, although, unlike the preceding imaging techniques, it is an
invasive procedure. The endoscopic ultrasound probe in the duodenum is in close proximity to the distal CBD and hence can identify the majority of stones at this level. This technique is particularly useful for identifying small calculi (microcalculi) in a non-dilated common bile duct.

![Endoscopic Ultrasound Scan](image)

**FIGURE 15.6** An endoscopic ultrasound scan with the probe in the first part of the duodenum. A. The gall bladder (GB) and multiple small, echo-poor stones within (microlithiasis). The patient had presented with recurrent episodes of unexplained abdominal pain. B. The common bile duct (CBD) and a stone (S) clearly identified within the lumen.

*Endoscopic retrograde cholangiography*. In experienced hands, visualization of the CBD will be successful in 98% of cases, providing good documentation of bile duct stones (*Figs 15.5* and *15.7*). However, small stones can still be missed. Endoscopic retrograde cholangiography (ERC) is an invasive procedure with recognized risks. In almost all circumstances, this is a therapeutic tool used to remove the stones that have been identified by the less invasive investigations described above.
FIGURE 15.7 An endoscopic retrograde cholangiopancreatogram (ERCP) carried out in a patient with abdominal pain, fluctuating jaundice and fever. The cholangiogram shows a dilated common bile duct (between thick arrows) and multiple stones within (arrows). These stones were removed at the time of ERCP by means of balloon and basket retrieval. Note the multiple clips to the left of the upper bile duct, that were placed at a prior laparoscopic cholecystectomy.

Differential diagnosis

Cholangitis may occur independently of gallstones in any condition associated with impaired biliary drainage. It is commonly linked with primary abnormalities of the biliary tree, such as sclerosing cholangitis and Caroli syndrome (a congenital disorder leading to ectasia/dilatation of the intrahepatic bile ducts). Cholangitis may also complicate post-traumatic or surgery-associated bile duct strictures. It is usual in malignant bile duct obstruction unless there has been prior endoscopic or surgical intervention. Jaundice may also be a feature of acute cholecystitis in the absence of bile duct stones. A stone impacted in the neck of the gall bladder (Hartmann's pouch) or the cystic duct itself may compress and obstruct the bile duct (Mirizzi syndrome). CBD stones may produce pain, but in the absence of jaundice, the differential diagnosis is that of biliary colic (see above).

Management

Acute cholangitis has a high morbidity and mortality, particularly in the elderly or those with serious co-morbidity. Successful management depends on intravenous antibiotics (as for acute cholecystitis) and urgent bile duct drainage. In most circumstances, the latter is achieved by the endoscopic retrograde approach (ERC, see above). Access to the bile duct is achieved by
sphincterotomy, and thereafter the stones can be removed by either balloon or basket catheters. In the severely ill patient, a piece of plastic tubing (termed a stent) can be inserted into the bile duct to maintain bile drainage without the need to remove the stones, hence minimizing the time required to complete the procedure. The residual stones can then be cleared and the stent removed endoscopically when the patient has recovered from the acute episode. If endoscopic drainage is not available or is prevented by an inability to access the second part of the duodenum, then a radiologically placed percutaneous biliary drain represents an alternative management option. Surgical drainage during an acute cholangitic episode has been associated with a high mortality and has been replaced by the endoscopic or percutaneous approach.

Urgent endoscopic bile duct clearance is also indicated in some patients with acute gallstone pancreatitis but only when this coexists with persisting bile duct obstruction (see below). Patients who have retained CBD stones after a previous cholecystectomy are also optimally managed by endoscopic clearance.

Patients shown to have CBD stones as well as gall bladder stones may be treated using different approaches:

**At the time of laparoscopic cholecystectomy**, which can also include exploration of the CBD via the cystic duct or via direct choledochotomy. By using these techniques, the surgeon can extract stones from the CBD. The skills and time required for bile duct exploration are considerably greater than those for laparoscopic cholecystectomy alone. This single-procedure approach minimizes the length of hospital admission. Concerns around an increased risk of bile duct injury with bile duct exploration have not been confirmed in controlled studies.

**Independently timed endoscopic approach**, either immediately before or after the cholecystectomy. Removal of CBD stones by this method is preferred in the UK. Large bile duct stones (>10 mm) may present a significant challenge to endoscopic removal. Mechanical lithotripsy facilitates stone fragmentation and removal into the duodenum. Extracorporeal shock wave stone fragmentation has been used but is not widely available. The recent increased availability of endoscopic cholangioscopy (direct visualization of the bile duct) has facilitated intraductal shock wave lithotripsy, utilizing electrohydraulic or laser probes.

**A combined laparoscopic and endoscopic approach**, in which an ERC and duct clearance are carried out under the same anaesthetic used for the laparoscopic cholecystectomy. This approach is currently receiving support, based on a shortened hospital stay and the use of only one anaesthetic.

### Complications of gallstones

- Acute cholecystitis and acute cholangitis have been discussed (see p. 492).
- Gallstone-related pancreatitis is discussed on pages 504–505.
- Gallstones can occasionally erode through the wall of the gall bladder into the intestine, giving rise to a biliary enteric fistula. Passage of a gallstone through to the small bowel can
give rise to an ileus or true obstruction.

- There is little evidence that gallstones are associated with an increased risk of adenocarcinoma of the gall bladder (see pp. 497–498).

## Miscellaneous Conditions of the Biliary Tract

### Gall bladder

There are a number of non-calculous conditions of the gall bladder, some of which have been associated with symptoms.

#### Acalculous cholecystitis

Almost 10% of gall bladders removed for biliary symptoms are shown to have chronic inflammation within the wall but an absence of gallstones. Such cases are described as acalculous cholecystitis. In many instances, the gall bladder inflammation is minor and of doubtful significance. In some cases, chemical inflammation of the gall bladder may occur from reflux of pancreatic enzymes back into the biliary tree, usually through the common channel at the ampulla of Vater. Bacterial and viral infections of the gall bladder have been recognized as a cause of acalculous cholecystitis. The decision to carry out cholecystectomy in the absence of defined gall bladder stones should be guided by the specific features of the history and by evidence of a diseased gall bladder wall on ultrasound scanning.

A distinct subtype of acalculous cholecystitis is characterized by severe necroinflammation of the gall bladder and generally occurs in an elderly and already critically ill group of patients, usually after major trauma or surgery. Around 20% of these patients develop inflammatory masses with subsequent cholestasis and jaundice; gall bladder perforation is a frequent complication. Morbidity and mortality are very high, and aggressive management of sepsis with antibiotics and cholecystostomy (percutaneous gall bladder drainage) or urgent cholecystectomy is required.

#### Cholesterolosis of the gall bladder

In cholesterolosis, cholesterol and other lipids are deposited in macrophages within the lamina propria of the gall bladder wall. These may be diffusely situated, giving a granular appearance to the gall bladder wall, or on occasion may be more discrete, giving a polypoid appearance (see below). Cholesterolosis of the gall bladder may coexist with gallstones but also occurs independently. Some degree of gall bladder cholesterolosis is found in up to 26% of laparoscopic cholecystectomy specimens, and as an incidental finding in up to 12% of autopsies in an elderly population. Interestingly, in contrast to cholelithiasis, rates are equal in men and women. It is doubtful whether isolated gall bladder cholesterolosis is a cause of symptoms.
Adenomyomatosis of the gall bladder

Adenomyomatosis is a gall bladder abnormality characterized by hyperplasia of the mucosa, thickening of the muscle wall and multiple intramural diverticula (the so-called ‘Rokitansky–Aschoff sinuses’).

The condition is usually detected as an incidental finding during investigation for possible gall bladder disease. It has been suggested that this condition is secondary to increased intraluminal gall bladder pressure but this is not proven. Gallstones frequently coexist, particularly when the adenomyomatosis is in a segmental distribution, but there is no evidence to support a direct relationship. It is unlikely that adenomyomatosis alone is a cause of biliary symptoms and it is not considered a pre-malignant state.

Chronic cholecystitis

There are no symptoms or signs that can conclusively be shown to be due to chronic cholecystitis. Symptoms attributed to this condition are vague, such as indigestion, upper abdominal discomfort or distension. There is no doubt that gall bladders studied histologically can show signs of chronic inflammation and, occasionally, a small, shrunken gall bladder is found either radiologically or on ultrasound examination. However, these findings can be seen in asymptomatic people and therefore this clinical diagnosis should not be made. Most patients with chronic right hypochondrial pain suffer from functional bowel disease (see p. 360).

Extrahepatic biliary tract

Primary sclerosing cholangitis

In up to 40% of patients with primary sclerosing cholangitis (PSC; see also pp. 476–477), the clinical course is influenced by a dominant hilar or distal biliary stricture. This is relevant in those patients who do not have established advanced liver involvement, in whom maintaining bile flow may protect the liver from secondary biliary injury. Drainage with a surgical hepaticojejunostomy has been beneficial in some cases, but outcomes of such restricted surgery in PSC are generally inferior to orthotopic liver transplantation. Repeated endoscopic balloon dilatation of the dominant stricture, with or without temporary short-term stenting, has been associated with sustained improvement in jaundice, and even prolonged transplant-free survival. A significant minority of dominant strictures in PSC, particularly those at the hilum, represent development of an associated cholangiocarcinoma (see below). Development of cholangiocarcinoma in this context carries a very poor prognosis and surgical resection is rarely feasible. A benign dominant stricture in a non-cirrhotic patient, with recurrent cholangitis, refractory jaundice and pruritus, may be an indication for orthotopic liver transplantation. Conversely, superadded cholangiocarcinoma is currently an absolute contraindication to liver transplantation in most healthcare systems.
**Autoimmune cholangitis**

Immunoglobulin (Ig) G4-associated cholangitis is the biliary manifestation of a multisystem fibroinflammatory disorder in which affected organs have a characteristic lymphoplasmacytic infiltrate rich in IgG4-positive cells (see p. 145). The original description of this condition was in the context of autoimmune pancreatitis, and around 70% of these patients have evidence of IgG4 cholangiopathy (see p. 506). However, IgG4 cholangiopathy can exist in the absence of pancreatic involvement.

The large majority of cases are recognized in middle-aged or elderly men. Presentation is varied, depending on the systems involved, but may include abdominal pain and jaundice. Both intra- and extrahepatic biliary strictures may be seen and the findings may be misinterpreted as representing cholangiocarcinoma or PSC. The diagnosis relies on clinical suspicion, confirmation of an elevated serum IgG4 level, a typical lymphocyttoplasmic infiltrate on histological examination of involved tissue, and clinical response to glucocorticosteroid treatment. The condition is almost always responsive to steroids but can lead to hepatic failure.

**Biliary cysts (choledochal malformation)**

Cystic malformations may occur anywhere in the biliary tree, although they are most commonly extrahepatic. The resulting dilatation of the bile duct may be of saccular, diverticular or fusiform configuration. In many cases, there is an associated abnormal pancreatobiliary junction – a congenital malunion where the pancreatic duct drains directly into the common bile duct. The majority of symptomatic cases present in childhood with features of cholangitis, jaundice or a palpable mass. The formation of stones and sludge within the cystic segment may predispose to acute relapsing pancreatitis. In adult life, choledochal cysts may be a differential diagnosis in patients presenting with symptoms suggestive of bile duct stones. Extrahepatic bile duct cysts must be fully resected to avoid recurrent biliary sepsis, as well as reducing the risk (approximately 15%) of subsequent cholangiocarcinoma.

**Benign bile duct strictures**

Benign strictures are a recognized complication of biliary surgery. They may result from inadvertent direct stapling of the duct, or may be a secondary consequence of ischaemic injury (often in association with a bile duct leak). Strictures may also occur at the level of any bile duct anastomosis, either enteric or duct-to-duct. Biliary stricturing is also a rare complication of major trauma to the right upper quadrant. The inflammation and fibrosis of chronic pancreatitis commonly impinges on the intrapancreatic common bile duct (see below). This can result in cholestasis, jaundice and cholangitis.

In most cases, initial therapy includes endoscopic balloon dilatation of the stricture and temporary bile duct stenting (see below). This may provide definitive management, but in some cases, surgical intervention with hepaticojejunostomy is required.
Haemobilia

Haemobilia describes blood in the biliary tree. This may be a consequence of liver trauma or a complication of liver surgery. Biopsy of the liver and erosion of a gallstone or hepatobiliary tumour into adjacent structures are also well-recognized causes. The end result is a fistula between a hepatic blood vessel and a bile duct.

Haemobilia may be a cause of significant gastrointestinal blood loss and should be suspected when melaena is accompanied by right-sided upper abdominal pain and jaundice, particularly in the context of recent hepatobiliary intervention. However, the bleeding may occur without any overt biliary symptoms. If the diagnosis is suspected, bleeding may be managed by occlusion of the feeding blood vessel by radiological embolization. Some patients will require surgery to control the bleeding point.

Tumours of the Biliary Tract

Gall bladder polyps

Polyps of the gall bladder are a common finding, being seen in approximately 4% of all patients referred for hepatobiliary ultrasonography. The vast majority of these are small (<5 mm) and non-neoplastic; they are inflammatory in origin or composed of cholesterol deposits (see above). Adenomas are the most common benign neoplasm of the gall bladder. Only a proportion of these have a cancerous potential. The only reliable predictor of malignant risk is polyp size (>10 mm). Cholecystectomy is recommended for any polyp of 10 mm in diameter or larger.

Carcinoma of the gall bladder

Adenocarcinoma of the gall bladder represents 1% of all cancers. The mean age of occurrence is the early sixties, with a female-to-male ratio of 3:1. Gall bladder stones are often found in association with gall bladder cancer; gallstones have been suggested as an aetiological factor but this relationship remains unproven. Diffuse calcification of the gall bladder (porcelain gall bladder), considered to be the end-stage of chronic cholecystitis, has also been associated with cancer of the gall bladder and is an indication for early cholecystectomy. Adenomatous polyps of the gall bladder in excess of 10 mm in diameter are also recognized as pre-malignant lesions (see above).

Carcinoma of the gall bladder may be detected incidentally at the time of planned cholecystectomy for gallstones; in such circumstances, resection of an early lesion may be curative. Radical surgery with negative resection margins offers the only potential cure. However, early lymphatic spread to the liver and adjacent biliary tract precludes curative resection in more advanced lesions. Palliative chemotherapy treatment may be given, usually with either 5-fluorouracil (5-FU)-based regimes, or gemcitabine (a nucleoside analogue) and
cisplatin (a platinum-containing anticancer drug), with some evidence of a modest improvement in survival. A small proportion of cases are sensitive to radiotherapy. However, the generally advanced stage of disease at presentation means that the overall 5-year survival is less than 5%.

**Cholangiocarcinoma (see also pp. 485–486)**

Cancers of the biliary tree are classified as intrahepatic (above the hilum of the liver) or extrahepatic (involving the hilum or bile duct distal to the hilum). The latter are classified either on the TMN classification or on the site of the lesion (Bismuth Corlette classification of biliary strictures). These malignancies represent approximately 1% of all cancers. A number of associations have been identified, such as that with choledochal malformation (see above) and with primary sclerosing cholangitis (see pp. 476–477). Chronic infection of the biliary tree with parasitic liver flukes, particularly *Opisthorchis viverrini* or *Clonorchis sinensis*, has also been strongly implicated in areas where they are endemic. Extrahepatic bile duct malignancy usually presents with jaundice and may be confirmed on imaging tests, initially ultrasound and thereafter CT and, in particular, magnetic resonance cholangiopancreatography (MRCP; [Fig. 15.8](#)). Typical findings are of a bile duct stricture with proximal biliary dilatation, with or without a visible mass. Histopathological diagnosis often proves difficult because the malignant cells are few in number and contained within a dense stroma. Endoscopically obtained cytology specimens have only 30% sensitivity. This yield can be enhanced by using additional endoscopic sampling techniques, such as transpapillary biopsy, and analytical enhancements, such as fluorescent *in situ* hybridization and digital image analysis. The recent application of direct endoscopic cholangioscopy has enabled direct visualization of biliary lesions and targeted biopsy.
**Figure 15.8** Magnetic resonance cholangiopancreatography (MRCP) image of hilar cholangiocarcinoma extending into left main duct. There is a normal-calibre distal bile duct (BD) and pancreatic duct (PD). The common hepatic duct and left main duct are strictured (arrowed). There is marked intrahepatic duct (IHD) dilatation.

Cholangiocarcinoma is often detected at a late stage and is characterized by early perineural, vascular and lymphatic spread. In a minority of cases, complete surgical resection is feasible, offering the only chance of cure. Cholangiocarcinoma of the common bile duct may be amenable to a limited bile duct resection. Very distal lesions require a pancreatoduodenectomy (Whipple procedure), and perihilar lesions frequently require partial hepatic resection in addition to biliary resection. In some international centres, extensive neoadjuvant chemoradiation therapy, followed by liver transplantation, has been used to cure localized hilar cholangiocarcinoma. Results from this emerging technique show promise, but cholangiocarcinoma remains an absolute contraindication to liver transplantation in most healthcare systems worldwide due to early disease recurrence.

The majority of patients with cholangiocarcinoma are treated palliatively with biliary decompression (see below) and gemcitabine- and cisplatin-based chemotherapy regimes.

### Secondary malignant involvement of the biliary tree

Carcinoma of the head of the pancreas frequently presents with common bile duct obstruction and jaundice. Metastases to the bile duct from distant cancers are uncommon. Melanoma is the most frequent neoplasm to do so. Infiltration of the bile duct is not uncommon in disseminated lymphoma. Other carcinomas that may give rise to bile duct metastases, in order of frequency, are those arising in the lung, breast and colon, as well as those from the pancreas (metastatic as compared to direct infiltration).
Management

Palliation of malignant bile duct obstruction

All patients must be fully staged for operability using the imaging techniques described above. However, in the greater proportion of patients, the treatment is palliative. Relief of bile duct obstruction has been shown to improve quality of life considerably and, with pain control, is the mainstay of effective palliation. Effective biliary decompression is also critical in jaundiced patients who wish to proceed with palliative chemotherapy. In recent years, endoscopic techniques have allowed the insertion of stents into the biliary tree to re-establish bile flow. The initial use of plastic stents has largely been replaced by self-expanding metal stents that have considerably longer periods of patency (*Fig. 15.9*). In the small proportion of patients in whom bile duct drainage is not possible endoscopically, the percutaneous route offers an alternative method of stent placement under radiological control.

**Further reading**

An ERCP in a patient presenting with painless jaundice. A. There is a tight stricture in the mid-common bile duct extending proximally over 4 cm (extent defined by arrows). The intrahepatic ducts (IHD) proximally are dilated. A guidewire (GW) has been placed endoscopically across the stricture. B. A self-expanding metal stent has been placed across the stricture and released. The stent is compressed at the level of the stricture (arrow) but will open fully over 24 h. The contrast in the intrahepatic ducts has largely drained through the stent. The distal margin of the stent is in the duodenum (D).

The Pancreas

Anatomy and function

Structure

The pancreas extends retroperitoneally across the posterior abdominal wall from the second part of the duodenum to the spleen. Anatomically, the pancreas is divided into a head, which rests within the concavity of the duodenum; a body, lying behind the base of the stomach; and a tail, which ends abutting the spleen. The neck of the pancreas lies between the body and head, and is in front of the superior mesenteric artery and vein. The head of the pancreas surrounds these two vessels. An uncinate process emerges from the lower part of the head, lying behind the superior mesenteric artery. The pancreas consists of exocrine and endocrine cells. The exocrine pancreas comprises 98% of the parenchyma.

The functional unit of the exocrine pancreas is composed of an acinus and its draining ductule. A ductule from the acinus drains into interlobular (intercalated) ducts, which, in turn, drain into the main pancreatic ductal system. The main pancreatic duct itself joins the common bile duct to enter the duodenum as a short single duct at the ampulla of Vater.

The endocrine component is scattered throughout the gland in the form of pancreatic islets
Exocrine function

The pancreatic acinar cells are responsible for the production of digestive enzymes. These include amylase, lipase, colipase, phospholipase and the proteases (trypsinogen and chymotrypsinogen). These enzymes are stored within the acinar cells in secretory granules and are released by exocytosis (Fig. 15.10). The enzymes released by the acinar cells are transported into the duodenum by a high-volume pancreatic secretion, the majority of which is produced by the ductal cells. This fluid has a high concentration of bicarbonate, which neutralizes the gastric acid that has emptied into the duodenum. The neutralization of gastric acid is essential to facilitate pancreatic enzyme activity, which is pH-dependent (requiring a neutral pH).
After ingestion of a meal, pancreatic exocrine secretion is regulated by cephalic, gastric and intestinal stimuli. The cephalic phase is stimulated by behavioural cues related to the sight, smell and taste of food. The input from these sensory stimuli is integrated in the central nervous system at the dorsal vagal complex, and the output is transmitted to the exocrine pancreas via the vagus nerve. The gastric phase of pancreatic secretion results from the effects of the meal in the stomach. The major stimulus of pancreatic secretion in the gastric phase is gastric distension, which causes secretion of an enzyme-rich fluid with little secretion of water and bicarbonate. This phase is also under vagal control. The intestinal phase of pancreatic secretion starts when protein, fat and gastric acid from the stomach enters the duodenum and continues for the duration of the digestive period. It is mediated by both hormones and enteropancreatic vagovagal reflexes. Feedback regulatory events eventually terminate pancreatic secretion.

- **Cholecystokinin (CCK)** plays a major role in meal-stimulated digestive enzyme secretion
during the intestinal phase of pancreatic secretion. The hormone is produced in *specialized gut endocrine cells (I cells)* of the mucosa of the small intestine and is secreted in response to intraluminal food. There are no CCK receptors in pancreatic cells of humans, and CCK acts via receptors on vagal afferent fibres to stimulate pancreatic secretion.

- **Secretin** is also released from *specialized enteroendocrine cells* of the small intestine during a meal and, in particular, during duodenal acidification. Secretin has a direct effect on the pancreatic acinar cells, as well as the ductal cells. There is also a vagal-mediated secretory response. Secretin action is mediated via G-coupled receptors and calcium-mediated enzyme release. Secretin results in a bicarbonate-rich pancreatic secretion.

  The efficiency of the digestive phase of pancreatic secretion requires a negative feedback mechanism to bring the process to a close. Completion of the postprandial secretory phase involves both neural and hormonal control.

- **Pancreatic polypeptide** is released from the *islet cells of the pancreas* in response to a meal and has an inhibitory effect on acinar enzyme secretion, via both a local effect and central receptors.

- **Somatostatin**, present within the pancreas, stomach and central nervous system, also has an inhibitory effect. It is released in response to food and its effect is mediated by both direct pancreatic acinar inhibition and a central nervous system inhibitory component.

- **Peptide YY (PYY)**, contained in *endoctrine cells of the distal small intestine* is released by nutrients within the ileum and inhibits pancreatic secretion by acting on the acinar cells themselves, as well as centrally via the inhibitory regulation of vagal nerve.

  There is also evidence that proteases within the duodenal lumen also have a negative feedback on acinar secretion. The gut-related peptides, leptin and ghrelin, as well as influencing appetite behaviour, are also regulatory factors in the exocrine function of the pancreas. This effect is believed to occur via hypothalamic centres.

**The endocrine pancreas**

This consists of hormone-producing cells arranged in nests or islets (islets of Langerhans). The hormones produced are secreted directly into the circulation and there is no access to the pancreatic ductular system. There are *five main types of islet cell* corresponding to different secretory components:

- The beta cells are the most common and are responsible for insulin production.
- The alpha cells produce glucagon.
- The D cells produce somatostatin.
- PP cells produce pancreatic polypeptide.
- Enterochromaffin cells produce serotonin.

  A number of other hormones have been identified within the endocrine pancreas, including gastrin-releasing peptide, neuropeptide Y and galanin. These are believed to be neurotransmitters active in the neuro-gastrointestinal axis.
Assessment of exocrine function

The assessment of pancreatic exocrine function is used in the investigation of patients with possible chronic pancreatic disease. Clinically evident fat malabsorption does not occur until there has been an 85–90% reduction in pancreatic lipase and is therefore a very late manifestation of pancreatic disease.

Direct tests of pancreatic function

These tests rely on the analysis of a duodenal aspirate following pancreatic stimulation.

The original test involved the oral administration of a specified meal (Lundh meal). Pancreatic stimulation is now achieved by intravenous secretin and cholecystokinin.

The aspirate is assessed for pancreatic enzymes and bicarbonate production. The procedure is time-consuming and requires a meticulous technique. There is good correlation with moderate to severe pancreatic function loss, but not with mild damage. These tests are not widely available.

The measurement of peak bicarbonate secretion following secretin stimulation is also performed using an endoscopic technique for aspirate collection. This method offers similar levels of predictive accuracy as seen with the secretin–cholecystokinin stimulation test but does require a 30-min endoscopic intubation.

Non-invasive indirect tests of pancreatic function

Faecal tests

- **Faecal elastase** is an enzyme produced in the pancreas; as it is not degraded in the intestine, it has high concentrations within the faeces. Diminished levels are seen in moderate and severe pancreatic insufficiency. This has replaced the faecal chymotrypsin test.

- **Faecal fat estimation** (rarely performed).

Oral pancreatic function tests

- **N-benzoyl-L-tyrosyl-p-aminobenzoic acid** (basis of the PABA test) and **fluorescein dilaurate** are oral compounds utilized in pancreatic function tests. Both are digested by pancreatic enzymes, releasing substrates that are excreted and measured in the urine. Both tests are commercially available and have good sensitivity in moderate to severe pancreatic exocrine failure.

Clinical application of pancreatic function tests

While the invasive duodenal aspiration tests represent the most sensitive and specific means of assessing pancreatic function, these are very rarely used outside specialized centres. The non-invasive tests are widely available but are only highly sensitive in the detection of severe
pancreatic insufficiency. The faecal elastase test (in a commercially available form) provides similar sensitivity and specificity, and is the test of choice as a screening tool for pancreatic insufficiency.

**Pancreatic imaging**

Imaging (see pp. 445–447) has a pivotal role in the investigation and management of pancreatic disease, which covers the spectrum of acute, chronic and malignant conditions.

- **A plain abdominal radiograph** may show the calcification associated with chronic pancreatitis, particularly when alcohol is the aetiology.

- **Transabdominal ultrasound** of the pancreas usually offers reasonable views of the pancreas; it is a useful screening investigation for inflammation or neoplasia, and is reasonably sensitive for detection of gallstone disease in a patient with pancreatitis. Views may be limited by overlying bowel gas, and ultrasound should not be relied on in the exclusion of pancreatic neoplasia, if clinical suspicion exists.

- **CT scan** with contrast enhancement and following a specific pancreatic protocol remains the ‘gold standard’ imaging technique for the investigation of pancreatic disease.

- **MRI scanning** represents an alternative to CT. MRCP gives clear definition of the pancreatic duct, as well as the biliary tree. Gallstones (including microcalculi) may also be identified in the biliary tree using MRI/MRCP.

- **Endoscopic ultrasound** is very useful for identifying distal common bile duct stones, which may be the aetiology of an episode of acute pancreatitis. Endoscopic ultrasound can identify the early changes of chronic pancreatitis before these are evident with other imaging methods. There is also an increasing role for this technique to stage the operability of pancreatic adenocarcinoma, particularly with respect to vascular invasion. Endoscopic ultrasound is now considered the imaging technique of choice for investigating cystic lesions of the pancreas (see below). The technique allows fine-needle aspiration and histological sampling, as well as the therapeutic option of cyst drainage. Endoscopic ultrasound is a sensitive means of detecting small pancreatic tumours, particularly those of neuroendocrine origin.

- **Endoscopic retrograde cholangiopancreatography (ERCP)** is an invasive procedure and whilst having a good safety profile, is associated with a small risk of serious adverse events: in particular, the precipitation of acute pancreatitis. The availability of MRCP and endoscopic ultrasound has provided alternative means of defining pancreatic pathology. ERCP has an increasing therapeutic role in pancreatic disease (see below).

  *In summary*, an initial transabdominal ultrasound, supplemented by CT, provides sufficient diagnostic information for most inflammatory and neoplastic conditions of the pancreas. MRI and MRCP are now widely available and provide additional information, particularly with respect to pancreatic ductular and biliary anatomy. Endoscopic ultrasound is a useful, albeit more invasive, tool for the investigation of both benign and malignant disease of the pancreas, and facilitates fine-needle aspiration and biopsy of targetable lesions.
Pancreatitis

Classification

Pancreatitis is divided into *acute* and *chronic*. By definition, acute pancreatitis is a process that occurs on the background of a previously normal pancreas and can return to normal after resolution of the episode. Nevertheless, acute alcoholic pancreatitis occurs only in chronic misuse of alcohol. In chronic pancreatitis, there is continuing inflammation with irreversible structural changes.

In practice, the differentiation between acute and chronic pancreatitis may be difficult. Any of the causes of acute pancreatitis, if untreated, may result in recurrent episodes, classified as *acute relapsing pancreatitis* and eventually resulting in permanent structural changes. In other cases, recurrent episodes of acute pancreatitis may represent exacerbations of an underlying chronic process.

Acute pancreatitis

Acute pancreatitis is a syndrome of inflammation of the pancreatic gland initiated by any acute injury. The causes of acute pancreatitis are listed in Box 15.2. In the Western world, gallstones and alcohol account for the vast majority of episodes. Alcohol also causes chronic pancreatitis (see below). The severity of the pancreatitis may range from mild and self-limiting to extremely severe, with extensive pancreatic and peripancreatic necrosis, as well as haemorrhage. In the most severe form (approximately 10% of cases), the mortality is between 40% and 80%.

### Pathogenesis
This is still not completely understood. A precipitating event, such as gallstones or alcohol, is thought to induce the acute episode.

#### Gallstone pancreatitis
The inducing effect is obstruction to pancreatic drainage at the ampulla by a stone or associated oedema. In this pathological situation, trypsinogen is cleaved (by cathepsin B) to trypsin, and trypsin degradation by chymotrypsin C is impaired and quickly overwhelmed. Intracellular calcium also increases and may also cause early activation of trypsinogen with upregulation of nuclear factor kappa B, leading to extensive acinar cell damage.

#### Alcohol-induced pancreatitis
There is also evidence that alcohol interferes with calcium homeostasis in pancreatic acinar cells. In addition, activation of pancreatic stellate cells by acetaldehyde occurs, with production of collagen and then matrix proteins.

Whatever the nature of the initiating insult, the pancreatic inflammatory response is secondary to the premature and exaggerated activation of digestive enzymes, principally trypsin, within the pancreas itself. In severe cases, the subsequent cascade of autodigestion, microvascular injury, systemic inflammatory response and bacterial translocation can result in a devastating outcome.

### Clinical features
Acute pancreatitis is a differential diagnosis in any patient with upper abdominal pain. The
pain usually begins in the epigastrium, accompanied by nausea and vomiting. As inflammation spreads throughout the peritoneal cavity, the pain becomes more intense. Involvement of the retroperitoneum frequently leads to back pain.

The patient may give a history of previous similar episodes or be known to have gallstones. An attack may follow an alcoholic binge. However, in many cases, there are no obvious aetiological factors.

Physical examination at the time of presentation may show little more than a patient in pain with some upper abdominal tenderness but no systemic abnormalities. In severe disease, the patient has a tachycardia and hypotension, and is oliguric. Abdominal examination may show widespread tenderness with guarding, as well as reduced or absent bowel sounds. Specific clinical signs that support a diagnosis of severe necrotizing pancreatitis include periumbilical (Cullen's sign) and flank bruising (Grey Turner's sign). In patients with gallstone aetiology, the clinical picture may also include the features of jaundice or cholangitis.

## Diagnosis

### Blood tests

- **Serum amylase** is an extremely sensitive test if it is three times the upper limit of normal when measured within 24 h of the onset of pain. A number of other conditions may occasionally cause a very elevated amylase (Box 15.3). Amylase levels gradually fall back towards normal over the next 3–5 days. With a late presentation, the serum amylase level may give a false-negative result.

### Box 15.3

**Elevation of serum amylase unrelated to pancreatitis**

**Leakage of upper gastrointestinal contents into the peritoneum**

- Upper gastrointestinal perforation
- Biliary peritonitis
- Intestinal infarction

**Inherited abnormalities of amylase**

- Macroamylasaemia

- **Urinary amylase** levels may be diagnostic, as these remain elevated over a longer period of time.

- **Serum lipase** levels are also raised in acute pancreatitis and these remain elevated for a longer period of time than amylase levels. However, overall, the accuracy of serum lipase is
not significantly greater than that of amylase and it is technically more difficult to measure.

- **CRP level** is useful in assessing disease severity and prognosis.
- **Other baseline investigations** include a full blood count, urea and electrolytes, blood glucose, liver biochemistry, plasma calcium and arterial blood gases. These are documented at presentation and then repeated at 24 and 48 h, providing a basis for assessing the severity of an attack (see below).

### Radiology

- An erect **chest X-ray** is mandatory to exclude gastroduodenal perforation, which also raises the serum amylase (**Box 15.3**). A supine abdominal film may show gallstones or pancreatic calcification.
- An **abdominal ultrasound scan** is used as a screening test to identify a possible biliary (gallstone) cause of pancreatitis. Gallstones are difficult to detect in the distal common bile duct but dilated intrahepatic ducts may be present in the presence of bile duct obstruction. Stones within the gall bladder are not sufficient to justify a diagnosis of gallstone-related pancreatitis. The ultrasound may also demonstrate pancreatic swelling and necrosis, as well as peripancreatic fluid collections if present. In severe pancreatitis, the pancreas may be difficult to visualize because of gas-filled loops of bowel.
- **Contrast-enhanced CT scanning** is essential in all but the mildest attacks of pancreatitis. It should be performed after 72 h to assess the extent of pancreatic necrosis. CT provides very valuable prognostic information. Later, repeated CT scans can detect other complications, including fluid collections, abscess formation and pseudocyst development (**Fig. 15.11**).
Acute pancreatitis. A. An abdominal CT scan with arterial phase contrast in a patient presenting with acute pancreatitis 48 h previously. The pancreas is swollen with very little uptake of contrast, suggesting a severe necrotizing process. There are peripancreatic inflammatory changes (inf). The liver and spleen are identified for reference. B. A coronal CT view in the same patient, carried out in second week after presentation. There is now a large fluid collection and debris within it. This is a precursor of a large pseudocyst (Ps), which extends down the left paracolic gutter into the pelvis. This has occurred as a consequence of a pancreatitis-induced ductal leak. The liver, stomach and duodenum are defined for reference. PV, portal vein.

- MRI (MRCP) assesses the degree of pancreatic damage and identifies gallstones within the biliary tree. MRI is particularly useful to differentiate between fluid and solid inflammatory masses.
- ERCP is used as a treatment measure to remove bile duct stones in selected cases of gallstone-related pancreatitis (see below).
**Assessment of disease severity**

The majority of cases of acute pancreatitis are mild and run a short, self-limiting course. However, approximately 25% run a more complicated course and in 10% this is life-threatening. The revised Atlanta criteria define mild, moderately severe or severe pancreatitis and are summarized in *Box 15.4*; they require assessment of organ failure using the Modified Marshall scoring system (*Box 15.5*). In practice, patients with moderately severe acute pancreatitis should be managed as having severe disease until sustained improvement is seen.

### Box 15.4

**Severity of acute pancreatitis: revised Atlanta criteria 2013**

**Mild**

- Absence of organ failure
- Absence of local complication

**Moderate/severe**

- Local complication and/or transient organ failure (<48 h)

**Severe**

- Persistent organ failure (>48 h), defined by the modified Marshall Score for the evolution of organ failure (see *Box 15.5*).

*As a score of ≥2 in any system defines the presence of organ failure.*

In severe cases, mortality may be as high as 80%. The initial clinical course is marked by a systemic inflammatory response syndrome (SIRS), haemodynamic instability and multiple organ failure. The consequences of SIRS, including respiratory and acute kidney injury, account for most of mortality within the first 7 days of an episode of severe acute pancreatitis.
After 7 days, the majority of deaths are linked to delayed complications, such as sepsis due to infected collections or haemorrhage due to inflammatory erosion into major vessels.

Accurate identification of patients likely to progress to severe pancreatitis permits appropriate monitoring and intensive care to be put in place. Early clinical assessment has been shown to have poor sensitivity for predicting a severe attack. Similarly, individual laboratory tests have very limited value. Therefore, multiple factors have been used to develop clinical scoring systems. The **Glasgow and Ranson scoring systems** (*Boxes 15.6 and 15.7*) are based on such parameters and have been shown to have 80% sensitivity for predicting a severe attack, although only after 48 hours from presentation. The **Acute Physiology and Chronic Health Evaluation (APACHE II) score** has been extensively adopted as a means of assessing the severity of a wide spectrum of illness. The APACHE scoring system is based on common physiological and laboratory values, patient age, and the presence or absence of a number of other chronic health problems, including obesity (*Box 15.8*). This scoring system appears to have a high sensitivity and can be applied as early as 24 hours after onset of symptoms. There is evidence that obesity affects the outcome of an episode of pancreatitis, perhaps because adipose tissue is a substrate for activated enzyme activity, worsening the inflammatory reaction. All scoring systems for predicting the severity of acute pancreatitis have their weaknesses and have proven to have modest utility in clinical practice. However, systematic classification tools can guide consistent clinical assessment, and are certainly necessary in clinical studies and audit of outcomes.

  – White blood cell count

\(^{*}\)APACHE is applied within 24 h of admission. Score can range from 0–71 (normal to abnormal). Higher scores correspond to more severe disease and a higher risk of death. Body mass index (BMI) is an additional parameter that can be added specifically in assessing severity of acute pancreatitis.

### Management

The initial management of acute pancreatitis is similar for all causes. A multiple factor scoring system (ideally, APACHE II with a modification for obesity) should be used at the end of the first 24 hours after presentation to allow identification of patients with a predicted severe attack. This should be repeated at 48 hours to identify a further subgroup who appear to be moving into the severe category. These patients should be managed on a high-dependency or intensive care unit and the case should be discussed with a specialist pancreatic unit at an early stage. Even patients outside the severe category may require considerable supportive care.

Early fluid losses in acute pancreatitis may be large, requiring well-maintained intravenous access and a urinary catheter to monitor circulating volume and renal function. Arterial and central venous catheterization may be necessary to facilitate close monitoring of hemodynamic status and permit repeat sampling of arterial blood gases.

– **Nasogastric suction.** This prevents abdominal distension and vomitus, and hence the risk of aspiration pneumonia.

– **Baseline arterial blood gases.** These are a key predictive factor for severity of an episode and determine the need for continuous oxygen administration.

– **Prophylactic antibiotics.** Controlled data for the use of antibiotics are available but the results are not uniform in showing benefit, particularly in demonstrating improved mortality. There is some evidence that the β-lactam imipenem reduces the incidence of infected pancreatic necrosis. Antibiotics should usually be reserved for cases where cholangitis or infected necrotic tissue is strongly suspected and, if possible, choice should be guided by blood culture results.

– **Analgesia requirements.** Tramadol or other opiates are the drugs of choice for immediate post-presentation pain control. Unless there is prompt resolution of pain, a patient-controlled system of administration is indicated to provide continuous and adequate pain relief. Fentanyl has been used widely for this application. There is a theoretical risk that morphine and diamorphine might exacerbate pancreatic ductular
hypertension by causing sphincter of Oddi contraction. Although there are no clinical data to support this risk, some clinicians therefore avoid these drugs in acute pancreatitis.

- **Feeding.** In a severe episode, there is little likelihood of oral nutrition for a number of weeks. Total parenteral nutrition has been associated with a high risk of infection and has been replaced by enteral nutrition. In the absence of gastroparesis, most patients will tolerate nasogastric administration of feed without exacerbation of pain. In those with gastroparesis or poorly tolerated nasogastric feeding (exacerbation of pain or precipitation of nausea and vomitus), post-pyloric feeding should be instituted by the endoscopic placement of a nasojejunal tube.

- **Anticoagulation.** Low-molecular-weight heparin should be given for prophylaxis of deep vein thrombosis.

  In a small proportion of patients, multiorgan failure will develop in the first few days after presentation, reflecting the extent of SIRS. Such patients may require positive-pressure ventilation and renal support (see p. 1156).

**Gallstone-related pancreatitis**

In patients with gallstone-related pancreatitis and associated bile duct obstruction (particularly when complicated by cholangitis), endoscopic intervention with sphincterotomy and stone extraction is the treatment of choice. In the absence of bile duct obstruction, sphincterotomy and stone extraction are only of proven benefit when the episode of pancreatitis is predicted to be severe. In less severe cases of gallstone-related pancreatitis, the presence of residual bile duct stones can be assessed electively by MRCP or endoscopic ultrasound in the recovery phase of the acute episode; if stones are present, they can be removed at the time of ERCP. To prevent a recurrent episode of gallstone pancreatitis, cholecystectomy should be carried out as soon as feasible after the acute episode has resolved.

**Complications**

(See **Box 15.9.**) After the first 7 days, the prognosis of acute pancreatitis is most closely related to the extent of pancreatic necrosis. This can be most accurately assessed by contrast-enhanced CT, which should be carried out in all patients with severe disease after the first week. Extensive necrosis (>50% of the pancreas) is associated with a high risk of further complicated disease, frequently requiring surgical intervention.

**Box 15.9**

**Complications of acute pancreatitis**

**Systemic**

- Systemic inflammatory response syndrome (SIRS)
- Multiorgan dysfunction
**Pancreas**
- Pancreatic fluid collections
- Necrosis ± infection
- Pancreatic abscess
- Pancreatic pseudocyst (after 4–6 weeks)

**Lungs**
- Pleural effusion
- Acute respiratory distress syndrome (ARDS) – hypoxia
- Pneumonia

**Kidney**
- Acute kidney injury

**Gastrointestinal tract**
- Gastrointestinal bleeding from gastric or duodenal erosions
- Paralytic ileus

**Hepatobiliary**
- Jaundice
- Common bile duct obstruction
- Portal vein thrombosis

**Metabolic**
- Hypoglycaemia
- Hyperglycaemia
- Hypocalcaemia

**Haematological**
- Disseminated intravascular coagulation (DIC)

In this minority of patients with extensive necrosis of the pancreatic and peripancreatic tissues, superimposed infection is associated with a greatly increased risk of mortality. A ‘step-up’, minimally invasive approach is now preferred, with open surgical debridement avoided if at all possible. Long courses of antibiotics are given, and percutaneous drainage and endoscopic ultrasound-guided endoscopic necrosectomy are used to clear infected collections. The aims of such interventions are to control infection, evacuate devitalized tissues (the culture medium for invasive infection) and promote conditions for healing.

The best outcomes from intervention are achieved when debridement is delayed until at least 4 weeks after the onset of pancreatitis. When the damaged area has been walled off and
liquefaction has begun, a pseudocyst develops. If necessary, acute sepsis may be controlled by percutaneous drainage of collections in the first instance.

Prognosis

The vast majority of patients with a mild to moderate episode of acute pancreatitis will make a full recovery with no long-term sequelae. Recurrent episodes of pancreatitis may occur, particularly if there has been any long-term pancreatic ductular damage. Patients with more severe acute pancreatitis may develop pancreatic insufficiency with respect to both exocrine (malabsorption) and endocrine function (diabetes); both of these carry their own significant, life-long morbidity.

Chronic pancreatitis

Aetiology

In developed countries, alcohol is reported to be the only aetiological factor in 60–80% of cases. There is a sizeable list of other reported aetiological factors, which can be categorized into toxic–metabolic, genetic, autoimmune, recurrent acute or severe acute pancreatitis, obstruction and idiopathic causes (Box 15.10).

Box 15.10

Causes of chronic pancreatitis

- Alcohol
- Chronic kidney disease
- Hereditary:
  - Cystic fibrosis
  - Trypsinogen and inhibitory protein defects
- Tropical
- Obstructive
- Trauma
- Idiopathic
- Hypercalcaemia
- Recurrent acute pancreatitis
- Autoimmune (IgG4)

Pathogenesis
There is increasing evidence that an increase in activated trypsin within the pancreas is a common pathway for the development of chronic pancreatitis. This may occur as a result of increased/premature activation of trypsinogen to trypsin, or of impaired inactivation/clearance of the activated enzyme from the pancreas. It is believed that the increased or prolonged intrapancreatic enzyme activity leads to the precipitation of proteins within the duct lumen in the form of plugs. These then form a nidus for calcification but are also the cause of ductal obstruction, leading to ductal hypertension and further pancreatic damage (Fig. 15.12).

![Histology of chronic pancreatitis](image.png)

**FIGURE 15.12** Histology of chronic pancreatitis. There is considerable loss of acini and replacement by fibrosis. Inflammatory cells are relatively inconspicuous at this late stage. Islets of Langerhans (one is arrowed) sometimes escape destruction but their loss can result in diabetes mellitus. (From Underwood JC (ed.). General and Systematic Pathology, 4th edn. Edinburgh: Churchill Livingstone; 2004, with permission.)

In the case of alcohol-related chronic pancreatitis, there is evidence that ethanol increases pro-enzyme activation, promoting trypsinogen activation, as well as diminishing the inactivation pathway. The observation that the vast majority of people drinking excess alcohol do not develop pancreatitis suggests that the disease process is a complex interaction of different mechanisms. It is proposed that the alcohol is only one factor that interacts with other environmental and/or genetic influences (see below).

**Genetic aspects of chronic pancreatitis**

A number of genetic factors have been identified that influence the process of trypsin activation and inactivation. Cationic trypsinogen is the major form of trypsinogen produced in the pancreas and encoded by the *PRSS1* gene (Fig. 15.13). Gain-of-function mutations of this gene are recognized as the major factor in hereditary pancreatitis, an autosomal dominant condition with variable penetrance.
Calcium levels within the pancreas have a role in the process of activation and inactivation of trypsinogen/trypsin and are, in part, modulated by the calcium-sensing receptor. Mutations coding for this receptor have been associated with pancreatitis and are believed to facilitate the damaging effects of alcohol on the pancreas.

The serine protease inhibitor Kazal type 1 (SPINK-1) is a specific trypsin inhibitor and is co-secreted with trypsinogen by the acinar cells. Loss-of-function mutations of the SPINK-1 gene have been associated with the development of chronic pancreatitis and identified, in particular, as a factor in the development of tropical pancreatitis (almost certainly interacting with environmental triggers).

Chymotrypsin C is produced in trace amounts by the acinar cells and has also been shown to have a role in trypsin inactivation. Loss-of-function mutations of the encoding gene have been identified in patients with chronic pancreatitis.

The cystic fibrosis transmembrane conductance regulator (CFTR) is expressed on the apical surface of the acinar cells and is responsible for maintaining a high-volume, bicarbonate-rich pancreatic secretion. This high-volume secretion is responsible for flushing the activated trypsin into the duodenum. The homozygote or complex heterozygote CFTR mutations associated with the cystic fibrosis disease state are almost always manifest by perinatal/early pancreatic exocrine failure (see p. 508). An increased frequency of a single CFTR mutation in patients with idiopathic chronic pancreatitis has been identified.

The identification of a genetic component to the development of chronic pancreatitis has led to speculation that, in many cases, the evolution of the disease is dependent on the complex interaction of gene–gene and gene–environmental factors.
Autoimmune chronic pancreatitis

Two types of autoimmune chronic pancreatitis (ACP) have been identified. The most common variant (type 1) is seen predominantly in middle-aged men and is associated with raised serum and tissue levels of IgG4. Other autoantibodies, including those directed towards nuclear and smooth muscle antigens, are also observed. Extrapancreatic tissue involvement is common, including the biliary tree (autoimmune cholangitis; see above), as well as thyroid, salivary gland and renal tissue (see p. 760). In all these disorders, there is a raised serum IgG4 level and, pathologically, there is a dense lymphoplasmacytic infiltrate with many IgG4-positive plasma cells, a mild to moderate eosinophil infiltrate and an obliteratorive phlebitis in some organs. ACP is one of the few settings in which the pathogenesis of the disease may be independent of the activated trypsin pathways.

The second variant (type 2) tends to occur in early midlife with an equal sex distribution and does not have the autoimmune markers or IgG4-positive cells. Some 30% of cases are associated with inflammatory bowel disease. The disease is much more likely to be restricted to the pancreas and lacks the associations with other organ/tissue involvement seen with the type 1 variant. The hallmark of both types of autoimmune pancreatitis is evidence of responsiveness to steroids (see 'Management' below).

The presentation of autoimmune pancreatitis is varied, particularly in type 1, in which extrapancreatic disease may predominate. Abdominal pain and weight loss are common features; jaundice may be an early symptom, both secondary to bile duct obstruction by the inflamed head of pancreas, and a manifestation of the cholangitis seen in type 1 cases.

Clinical features

Pain is the most common presentation of chronic pancreatitis. It is usually epigastric and often radiates through into the back. The pattern of pain may be episodic, with short periods of severe pain, or is chronic and unremitting. For those with an alcohol-related aetiology, exacerbations of the pain may follow further alcohol excess, although this is not a uniform relationship. Alcohol excess or meals with a high fat content may also lead to exacerbations of pain, independent of the aetiology.

During periods of abdominal pain, anorexia is common and weight loss may be severe. This is particularly so in those patients with chronic, unremitting symptoms. Exocrine insufficiency may develop at any time and occasionally malabsorption is the presenting feature in the absence of abdominal pain. Diabetes occurs in approximately 30% of cases and is usually a late event in the disease process, almost always following the development of exocrine insufficiency. Jaundice secondary to obstruction of the common bile duct during its course through the fibrosed head of the pancreas may also occur and may be a presenting feature in a small proportion of patients.

Investigations
The extent to which investigations are required is dependent on the clinical setting.

- **Serum amylase and lipase** levels may be elevated, but in advanced disease there may not be sufficient residual acinar tissue to produce this elevation.

- **Serum IgG4 levels** should be measured in those cases with suspected autoimmune pancreatitis.

- **Faecal elastase** level will be abnormal in the majority of patients with moderate to severe pancreatic disease.

- **Gene mutation analysis** should be carried out in selected cases in whom the aetiology is uncertain. This is most relevant in patients presenting below the age of 40. Common mutations of the *PRSS1*, *SPINK-1* and *CFTR* encoding genes are available via reference centres.

- **Transabdominal ultrasound scan** is used for initial assessment.

- **Contrast-enhanced CT scanning** provides a more detailed assessment. In the presence of pancreatic calcification and a dilated pancreatic duct, the diagnosis of chronic pancreatitis can be readily established *(Fig. 15.14)*. This may be much more difficult when these features are not present, and in particular with an atypical presentation such as steatorrhoea.

![Contrast-enhanced CT scan in a patient with chronic pancreatitis. Multiple calcific densities (arrowed) are demonstrated along the line of the main pancreatic duct.](image)

- **MRI with MRCP** is utilized to define more subtle abnormalities of the pancreatic duct, which may be seen in non-dilated chronic pancreatitis.

- **Endoscopic ultrasound** is used increasingly when doubt about the diagnosis remains after the above imaging, or specifically when complications of chronic pancreatitis, including pseudocyst formation and the possible development of malignancy, need assessment.

- **MRCP** has replaced diagnostic ERCP.
Differential diagnosis

The differential diagnosis is that of pancreatic malignancy. Carcinoma of the pancreas can reproduce many of the symptoms and imaging abnormalities that are commonly seen with chronic pancreatitis. The diagnosis of malignancy should be considered in patients with a short history in whom there is a localized pancreatic mass. Considerable difficulties may arise when a malignancy develops on the background of established chronic pancreatitis (the latter being a recognized pre-malignant lesion).

High-quality imaging is able to define malignant features with a localized mass lesion, local invasion and lymph node enlargement. Endoscopic ultrasound provides the most accurate assessment of a potential mass lesion.

Management

In patients with alcohol-related chronic pancreatitis, long-term abstinence is likely to be of benefit, although this has been difficult to prove. Autoimmune pancreatitis is steroid-responsive and failure to respond would put the diagnosis in question. Relapse is common when the steroids are withdrawn, and long-term immunomodulators (e.g. azathioprine) may be required.

Abdominal pain

For short-term flare-ups of pain, a combination of a non-steroidal anti-inflammatory drug (NSAID) and an opiate (tramadol) is usually sufficient for symptomatic relief. In patients with chronic unremitting pain, this may be inadequate and also risks opiate dependence.

Tricyclic antidepressants (e.g. amitriptyline) and membrane-stabilizing agents (e.g. pregabalin) are used for chronic pain and reduce the need for opiates. Coeliac axis nerve block may produce good pain relief but is unreliable in its extent and duration of action. In the majority of patients, some spontaneous improvement in pain control occurs with time. After a 6–10-year period, some 60% of patients will become pain-free. For patients with recurrent severe or debilitating chronic pain, both endoscopic and surgical intervention has been used. This is particularly the case in patients with chronic calcific disease with a dilated pancreatic duct upstream of a ductular stricture and/or stone. The endoscopic approach has centred on improving duct drainage by removing intraductal stones and duct stenting to maintain patency. Extracorporeal shock wave lithotripsy has been used to fragment stones within the head of the pancreas.

Surgical intervention usually involves a duct drainage procedure, which can be combined with partial resection of the diseased head of pancreas. Trials have reported improved pain control following surgical intervention, as compared with the endoscopic approach. However, many patients have a high level of debility (and often continued alcohol excess) and are unsuitable for major surgery. In such circumstances, endoscopic therapy is justified as a first measure and there is no evidence that this adversely influences subsequent surgery.
Malabsorption

The steatorrhoea associated with pancreatic insufficiency may be high, with up to 30 mmol of fat lost per 24 h. This will usually improve with pancreatic enzyme supplements. Current preparations are presented in the form of microspheres, which reduce the problems of acid degradation in the stomach. An acid suppressor (H₂-receptor antagonist or proton-pump inhibitor) is also given. Despite this, a proportion of patients continue to malabsorb, usually reflecting the inadequate mixing of the pancreatic supplements with the food, as well as the low pH in the duodenum secondary to inadequate pancreatic bicarbonate production. There is no justification to reduce fat intake below the recommended levels of a normal diet, as this will contribute to the malnutrition seen in patients with chronic pancreatitis. Dietetic input is valuable for the management of malabsorption and also for monitoring and alleviating the malnutrition that is often seen secondary to abdominal pain and food aversion.

Diabetes

Diabetes associated with pancreatic endocrine failure may be difficult to control, with a rapid progression from oral hypoglycaemic agents to an insulin requirement. Brittle control is a common problem secondary to inadequate glucagon production by the damaged pancreas.

Autoimmune pancreatitis

Most patients respond to glucocorticoid therapy, e.g. prednisolone 40 mg daily for 4–6 weeks. Relapses are treated with azathioprine.

Specific complications

The most common structural complication of chronic pancreatitis is a pancreatic pseudocyst, a fluid collection surrounded by granulation tissue (see p. 505). These usually occur in relationship to a period of enhanced inflammatory activity within the pancreas giving abdominal pain but may develop silently during what would appear to be a stable phase. Intraperitoneal rupture, bleeding or cyst infection may occur. The larger cysts may occlude nearby structures, including the duodenum and the bile duct. In pseudocysts less than 6 cm in diameter, spontaneous resolution can be anticipated. In larger cysts that have been present for a period in excess of 6 weeks, resolution is less common and a long-term complication rate of approximately 30% can be anticipated. Many pseudocysts are closely opposed to the posterior wall of the stomach or duodenum, and can be successfully drained endoscopically using endoscopic ultrasound to identify the optimum drainage site. A direct fistula is created between the pseudocyst lumen and the gastric or duodenal lumen, which is then kept patent by the insertion of plastic stents. This approach will be successful in approximately 75% of cases. Surgical drainage is required for failures of endoscopic therapy or in circumstances where the pseudocyst anatomy does not allow endoscopic access.

Ascites and, occasionally, pleural effusions can be a direct consequence of chronic pancreatitis when there has been disruption of the main pancreatic duct. A high ascites or
pleural fluid amylase will confirm the aetiology. Such disruptions of the main pancreatic duct require surgical intervention.

There is an increased risk of **pancreatic cancer** in patients with chronic pancreatitis. The risk of malignancy is closely related to the duration of the inflammatory process. The highest incidence has been reported in hereditary pancreatitis, with a 50-fold increase and a lifetime risk as high as 40%. This reflects the early onset (in childhood) of the disease. Increases of 20–30-fold have been described in patients carrying other gene mutations and early onset of disease. The lifetime risk of malignancy in other causes of chronic pancreatitis, such as alcohol, which develop much later is 10–15%. Cancer surveillance programmes have been proposed for the very high-risk groups (hereditary pancreatitis and other causes of early-onset disease), usually starting around the age of 40 years and relying on yearly imaging and tumour marker measurement.

**Cystic fibrosis**

Some 85% of people with cystic fibrosis (see pp. 1088–1089) will have pancreatic exocrine failure, and in the majority of these, this will develop *in utero* or the perinatal period. Malabsorption and failure to thrive are common presentations in the perinatal period and first year of life, and diabetes will develop subsequently in 30% of these cases during their lifetime.

In the remaining 15% of cases, there is an insufficiency of pancreatic exocrine secretion, which may persist throughout the patient's lifetime. This reflects residual *CFTR* function and is associated with class IV and V mutations. The patients tend to present later in life and have less severe pulmonary involvement, although this is not uniform. Some of these cases will progress to pancreatic exocrine insufficiency at variable times in the course of their disease. A small proportion develop symptomatic pancreatitis as part of this process.

The **management** of pancreatic exocrine insufficiency in cystic fibrosis is necessary to optimize growth and overall nutrition. **Pancreatic enzyme supplements** are closely titrated against the level of steatorrhea. **Fat intake** should be maintained to avoid nutritional deficit. A daily **lipase intake** of up to 10 000 units/kg body weight is required. The efficacy of the supplements may be improved by the use of a **proton-pump inhibitor**. These drugs reduce the risk of acid denaturation of the enzymes and also prevent acidification of the duodenum, which also impairs the enzymes' activity. Despite optimizing the use of enzyme supplements, a degree of fat malabsorption may persist. This reflects other luminal abnormalities of fat absorption in cystic fibrosis that are related to viscous mucus, small bowel bacterial colonization, and poor mixing of the food bolus with bile.

**Further reading**

Pancreatic Cancer

The many types of pancreatic cancer can be divided into two main groupings. The vast majority of cases (about 99%) occur in the exocrine component of the pancreas. There are several subtypes of exocrine pancreatic cancer, but their diagnosis and treatment have much in common. A small minority of pancreatic cancers arise in the endocrine or hormone-producing tissue of the pancreas and have different clinical characteristics.

Pancreatic adenocarcinoma

The incidence of pancreatic cancer in the West has been estimated at approximately 10 cases per 100,000, with no increase over the last 20 years. The diagnosis is rarely made in persons younger than 40 years of age, and the median age at diagnosis is 71 years. Approximately 60% of patients with this condition are male. It is the eighth leading cause of death from cancer in men and the ninth leading cause of death from cancer in women throughout the world. Some 96% of pancreatic cancers are adenocarcinoma in type and the large majority are of ductal origin.

Aetiology

Smoking is associated with a twofold increase. Excessive intake of alcohol or coffee and excessive use of aspirin have also been implicated. There is an increased incidence of pancreatic cancer among patients with a history of diabetes and chronic pancreatitis. The risk of developing pancreatic cancer is most marked in those patients with a genetic mutation predisposing to chronic pancreatitis (there is a 50 times increased risk in the presence of a PRSS-1 mutation; see Fig. 15.13). Although it is estimated that 5–10% of pancreatic cancers have an inherited component, the genetic basis for familial aggregation has not been identified in most cases. A subgroup of such high-risk kindreds carry germline mutations of DNA repair genes, such as BRCA2 and the partner and localizer of BRCA2. Among people with a known family history of pancreatic cancer in a first-degree relative, the relative risk of the development of pancreatic cancer is increased by a factor of 2, 6 and 30 in people with one, two and three affected family members, respectively (Box 15.11).

Box 15.11

Relative risks of pancreatic cancer in patients with a family history or associated gene mutations
### Pathogenesis

Data suggest that pancreatic cancer results from the successive accumulation of gene mutations \((\text{Fig. 15.15})\). The cancer originates in the ductal epithelium and evolves from pre-malignant lesions to fully invasive cancer. The lesion called **pancreatic intraepithelial neoplasia (PanIN)** is the best-characterized histological precursor of pancreatic cancer. The progression from minimally dysplastic epithelium (PanIN grades 1A and 1B) to more severe dysplasia (grades 2 and 3) and finally to invasive carcinoma is paralleled by the successive accumulation of mutations. More than 90% of cases of pancreatic intraepithelial neoplasia of all grades have \(\text{KRAS}\) mutations. The mutational inactivation of the \(\text{CDKN2A}, \text{p53}\) and \(\text{SMAD}\) family member (\(\text{SMAD4}\)) tumour suppressors is detected with increasing frequency in type 2 and type 3 lesions of pancreatic intraepithelial neoplasia, suggesting that they are rate-limiting events for tumour progression. Exome-sequencing studies have identified additional loss-of-function mutations encoding components of the SWI/SNF nucleosome remodelling complex, which are cumulatively detected in approximately 10–15% of pancreatic adenocarcinomas, as well as other, less frequent, alterations.

A small percentage of pancreatic adenocarcinomas arise from cystic lesions, including *intraductal papillary mucinous neoplasms (IPMN)* and *mucinous cystic neoplasia* (see below). There is evidence that these cystic neoplasms demonstrate a similar multistep genetic and histological progression to invasive adenocarcinoma, although there are recognized differences in the mutational events that occur.

**Clinical features**

Approximately two-thirds of pancreatic cancers are located in the head of the pancreas, and the remainder in the body and tail ([Fig. 15.16](#)). Patients with pancreatic cancer most commonly present with abdominal pain, anorexia and weight loss. Many patients have experienced low-grade symptoms for a number of months before they present for investigation. New onset of depressive symptoms has also been identified as an early manifestation. In many cases, the onset of these non-diagnostic symptoms is at a stage when there is already advanced local or metastatic disease. The pain associated with pancreatic cancer frequently radiates through into the back and, in some cases, is partially relieved by leaning forwards. Jaundice is a common, and maybe an early, manifestation of tumours of the ampulla and pancreatic head. This reflects the occlusion or compression of the distal common bile duct as it traverses the head of pancreas before entering the duodenum at the level of the ampulla. The patient may have noticed pale stools, dark urine and itching associated with bile duct obstruction in the absence (or prior to the onset) of detectable jaundice. Diabetes is present in at least 50% of patients with pancreatic cancer and may predate any other manifestation of disease. The obstruction of the pancreatic duct by the cancer may also lead to symptoms of malabsorption and overt steatorrhoea. An episode of symptomatic pancreatitis may, on occasion, be the presenting clinical picture. Other unusual presenting features can include thromboembolic phenomena, polyarthritis and skin nodules. These manifestations, distant to the tumour itself, have not been fully explained but may precede the development of a detectable pancreatic mass lesion by many months.
Signs

At the time of first presentation, there may be an absence of physical signs. Evidence of weight loss is common. Jaundice may be present with associated scratch marks prompted by pruritus. In a proportion of cases, the gall bladder will be palpable (Courvoisier's sign) secondary to an obstructed bile duct (or cystic duct). A palpable epigastric or central abdominal mass may be present as a reflection of advanced local disease. Liver metastases may be reflected in hepatomegaly.

Diagnosis and investigations

Patients with pancreatic adenocarcinoma frequently present for investigation at a stage in tumour development that precludes treatment of a curative nature. In many cases, symptoms have been present for a number of months but have not led to investigation that is specifically aimed at confirming/excluding a pancreatic cancer. To improve outcome from this cancer, there is increasing emphasis on earlier diagnosis. This is focused on targeted investigation for patients recognized as high-risk (see above). More emphasis is also placed on earlier referral for investigation in patients over the age of 40 who have low-grade symptoms that persist after initial assessment and empirical therapy. The upper gut symptoms frequently prompt referral for an upper gastrointestinal endoscopy. In most cases, this will not add diagnostic information and it is essential that a negative endoscopy does not delay further investigation – in particular, imaging.

- **Transabdominal ultrasound** is the initial imaging investigation in the majority of patients. In the presence of bile duct obstruction, this will confirm dilated intrahepatic bile ducts, as well as a mass in the head of the pancreas. Ultrasound is less reliable when the cancer is found in the body and tail of the pancreas because of overlying bowel gas, and has a sensitivity of
detection of 60%. A negative transabdominal ultrasound scan should not be considered as excluding the diagnosis.

- **Contrast-enhanced CT scan** should confirm the presence of a mass lesion in most cases of pancreatic adenocarcinoma *(Fig. 15.17)*. Lymph node involvement and metastatic disease will also be identified. If there is a high index of suspicion, a dual-phase pancreatic protocol CT scan should be requested from the outset. A high-quality pancreatic protocol CT is required as a staging procedure prior to planned curative surgery. Extending the CT to the chest will exclude pulmonary metastases.

![FIGURE 15.17 A contrast-enhanced CT scan showing a cancer of the body of the pancreas. There is retroperitoneal tumour extension enclosing the branches of the coeliac axis (arrowed).](image)

- **Endoscopic ultrasound** is the most sensitive (>85%) non-surgical procedure for the detection of pancreatic cancer *(Fig. 15.18)*. In most cases, it does not add to the diagnostic and staging information provided by the CT scan. However, the procedure is valuable for the definition of small (<2 cm) lesions of the pancreas, which may be missed on CT. Endoscopic ultrasound is now the approach of choice for obtaining cytological confirmation of the underlying malignancy. A histological/cytological diagnosis is essential prior to planned chemotherapy. There are concerns that needle sampling of the tumour prior to a planned curative resection might lead to cancer cell seeding. This has been reported as a rare event (1–2%).
An endoscopic ultrasound scan with the probe in the distal stomach in a patient with pancreatic cancer. The patient presented with intractable periumbilical pain. A mass lesion of the pancreatic body is defined (tumour). There is invasion by the lesion into the splenic vein (SV, vasc invasion). The line of a transendoscopic needle is seen (needle tip), which has been placed under the guidance of the ultrasound probe to obtain a needle aspirate for cytological diagnosis.

- MRI and positron emission tomography (PET) scanning are techniques that are useful in a small proportion of patients when the local tumour or possibility of metastases has not been adequately defined.

- Several tumour markers have been evaluated for the diagnosis and monitoring of pancreatic cancer. The CA19–9 has reasonable sensitivity (80%) but a high false-positive rate. In individual patients, single values of these tumour markers may be of little help but a progressive elevation over time is often diagnostic; in such circumstances, tumour marker levels can be used to monitor response to treatment.

**Differential diagnosis**

The diagnosis should not be difficult in the presence of painless jaundice or epigastric pain radiating into the back with progressive weight loss. Unfortunately, many patients present with very minor symptoms, including pain, change in bowel habit and weight loss. Imaging, particularly abdominal CT, should be performed if pancreatic cancer is suspected. IgG4-related autoimmune pancreatitis is now recognized as a differential diagnosis in patients presenting with abdominal pain, jaundice and an abnormal pancreas on imaging (localized or diffuse enlargement; see above). Pancreatic cancer may rarely present with recurrent episodes of typical acute pancreatitis.

**Management**

The 5-year survival rate for carcinoma of the pancreas is approximately 3%. Some 90% of patients with a diagnosis of pancreatic adenocarcinoma will have a cause of death directly related to the disease. Surgical intervention represents the only chance of long-term survival.
Approximately 20% of all cases have a localized tumour suitable for resection, but in an elderly population, many of these have co-morbid factors that preclude such major surgery. Assessment of the primary tumour and involvement of local vessels, including the coeliac artery, superior mesenteric artery and vein, portal vein and hepatic artery, is critical in determining resectability. Strategies for management are optimally defined as part of a multidisciplinary team approach.

When treatment is considered of curative intent, a pancreatoduodenectomy (Whipple procedure) is required to remove tumours of the head and neck of the pancreas. Tumours of the body and tail are resected as part of a distal pancreatectomy, which is increasingly carried out by the laparoscopic approach. Adjuvant and neo-adjuvant chemotherapy (fluorouracil or gemcitabine) have been used in those undergoing attempted curative resection, with some evidence of improved survival. There is early evidence that more intensive multidrug regimes (the addition of irinotecan and oxaliplatin) may further improve outcome but at the expense of increased drug toxicity. Radiotherapy has been evaluated as adjuvant treatment but does not have an established role.

In the large majority of cases, therapy is considered non-curative. Chemotherapy (see above) is widely used in this setting, with increasing emphasis on multidrug regimens (see p. 638). The mainstay of palliative therapy is the attention to detail in managing the generalized and specific complications of pancreatic cancer.

- **Pain** is a debilitating feature in many cases. Management is best directed by dedicated pain teams. Opiates are a mainstay. There is some evidence that early intervention with coeliac axis block may have benefits.

- **Nutritional deficit** is a frequent feature at presentation and may be exacerbated by chemotherapy. Early dietetic support may alleviate this. Malabsorption is common with pancreatic cancer and can be managed by the introduction of pancreatic enzyme supplementation. The adverse metabolic effects of diabetes can be avoided by early detection and management.

- **Obstructive jaundice** will occur at some stage in 70% of cases and is frequently associated with anorexia and nausea, as well as pruritus. Endoscopic placement of endoprosthesis (stents) offers excellent palliation (see pp. 498–499).

- **Duodenal obstruction** is seen in up to 20% of cases, particularly when the tumour is situated in the head or uncinate process of the pancreas. Endoscopic stenting is the treatment of choice with excellent palliation. Surgical bypass is an option in selected cases.

### Pancreatic cystic neoplasms

Cystic lesions of the pancreas are common. Around 75% of these lesions will be pseudocysts (see p. 508) but, of the remainder, the majority are true cystic neoplasms. Careful characterization of lesions with CT and MRI, and discussion in a specialist pancreatic multidisciplinary team, are crucial. There is a high potential for the development of malignancy in true cystic neoplasms and therefore resection is generally recommended. The decision to
operate may be difficult in patients with small (<3 cm) lesions of the head of the pancreas (in the absence of confirmed malignancy at presentation) and in those with significant co-morbidity. An initially conservative approach with follow-up imaging may be justified. Differentiation between pseudocysts and true cystic neoplasms may be difficult, even with multiple imaging techniques. Endoscopic ultrasound scanning and fine-needle aspiration are frequently helpful in characterizing cystic lesions of the pancreas. Endoscopic ultrasound appearance (Fig. 15.19), cytology, and the measurement of cyst fluid carcinoembryonic antigen and amylase may help to categorize cystic lesions and identify malignant change.

**Serous cystadenomas** are composed of multiple small, cystic cavities lined by cuboidal, glycogen-rich, mucin-poor cells. These lesions tend to occur in an elderly age group and are often an asymptomatic finding. Malignant transformation in a serous cystadenoma is extremely rare and so surgical resection is rarely required. Larger serous cystadenomas may cause local compressive complications, including pain, which may warrant surgical resection.

**Solid pseudopapillary neoplasms** are rare lesions, usually found in women in their fourth decade; they may occur anywhere in the pancreas. Resection is required, as around 20% show malignant features on histological examination.

**Mucinous cystadenomas** are almost exclusively found in women, usually in the fifth or
sixth decade, and are sited in the pancreatic body and tail. Multilocular cysts are lined by tall, mucin-synthesizing cells. Around 20% of these lesions are malignant at the time of presentation and the majority appear to have malignant potential. Surgical resection is generally mandated.

**Intraductal papillary mucinous neoplasm (IPMN)** is a pancreatic cystic neoplasm that can arise in either the main pancreatic duct (main duct IPMN) or its side branches (branch duct IPMN). The majority are found in men between the ages of 60 and 70. Presentation is usually with pancreatic pain but branch duct IPMN is often an incidental finding. IPMNs are slowly progressive but carry a significant malignant potential. Generally, all main duct IPMNs and large branch duct IPMNs should be resected. Small branch duct IPMNs have a much lower malignant potential and are generally kept under radiological surveillance.

**Cystic degeneration** of a pancreatic adenocarcinoma or pancreatic neuroendocrine tumour can occur.

---

**Pancreatic neuroendocrine tumour**

Pancreatic neuroendocrine tumours (NETs) are thought to arise from the cells of the islets of Langerhans and can secrete a variety of active hormones, most frequently insulin. Pancreatic NETs have increased in incidence over the last two decades, reaching an incidence of 4–5/1000000 population. They represent a heterogeneous group of tumours with varying symptomology, tumour biology and prognosis. Between 25% and 50% of the patients present with symptoms related to hormones released from the tumour. The remainder have ‘non-functioning’ tumours that may be an incidental finding or present with symptoms related to tumour bulk, such as obstruction, jaundice, bleeding or abdominal mass. The increasing incidence of pancreatic NETs has been attributed to the widespread use of high-resolution cross-sectional imaging, leading to incidental detection of asymptomatic lesions.

In addition to insulin and glucagon, pancreatic NETs may synthesize ectopic hormones that are not usually found in the pancreas, such as gastrin, adrenocorticotrophin, vasoactive intestinal peptide and growth hormone. While many pancreatic endocrine tumours are multihormonal, one peptide tends to predominate and is responsible for any clinical syndrome (see below). Non-functioning pancreatic NETs often contain peptide hormone on immunostaining, but this remains functionally inactive. The majority of endocrine neoplasia pancreatic tumours are malignant in their behaviour. Between 10% and 15% of pancreatic NETs are linked to an inherited syndrome, such as the multiple endocrine neoplasia type 1 (MEN-1) or von Hippel–Lindau (VHL) syndrome (see p. 791).

---

**Clinical syndromes**

**Insulinoma** is described on pages 1275–1276.

A gastrinoma accounts for approximately 1 in 1000 cases of duodenal ulcer disease. This results from hypersecretion of gastric acid secondary to ectopic gastrin secretion within the endocrine pancreas (Zollinger–Ellison syndrome). Recurrent severe duodenal ulceration occurs, with only a partial response to acid suppression. The diagnosis is confirmed by an
elevated gastrin level. High-dose proton-pump inhibitors are used to suppress symptoms.

A **VIPoma** is an endocrine pancreatic tumour producing vasoactive intestinal polypeptide (VIP). This causes secretory diarrhoea secondary to the stimulation of adenyl cyclase within the enterocyte (*Verner–Morrison or watery diarrhoea syndrome*). The clinical syndrome is one of profuse watery diarrhoea, hypokalaemia and a metabolic acidosis. To produce the syndrome, the tumours are usually in excess of 3 cm in diameter.

**Glucagonomas** are rare α-cell tumours that are responsible for a syndrome of migratory necrolytic dermatitis, weight loss, diabetes mellitus, deep vein thrombosis, anaemia and hypoalbuminaemia. The diagnosis is made by measuring pancreatic glucagon in the serum.

**Somatostatinomas** are rare malignant D-cell tumours of the pancreas. These tumours cause diabetes mellitus, gallstones and diarrhoea/steatorrhoea. They can be diagnosed by high serum somatostatin levels.

### Investigations

Diagnosis is based on a combination of biochemical and histopathological markers. The biochemical diagnosis includes measurement of circulatory chromogranin A or specific hormones such as gastrin, insulin, glucagon and VIP. The histopathology includes features such as positive staining for chromogranin A and specific hormones such as gastrin, pro-insulin and glucagon.

Tumour localization depends on cross-sectional imaging, including CT and MRI scanning. The majority of NETs express somatostatin receptors, and a radiolabelled somatostatin analogue (such as octreotide) provides a means of tumour localization using scintigraphy. PET scanning with specific isotopes such as $^{11}$C-5-hydroxytryptamine ($^{11}$C-5-HTP), fluorodopa and $^{68}$Ga (DOTA)-octreotate has shown promise in the localization of disease.

Identification of the primary and possibly metastatic lesions may be difficult despite multiple imaging techniques. Endoscopic ultrasound is the most sensitive means of detecting small primary NETs in the pancreas. It also offers the opportunity to undertake fine needle aspiration sampling of lesions, affording a cytopathological diagnosis (Fig. 15.20).
Management (see also pp. 638–639)

Treatment of pancreatic NETs requires a multidisciplinary approach and depends on the presence or absence of metastatic (usually hepatic) disease. Where possible, surgical resection of the primary lesion is the optimal management of pancreatic endocrine tumours, as it offers the only possible cure. The propensity of many endocrine tumours to metastasize early precludes cure in many cases. Debulking of the tumour, including liver metastases, is frequently carried out to facilitate systemic treatment.

*Somatostatin analogues*, such as octreotide and lanreotide, are used to control hormonal-
related symptoms and also have a tumour-modulating effect. There is some evidence that somatostatin analogues combined with interferon-alfa also control tumour proliferation. Radionuclide therapy using somatostatin analogues has proven benefit in patients with tumours that express a high content of somatostatin receptors.

The *chemotherapeutic agents*, streptozotocin, 5-fluorouracil and doxorubicin, produce partial remission in approximately 40% of cases. Recent advances include the introduction of tyrosine kinase and the mammalian target of rapamycin (mTOR) inhibitors. Pancreatic NETs show a very high degree of vascularization, as well as abundant production and secretion of growth factors. There is preliminary evidence of benefit from anti-angiogenesis therapy utilizing vascular endothelial growth factor (VEGF) antagonists.

In patients with extensive liver metastasis, occlusion of the arterial blood flow by hepatic arterial embolization may control hormone-related symptoms. In most cases, the tumours are slowly progressive and may allow a reasonable quality of life for many years.

Introduction

Blood consists of:
- red cells
• white cells
• platelets
• plasma, in which the above elements are suspended.

Plasma is the liquid component of unclotted blood, which contains soluble fibrinogen. Serum is what remains after the formation of the fibrin clot.

**The formation of blood cells (haemopoiesis)**

The haemopoietic system includes the bone marrow, liver, spleen, lymph nodes and thymus. There is huge turnover of cells with the red cells surviving 120 days, platelets around 7 days but granulocytes only 7 hours. The production of as many as $10^{13}$ new myeloid cells (all blood cells except for lymphocytes) per day in the normal healthy state requires tight regulation according to the needs of the body.

Blood islands are formed in the yolk sac in the third week of gestation and produce primitive blood cells, which migrate to the liver and spleen. These organs are the chief sites of haemopoiesis from 6 weeks' to 7 months' gestation, when the bone marrow becomes the main source of blood cells. In childhood and adult life, the bone marrow is the only source of blood cells in a normal person.

At birth, haemopoiesis is present in the marrow of nearly every bone. As the child grows, the active red marrow is gradually replaced by fat (yellow marrow) so that haemopoiesis in the adult becomes confined to the central skeleton and the proximal ends of the long bones. Only if the demand for blood cells increases and persists do the areas of red marrow extend. Pathological processes interfering with normal haemopoiesis may result in resumption of haemopoietic activity in the liver and spleen, which is referred to as *extramedullary haemopoiesis*.

All blood cells are derived from pluripotent stem cells. These stem cells have two key properties – the first is **self-renewal**, i.e. the production of more stem cells, and the second is its **proliferation and differentiation** into progenitor cells, committed to one specific cell line. Pluripotential stem cells differentiate into mature blood cells through intermediate progenitor cells, which have lost the ability to self-renew but have high proliferative capacity. These progenitor cells can be broadly classified according to the blood cells that they are programmed to make (**Fig. 16.1**). For example, the common lymphoid progenitor (CLP) gives rise to T and B lymphoid cells; the former occurs in the thymus whereas B cell production primarily occurs in the bone marrow. The common myeloid progenitor gives rise to all non-lymphoid cells in the bone marrow via a series of intermediate progenitor cells. These cells cannot be recognized in bone marrow biopsies but are recognized by their ability to form colonies (reflecting their high proliferative capacity) when haemopoietic cells are immobilized in a soft gel matrix, the so-called colony-forming unit (CFU), which are named according to the type of cell they produce.
FIGURE 16.1 Roadmap of normal blood cell development. The process by which a haemopoietic stem cell develops into mature blood cells through a series of progenitor cell intermediates. The mature blood cells are platelets (P), erythrocytes (E), neutrophils (N), eosinophils (Eo), basophils (B), monocytes (M), B lymphocytes (BL) and T lymphocytes (TL). Some growth factors, which promote certain stages of blood cell development, are: SCF (stem cell factor), TPO (thrombopoietin), G-CSF (granulocyte-colony-stimulating factor), EPO (erythropoietin), IL-7 (interleukin 7) and Flt3 (Fms-like tyrosine kinase 3).

These haemopoietic stem and progenitor cells interact closely with a number of components contained within the specialized microenvironment of the bone marrow. This includes non-haemopoietic stromal cells, blood vessels and extracellular matrix, together creating a nurturing microenvironment for blood cell development. Central to this microenvironment are haemopoietic growth factors produced by stromal cells in the bone marrow and elsewhere, which are key regulators of blood cell production.
Haemopoietic growth factors

Haemopoietic growth factors are glycoproteins, which regulate the differentiation and proliferation of haemopoietic progenitor cells and the function of mature blood cells. Some growth factors are present in the circulation whereas other growth factors are produced within the bone marrow microenvironment by stromal cells such as fibroblasts, osteoblasts or endothelial cells or at sites of inflammation by activated T cells, monocytes and macrophages. Growth factors act on their respective cell surface receptors, expressed on haemopoietic cells at various stages of development, to maintain the haemopoietic progenitor cells and to stimulate increased production of one or more cell types in response to stresses such as blood loss and infection (Fig. 16.1).

These haemopoietic growth factors, including erythropoietin (EPO), interleukin (IL) 3, IL-6, IL-7, IL-11, IL-12, β-catenin, stem cell factor (SCF, Steel factor or C-kit ligand) and Fms-like tyrosine kinase 3 (Flt3), act via their specific receptor on cell surfaces to stimulate downstream signalling within the cell, such as the cytoplasmic Janus kinase (JAK) pathway (see pp. 96–97). This, in turn, activates signalling cascades within the cell, ultimately altering gene expression in the cell nucleus, and thus influencing behaviour of the cell: for example, to promote proliferation. Colony-stimulating factors (CSFs; the prefix indicates the cell type – see Fig. 16.1), as well as interleukins and EPO, regulate the lineage-committed progenitor cells.

Thrombopoietin (TPO) is produced in the kidneys, liver and certain bone marrow stromal cells, and acts to control platelet production, along with IL-6 and IL-11. In addition to these factors, which stimulate haemopoiesis, there are other factors that inhibit the process; these include tumour necrosis factor (TNF) and transforming growth factor beta (TGF-β).

Uses in treatment

Many growth factors have been produced by recombinant DNA techniques and are being used clinically. Examples include granulocyte-colony-stimulating factor (G-CSF), which is used to accelerate haemopoietic recovery after chemotherapy and haemopoietic cell transplantation, and erythropoietin, which is used to treat anaemia in patients with chronic kidney disease and in patients with certain blood cancers. Thrombopoietin receptor agonists are being used to treat patients with immune thrombocytopenic purpura.

Peripheral blood

Automated cell counters are used to measure the haemoglobin (Hb) concentration and the number and size of red cells, white cells and platelets (Box 16.1). Other indices can be derived from these values. A blood film is still an essential adjunct to the above, as definitive abnormalities of cells can be seen.

- **The mean corpuscular volume (MCV)** of red cells is a useful index and is used to classify anaemia (see p. 522).
- **The red cell distribution width (RDW)** is calculated by dividing the standard deviation of
the red cell width by the *mean cell width* × 100. An elevated RDW suggests variation in red cell size, i.e. anisocytosis, and this is seen in iron deficiency. In β-thalassaemia trait, the RDW is usually normal.

- **The white cell count (WCC)** (or white blood count, WBC) gives the total number of circulating leucocytes, and many automated cell counters produce differential counts as well, specifically enumerating numbers of neutrophils, monocytes and lymphocytes.

- **Reticulocytes** are young red cells and usually comprise <2% of the red cells. The reticulocyte count gives a guide to the erythroid activity in the bone marrow. An increased count is seen with increased marrow maturity: for example, following haemorrhage or haemolysis, and during the response to treatment with a specific haematinic. A low count in the presence of anaemia indicates an inappropriate response by the bone marrow and may be seen in bone marrow failure (from whatever cause) or where there is a deficiency of a haematinic.

- **Erythrocyte sedimentation rate (ESR)** is the rate of fall of red cells in a column of blood and is a measure of the acute-phase response. The pathological process may be immunological, infective, ischaemic, malignant or traumatic. A raised ESR reflects an increase in the plasma concentration of large proteins, such as fibrinogen and immunoglobulins. These proteins cause rouleaux formation, with red cells clumping together and therefore falling more rapidly. The ESR increases with age, and is higher in females than in males.

- **Plasma viscosity** is a measurement used instead of the ESR in some laboratories. It is also dependent on the concentration of large molecules such as fibrinogen and immunoglobulins. It is not affected by the level of Hb.

- **C-reactive protein (CRP)** is a pentraxin, one of the proteins produced in the acute-phase response. It is synthesized exclusively in the liver and rises within 6 hours of an acute event. The CRP level rises with fever (possibly triggered by IL-1, IL-6, TNF-α and other cytokines), in inflammatory conditions and after trauma. It follows the clinical state of the patient much more rapidly than the ESR and is unaffected by the level of Hb, but it is less helpful than the ESR or plasma viscosity in monitoring chronic inflammatory diseases. The measurement of CRP is easy and quick to perform using an immunoassay that can be automated.

ESR, erythrocyte sedimentation rate; Hb, haemoglobin; MCH, mean corpuscular haemoglobin; MCHC, mean corpuscular haemoglobin concentration; MCV, mean corpuscular volume of red cells; PCV, packed cell volume; RCC, red cell count; RDW, red blood cell distribution width; WCC, white cell count.

The Red Cell

Erythropoiesis

Red cell precursors pass through several stages in the bone marrow. The earliest morphologically recognizable cells are proerythroblasts. Smaller erythroblasts result from cell divisions, and precursors at each stage progressively contain less RNA and more Hb in the cytoplasm. The nucleus becomes more condensed and is eventually lost from the late normoblast in the bone marrow when the cell becomes a reticulocyte.

- **Reticulocytes** contain residual ribosomal RNA and are still able to synthesize Hb. They remain in the marrow for about 1–2 days and are released into the circulation, where they lose their RNA and become mature red cells (erythrocytes) after another 1–2 days. Mature red cells are non-nucleated biconcave discs.

- Nucleated red cells (late erythroblasts) are not normally present in peripheral blood, but are present if there is extramedullary haemopoiesis and in some marrow disorders (see p. 563).

- About 10% of erythroblasts die in the bone marrow, even during normal erythropoiesis. Such ineffective erythropoiesis is substantially increased in some anaemias, such as thalassaemia major and megaloblastic anaemia.

- **Erythropoietin** is a hormone that controls erythropoiesis. The gene for erythropoietin is on chromosome 7 and codes for a heavily glycosylated polypeptide of 165 amino acids. Erythropoietin has a molecular weight of 30 400 and is produced in the peritubular cells in the kidneys (90%) and in the liver (10%). Its production is regulated mainly by tissue oxygen tension. Production is increased if there is hypoxia from whatever cause: for example, anaemia or cardiac or pulmonary disease. The erythropoietin gene is one of a number of...
genes that is regulated by the hypoxic sensor pathway. The 3′-flanking region of the erythropoietin gene has a hypoxic response element, which is necessary for the induction of transcription of the gene in hypoxic cells. Hypoxia-inducible factor 1 (HIF-1) is a transcription factor, which binds to the hypoxia response element and acts as a master regulator of several genes that are responsive to hypoxia. Erythropoietin stimulates an increase in the proportion of bone marrow precursor cells committed to erythropoiesis, and CFU-E are stimulated to proliferate and differentiate. Increased ‘inappropriate’ production of erythropoietin occurs in certain tumours such as renal cell carcinoma and from other causes (see Box 16.17).

**Haemoglobin synthesis**

Haemoglobin performs the main functions of red cells, carrying O₂ to the tissues and returning CO₂ from the tissues to the lungs. Each normal adult Hb molecule (HbA) has a molecular weight of 68 000 and consists of two α and two β globin polypeptide chains (α₂β₂). HbA comprises about 97% of the Hb in adults. Two other haemoglobin types, HbA₂ (α₂δ₂) and HbF (α₂γ₂), are found in adults in small amounts (1.5–3.2% and <1%, respectively) (see pp. 534–535).

Haem synthesis occurs in the mitochondria of the developing red cell (Fig. 16.2). The major rate-limiting step is the conversion of glycine and succinic acid to δ-aminolaevulinic acid (ALA) by ALA synthase. Vitamin B₆ is a coenzyme for this reaction, which is inhibited by haem and stimulated by erythropoietin. Two molecules of δ-ALA condense to form a pyrrole ring (porphobilinogen). These rings are then grouped in fours to produce protoporphyrins and, with the addition of iron, haem is formed. Haem is then inserted into the globin chains to form a haemoglobin molecule. The structure of Hb is shown in Figure 16.3.
FIGURE 16.2 Haemoglobin synthesis. Transferrin attaches to a surface receptor on developing red cells. Iron is released and transported to the mitochondria, where it combines with protoporphyrin to form haem. Protoporphyrin itself is manufactured from glycine and succinyl CoA. Haem combines with α and β chains (formed on ribosomes) to make haemoglobin.
Haemoglobin function

The biconcave shape of red cells provides a large surface area for the uptake and release of oxygen and carbon dioxide. Haemoglobin becomes saturated with oxygen in the pulmonary capillaries, where the partial pressure of oxygen is high and Hb has a high affinity for oxygen. Oxygen is released in the tissues, where the partial pressure of oxygen is low and Hb has a low affinity for oxygen.

In adult haemoglobin (Hb), a haem group is bound to each of the four globin chains; the haem group has a porphyrin ring with a ferrous atom, which can reversibly bind one oxygen molecule. The haemoglobin molecule exists in two conformations, Relaxed (R) and Taut (T), corresponding to oxyhaemoglobin and deoxyhaemoglobin, respectively (Fig. 16.4). The binding of one oxygen molecule to deoxyhaemoglobin increases the oxygen affinity of the remaining binding sites; this property is known as ‘cooperativity’ and is the reason for the sigmoid shape of the oxygen dissociation curve (see Figure 25.2). The binding of oxygen can also be influenced by secondary effectors such as hydrogen ions, carbon dioxide and red cell...
2,3-bisphosphoglycerate (2,3-BPG). Red cell metabolism produces 2,3-BPG from glycolysis, and the binding of 2,3-BPG stabilizes the T conformation, thus reducing its affinity for oxygen and increasing release of oxygen in the tissues. The \( P_{50} \) is the partial pressure of oxygen at which the haemoglobin is 50% saturated with oxygen. When the primary limitation to oxygen transport is in the periphery – for example, during heavy exercise or in anaemia – the \( P_{50} \) is increased to enhance oxygen unloading. Furthermore, hydrogen ions and carbon dioxide added to blood cause a reduction in the oxygen-binding affinity of haemoglobin (the Bohr effect), also helping the exchange of carbon dioxide and oxygen in the tissues. When the primary limitation is in the lungs – for example, in lung disease or high-altitude exposure – the \( P_{50} \) is reduced to enhance oxygen loading. A summary of normal red cell production and destruction is given in Figure 16.5.

![Image](FIGURE16.4.png)

**FIGURE 16.4** Oxygenated and deoxygenated haemoglobin molecule. The haemoglobin molecule is predominantly stabilized by \( \alpha-\beta \) chain bonds rather than \( \alpha-\alpha \) and \( \beta-\beta \) chain bonds. The structure of the molecule changes during \( O_2 \) uptake and release. When \( O_2 \) is released, the \( \beta \) chains rotate on the \( \alpha_1\beta_2 \) and \( \alpha_2\beta_1 \) contacts, allowing the entry of 2,3-BPG, which causes a lower affinity of haemoglobin for \( O_2 \) and improved delivery of \( O_2 \) to the tissues.
Anaemia: an Introduction

Anaemia is present when there is a decrease in Hb in the blood below the reference level for
the age and sex of the individual (see Box 16.1). Alterations in the Hb may occur as a result of changes in the plasma volume, as shown in Figure 16.6. A reduction in the plasma volume will lead to a spuriously high Hb; this is seen with dehydration and in the clinical condition of apparent polycythaemia (see p. 550). A raised plasma volume produces a spurious anaemia, even when combined with a small increase in red cell volume, as occurs in pregnancy.

The various types of anaemia, classified by MCV, are shown in Figure 16.7. There are three major types:

• hypochromic microcytic with a low MCV
• normochromic normocytic with a normal MCV
• macrocytic with a high MCV.
Clinical features

Patients with anaemia may be asymptomatic. A slowly falling level of Hb allows for haemodynamic compensation and enhancement of the oxygen-carrying capacity of the blood. A rise in 2,3-BPG causes a shift of the oxygen dissociation curve to the right, so that oxygen is more readily given up to the tissues. Where blood loss is rapid, more severe symptoms will occur, particularly in elderly people.

Symptoms

These are all non-specific:
• fatigue, headaches and faintness
• breathlessness
• angina
• intermittent claudication
• palpitations.

Anaemia exacerbates cardiorespiratory problems especially in the elderly. For example, angina or intermittent claudication may be precipitated by anaemia. A good way to assess the effects of anaemia is to ask about breathlessness in relation to different levels of exercise (e.g. walking on the flat or climbing one flight of stairs).

Signs

• Pallor.
• Tachycardia.
• Systolic flow murmur.
• Cardiac failure.

Specific signs seen in the different types of anaemia will be discussed in the appropriate sections. Examples include:
• koilonychia – spoon-shaped nails seen in longstanding iron deficiency anaemia
• jaundice – found in haemolytic anaemia
• bone deformities – found in thalassaemia major
• leg ulcers – occur in association with sickle cell disease.

Anaemia is not a final diagnosis, and a cause should always be sought.

Investigations

Peripheral blood
A low Hb should always be evaluated with:
• The red cell indices.
• The WCC.
• The platelet count.
• The reticulocyte count (as this indicates marrow activity).
• The blood film, as abnormal red cell morphology (see Fig. 16.9) may indicate the diagnosis. Where two populations of red cells are seen, the blood film is said to be dimorphic. This may, for example, be seen in patients with ‘double deficiencies’ (e.g. combined iron and folate deficiency in coeliac disease, or following treatment of anaemic patients with the appropriate haematinic).

Bone marrow
Techniques for obtaining bone marrow are shown in Box 16.2.

Box 16.2
Techniques for obtaining bone marrow
The technique should be explained to the patient and consent obtained.

Aspiration
• Site – usually iliac crest
• Give local anaesthetic injection
• Use special bone marrow needle (e.g. Salah)
• Aspirate marrow
• Make smear with glass slide
• Stain with:
  – Romanowsky technique
  – Perls' reaction (acid ferrocyanide) for iron

**Trephine**

Indications include:
• ‘Dry tap’ obtained with aspiration
• Better assessment of cellularity, e.g. aplastic anaemia
• Better assessment of presence of infiltration or fibrosis

**Technique**
• Site – usually posterior iliac crest
• Give local anaesthetic injection
• Use special needle (e.g. Jamshidi – longer and wider than for aspiration)
• Obtain core of bone
• Fix in formalin; decalcify – this takes a few days
• Stain with:
  – Haematoxylin and eosin
  – Reticulin stain

Examination of the bone marrow is performed to investigate abnormalities found in the peripheral blood further *(Box 16.2)*. Aspiration provides a film that can be examined by microscopy for the morphology of the developing haemopoietic cells. The trephine provides a core of bone that is processed as a histological specimen and allows an overall view of the bone marrow architecture, cellularity and presence/absence of abnormal infiltrates.

The following are assessed:
• cellularity of the marrow
• type of erythropoiesis (e.g. normoblastic or megaloblastic)
• cellularity of the various cell lines
• infiltration of the marrow, i.e. presence of non-haemopoietic cells such as cancer cells
• iron stores.

Special tests may be performed for further diagnosis: cytogenetic investigations, immunological investigations, cytochemical markers, biochemical analyses and microbiological culture.

**Microcytic Anaemia**

Iron deficiency is the most common cause of anaemia in the world, affecting 30% of the
world's population. This is because of the body's limited ability to absorb iron and the frequent loss of iron owing to haemorrhage. Although iron is abundant, most is in the insoluble ferric (Fe$^{3+}$) form, which has poor bioavailability. Ferrous (Fe$^{2+}$) iron is more readily absorbed.

The other causes of a microcytic hypochromic anaemia are anaemia of chronic disease, sideroblastic anaemia and thalassaemia. In thalassaemia (see pp. 535–538), there is a defect in globin synthesis, in contrast to the other three causes of microcytic anaemia, where the defect is in the synthesis of haem.

**Iron**

**Dietary intake**

The average daily diet in the UK contains 15–20 mg of iron, although normally only 10% of this is absorbed. Absorption may be increased to 20–30% in iron deficiency and pregnancy.

Non-haem iron is mainly derived from cereals, which are commonly fortified with iron; it forms the main part of dietary iron. Haem iron is derived from haemoglobin and myoglobin in red or organ meats. Haem iron is better absorbed than non-haem iron, whose availability is more affected by other dietary constituents.

**Absorption**

Factors influencing iron and haem iron absorption (*Fig. 16.8*) are shown in *Box 16.3.*
Iron absorption. A. Regulation of the absorption of intestinal iron. The iron-absorbing cells of the duodenal epithelium originate in the intestinal crypts and migrate towards the tip of the villus as they differentiate (maturation axis). Absorption of intestinal iron is regulated by at least three independent mechanisms, although the protein hepcidin is key. First, iron absorption is influenced by recent dietary iron intake (dietary regulator). After a large dietary bolus, absorptive cells are resistant to iron uptake for several days. Second, iron absorption can be modulated considerably in response to body iron stores (stores regulator). Third, a signal communicates the state of bone marrow erythropoiesis to the intestine (erythroid regulator). B. Duodenal crypt cells sense body iron status through the binding of transferrin to the HFE/B2M/TfR1 gene complex. Cytosolic enzymes change the oxidative state of iron from ferric (Fe$^{3+}$) to ferrous (Fe$^{2+}$). A decrease in crypt cell iron concentration upregulates the divalent metal transporter (DMT1). This increases as crypt cells migrate up the villus and become mature absorptive cells. C. Apical cell. Dietary iron is reduced from the ferric to the ferrous state by brush border ferrireductase. DMT1 facilitates iron absorption from the intestinal lumen. The export proteins, e.g., ferroportin 1 and hephaestin, transfer iron from the enterocyte into the circulation, depending on the hepcidin level. A second pathway absorbs intact haem iron into the circulation via BCRP and FLVCR. BCRP, breast cancer resistant protein; B2M, β2-microglobulin; FLVCR, feline leukaemia virus subgroup C; HCP1, haem carrier protein-1; HFE, hereditary haemochromatosis gene; TfR1, transferrin receptor.

Box 16.3

Factors influencing iron absorption

- Haem iron is absorbed better than non-haem iron
- Ferrous iron is absorbed better than ferric iron
- Gastric acidity helps to keep iron in the ferrous state and soluble in the upper gut
- Formation of insoluble complexes with phytate or phosphate decreases iron absorption
- Iron absorption is increased with low iron stores and increased erythropoietic activity, e.g.
bleeding, haemolysis, high altitude

• Absorption is decreased in iron overload, except in hereditary haemochromatosis, where it is increased

Dietary haem iron is more rapidly absorbed than non-haem iron derived from vegetables and grain. Most haem is absorbed in the proximal intestine, with absorptive capacity decreasing distally. The intestinal haem transporter HCP1 (haem carrier protein 1) has been identified and found to be highly expressed in the duodenum. It is upregulated by hypoxia and iron deficiency. Some haem iron may be reabsorbed intact into the circulation via the cell by two exporter proteins: BCRP (breast cancer resistant protein) and FLVCR (feline leukaemia virus subgroup C) (Fig. 16.8).

Non-haem iron absorption occurs primarily in the duodenum. Non-haem iron is dissolved in the low pH of the stomach and reduced from the ferric to the ferrous form by a brush border ferrireductase. Cells in duodenal crypts are able to sense the body's iron requirements and retain this information as they mature into cells capable of absorbing iron at the tips of the villi. A protein, divalent metal transporter 1 (DMT1) or natural resistance-associated macrophage protein (NRAMP2), transports iron (and other metals) across the apical (luminal) surface of the mucosal cells in the small intestine.

Once inside the mucosal cell, iron may be transferred across the cell to reach the plasma, or be stored as ferritin; the body's iron status at the time the absorptive cell developed from the crypt cell is probably the crucial deciding factor. Iron stored as ferritin will be lost into the gut lumen when the mucosal cells are shed; this regulates iron balance. The mechanism of transport of iron across the basolateral surface of mucosal cells involves a transporter protein, ferroportin 1 (FPN 1) through its iron-responsive element (IRE). This transporter protein requires an accessory, multicopper protein, hephaestin (Fig. 16.8).

The body iron content is closely regulated by the control of iron absorption but there is no physiological mechanism for eliminating excess iron from the body. The key molecule regulating iron absorption is hepcidin, a 25-amino acid peptide synthesized in the liver. Hepcidin acts by regulating the activity of the iron-exporting protein ferroportin by binding to ferroportin, causing its internalization and degradation, and thereby decreasing iron efflux from iron-exporting tissues into plasma. Therefore, high levels of hepcidin (occurring in inflammation states) via inflammatory cytokines, e.g. IL-6, will destroy ferroportin and limit iron absorption, and low levels of hepcidin (e.g. in anaemia, low iron stores, hypoxia) will encourage iron absorption. For example, in patients with haemochromatosis (see Fig. 14.27), mutations in the genes HFE, HJV and TfR2 will interrupt hepcidin synthesis. Therefore, in the intestinal cells, a deficiency of hepcidin would lead to less ferroportin being bound and thus more iron will be released into the plasma.

A longstanding mystery is why anaemias characterized by ineffective erythropoiesis, such as thalassaemia, are associated with excessive and inappropriate iron absorption. Preliminary evidence again suggests that the increased iron absorption in β-thalassaemia is mediated by downregulation of hepcidin and upregulation of ferroportin.
Transport in the blood

The normal serum iron level is about 13–32 µmol/L; there is a diurnal rhythm with higher levels in the morning. Iron is transported in the plasma bound to transferrin, a β-globulin that is synthesized in the liver. Each transferrin molecule binds two atoms of ferric iron and is normally one-third saturated. Most of the iron bound to transferrin comes from macrophages in the reticuloendothelial system and not from iron absorbed by the intestine. Transferrin-bound iron becomes attached by specific receptors to erythroblasts and reticulocytes in the marrow and the iron is removed (see Fig. 16.2).

In an average adult male, 20 mg of iron, chiefly obtained from red cell breakdown in the macrophages of the reticuloendothelial system, is incorporated into Hb every day.

Iron stores

About two-thirds of the total body iron is in the circulation as haemoglobin (2.5–3 g in a normal adult man). Iron is stored in reticuloendothelial cells, hepatocytes and skeletal muscle cells (500–1500 mg). About two-thirds of this is stored as ferritin and one-third as haemosiderin in normal individuals. Small amounts of iron are also found in plasma (about 4 mg bound to transferrin), with some in myoglobin and enzymes.

**Ferritin** is a water-soluble complex of iron and protein. It is more easily mobilized than haemosiderin for Hb formation. It is present in small amounts in plasma.

**Haemosiderin** is an insoluble iron–protein complex found in macrophages in the bone marrow, liver and spleen. Unlike ferritin, it is visible by light microscopy in tissue sections and bone marrow films after staining by Perls' reaction.

Requirements

Each day, 0.5–1.0 mg of iron is lost in the faeces, urine and sweat. Menstruating women lose 30–40 mL of blood/month, an average of about 0.5–0.7 mg of iron/day. Blood loss through menstruation in excess of 100 mL will usually result in iron deficiency, as increased iron absorption from the gut cannot compensate for such losses of iron. The demand for iron also increases during growth (about 0.6 mg/day) and pregnancy (1–2 mg/day). In the normal adult, the iron content of the body remains relatively fixed. Increases in the body iron content (haemochromatosis) are classified into:

- hereditary haemochromatosis (see pp. 477–479), where a mutation in the HFE gene causes increased iron absorption
- secondary haemochromatosis (transfusion siderosis; see p. 537), due to iron overload in conditions treated by regular blood transfusion.

Iron deficiency

Iron deficiency anaemia develops when there is inadequate iron for haemoglobin synthesis. The causes are:

- blood loss
• increased demands such as growth and pregnancy
• decreased absorption (e.g. post-gastrectomy)
• poor intake.

Most iron deficiency is due to blood loss, usually from the uterus or gastrointestinal tract. Premenopausal women are in a state of precarious iron balance owing to menstruation. A common cause of iron deficiency worldwide is blood loss from the gastrointestinal tract resulting from parasites such as hookworm infestation. The poor quality of the diet, predominantly containing vegetables, also contributes to the high prevalence of iron deficiency in developing countries. Even in developed countries, iron deficiency is not uncommon in infancy, when iron intake is insufficient for the demands of growth. It is more prevalent in infants born prematurely or where the introduction of mixed feeding is delayed.

Clinical features

The symptoms of anaemia are described on page 521. The well-known clinical features of iron deficiency listed below are generally only seen in cases of very longstanding iron deficiency:
• brittle nails
• spoon-shaped nails (koilonychia)
• atrophy of the papillae of the tongue
• angular stomatitis
• brittle hair
• a syndrome of dysphagia and glossitis (Plummer–Vinson or Paterson–Brown–Kelly syndrome; see p. 373).

The diagnosis of iron deficiency anaemia relies on a clinical history, which should include questions about dietary intake, self-medication with non-steroidal anti-inflammatory drugs (NSAIDs; may give rise to gastrointestinal bleeding), and the presence of blood in the faeces (which may be a sign of haemorrhoids or carcinoma of the lower bowel). In women, a careful enquiry should be made about the duration of periods, the occurrence of clots and the number of sanitary towels or tampons used (normal 3–5 per day).

Investigations

• **Blood count and film.** A characteristic blood film is shown in *Figure 16.9*. The red cells are microcytic (MCV <80 fl) and hypochromic (mean corpuscular haemoglobin (MCH) <27 pg). There is poikilocytosis (variation in shape) and anisocytosis (variation in size).
• **Serum iron and iron-binding capacity.** The serum iron falls and the total iron-binding capacity (TIBC) rises in iron deficiency compared with normal. Iron deficiency is regularly present when the transferrin saturation (i.e. serum iron divided by TIBC) falls below 19% (Box 16.4).

• **Serum ferritin.** The level of serum ferritin reflects the amount of stored iron. The normal values for serum ferritin are 30–300 µg/L (11.6–144 nmol/L) in males and 15–200 µg/L (5.8–96 nmol/L) in females. In simple iron deficiency, a low serum ferritin confirms the diagnosis. However, ferritin is an acute-phase reactant, and levels increase in the presence of inflammatory or malignant diseases and also in the presence of liver damage. This can result
in a normal ferritin level, even in the presence of iron deficiency. Very high levels of ferritin may be observed in hepatitis and in a rare disease, haemophagocytic lymphohistiocytosis (see p. 258).

**Serum soluble transferrin receptors.** The number of transferrin receptors increases in iron deficiency. The results of this immunoassay compare well with results from bone marrow aspiration at estimating iron stores. This assay can help to distinguish between iron deficiency and anaemia of chronic disease (Box 16.4), and may avoid the need for bone marrow examination, even in complex cases. It may sometimes be helpful in the investigation of complicated causes of anaemia.

**Other investigations.** These will be indicated by the clinical history and examination. Investigations of the gastrointestinal tract are often required to determine the cause of the iron deficiency (see p. 387).

### Differential diagnosis

The presence of anaemia with microcytosis and hypochromia does not necessarily indicate iron deficiency. The most common of the other causes are thalassaemia, sideroblastic anaemia and anaemia of chronic disease, and in these disorders the iron stores are normal or increased. The differential diagnosis of microcytic anaemia is shown in **Box 16.4**.

### Management

The correct management of iron deficiency is to find and treat the underlying cause, and to give iron to correct the anaemia and replace iron stores. Patients with iron deficiency who are taking iron will increase their Hb level by approximately 10 g/L/week, unless of course other factors, such as bleeding, are present.

Oral iron is all that is required in most cases. The best preparation is ferrous sulphate (200 mg three times daily, a total of 180 mg ferrous iron), which is absorbed best when the patient is fasting. If the patient has side-effects such as nausea, diarrhoea or constipation, taking the tablets with food or reducing the dose using a preparation with less iron, such as ferrous gluconate (300 mg twice daily, only 70 mg ferrous iron), is all that is usually required to reduce the symptoms.

In developing countries, distribution of iron tablets and fortification of food are the main approaches for the alleviation of iron deficiency. However, iron supplementation programmes have been ineffective, probably mainly because of poor compliance.

Oral iron should be given for long enough to correct the Hb level and to replenish the iron stores; this can take 6 months. The most common causes of failure to respond to oral iron are:

- lack of compliance
- continuing haemorrhage
- incorrect diagnosis, e.g. thalassaemia trait.
These possibilities should be considered before parenteral (injected) iron is used. However, parenteral iron is required by occasional patients: for example, those who are intolerant to oral preparations, those with severe malabsorption and those with chronic disease (e.g. inflammatory bowel disease). Iron stores are replaced much faster with parenteral iron than with oral iron but the haematological response is no quicker. Parenteral iron can be given by slow intravenous infusion of low-molecular-weight iron dextran (test dose required), iron sucrose, ferric carboxymaltose or iron isomaltoside 1000; oral iron should be discontinued.

### Anaemia of chronic disease

One of the most common types of anaemia, particularly in hospital patients, is the anaemia of chronic disease, occurring in individuals with chronic infections such as tuberculosis or chronic inflammatory disease such as Crohn's disease, rheumatoid arthritis, systemic lupus erythematosus (SLE), polymyalgia rheumatica and malignant disease. There is decreased release of iron from the bone marrow to developing erythroblasts, an inadequate erythropoietin response to the anaemia, and decreased red cell survival.

The exact mechanisms responsible for these effects are not clear but it seems likely that high levels of hepcidin expression play a key role (see above). Measurement of hepcidin levels is emerging as a useful test to help distinguish anaemia of chronic disease from iron deficiency anaemia.

The serum iron and the TIBC are low, and the serum ferritin is normal or raised because of the inflammatory process. The serum soluble transferrin receptor level is normal (Box 16.4). Stainable iron is present in the bone marrow but iron is not seen in the developing erythroblasts. Patients do not respond to iron therapy, and treatment is, in general, that of the underlying disorder. Recombinant erythropoietin therapy is used in the anaemia of renal disease (see p. 778), and occasionally in inflammatory disease (rheumatoid arthritis, inflammatory bowel disease).

### Sideroblastic anaemia

Sideroblastic anaemias are inherited or acquired disorders characterized by a refractory anaemia, a variable number of hypochromic cells in the peripheral blood, and excess iron and ring sideroblasts in the bone marrow. The presence of ring sideroblasts is the diagnostic feature of sideroblastic anaemia. There is accumulation of iron in the mitochondria of erythroblasts owing to disordered haem synthesis, forming a ring of iron granules around the nucleus that can be seen with Perls' reaction. The blood film is often dimorphic; ineffective haem synthesis is responsible for the microcytic hypochromic cells. Sideroblastic anaemias can be inherited as an X-linked disease transmitted by females. Acquired causes include myelodysplasia, myeloproliferative disorders, myeloid leukaemia, drugs (e.g. isoniazid), alcohol misuse and lead toxicity. It can also occur in other disorders such as rheumatoid arthritis, carcinomas, and megaloblastic and haemolytic anaemias. A structural defect in δ-aminolaevulinic acid (ALA) synthase, the pyridoxine-dependent enzyme responsible for the
first step in haem synthesis (see Fig. 16.2), has been identified in one form of inherited sideroblastic anaemia. Primary acquired sideroblastic anaemia is one of the myelodysplastic syndromes (see pp. 551–552) and this is the cause of the vast majority of cases of sideroblastic anaemia in adults. Lead toxicity is described on page 77.

Management

Some patients respond when drugs or alcohol are withdrawn, if these are the causative agents. In occasional cases, there is a response to pyridoxine. Treatment with folic acid may be required to treat accompanying folate deficiency.

Further reading

Normocytic Anaemia

Normocytic, normochromic anaemia is seen in anaemia of chronic disease, in some endocrine disorders (e.g. hypopituitarism, hypothyroidism and hypoadrenalism) and in some haematological disorders (e.g. aplastic anaemia and some haemolytic anaemias) (see Fig. 16.7). In addition, this type of anaemia is seen acutely following blood loss.

Macrocytic Anaemias

These can be divided into megaloblastic and non-megaloblastic types, depending on bone marrow findings.

Megaloblastic anaemia

Megaloblastic anaemia is characterized by the presence in the bone marrow of erythroblasts with delayed nuclear maturation because of defective DNA synthesis (megaloblasts). Megaloblasts are large and have large immature nuclei. The nuclear chromatin is more finely dispersed than normal and has an open, stippled appearance (*Fig. 16.10*). In addition, giant metamyelocytes are frequently seen in megaloblastic anaemia. These cells are about twice the size of normal cells and often have twisted nuclei. Megaloblastic changes occur in:

• vitamin B₁₂ deficiency or abnormal vitamin B₁₂ metabolism
• folic acid deficiency or abnormal folate metabolism
• other defects of DNA synthesis, such as congenital enzyme deficiencies in DNA synthesis (e.g. orotic aciduria), or those resulting from therapy with drugs interfering with DNA synthesis (e.g. hydroxycarbamide (hydroxyurea), azathioprine)
• myelodysplasia due to dyserythropoiesis.

**HAEMATOLOGICAL FINDINGS**

• Anaemia may be present. The MCV is characteristically >96 fL unless there is a coexisting cause of microcytosis, in which case there may be a dimorphic picture with a normal/low average MCV.
• The peripheral blood film shows oval macrocytes with hypersegmented polymorphs with six or more lobes in the nucleus (*Fig. 16.11*).
• If severe, there may be leucopenia and thrombocytopenia.

**Biochemical basis of megaloblastic anaemia**

The key biochemical problem common to both vitamin B\textsubscript{12} and folate deficiency is a block in DNA synthesis owing to an inability to methylate deoxyuridine monophosphate to deoxythymidine monophosphate, which is then used to build DNA (Fig. 16.12). The methyl group is supplied by the folate coenzyme, methylene tetrahydrofolate.

![Diagram](image)

**FIGURE 16.12** Biochemical basis of megaloblastic anaemia. The metabolic relationship between vitamin B\textsubscript{12} and folate, and their role in DNA synthesis. THFA, tetrahydrofolate.

Deficiency of folate reduces the supply of this coenzyme; deficiency of vitamin B\textsubscript{12} also reduces its supply by slowing the demethylation of methylenetetrahydrofolate (methyl THF) and preventing cells receiving tetrahydrofolate for synthesis of methylene tetrahydrofolate polyglutamate.

Other congenital and acquired forms of megaloblastic anaemia are due to interference with
purine or pyrimidine synthesis, causing an inhibition in DNA synthesis.

**Vitamin B\textsubscript{12} (cobalamin)**

Vitamin B\textsubscript{12} is synthesized by certain microorganisms, and humans are ultimately dependent on animal sources. It is found in meat, fish, eggs and milk, but not in plants. Vitamin B\textsubscript{12} is not usually destroyed by cooking. The average daily diet contains 5–30 µg of vitamin B\textsubscript{12}, of which 2–3 µg is absorbed. The average adult stores some 2–3 mg, mainly in the liver, and it may take 2 years or more after absorptive failure before vitamin B\textsubscript{12} deficiency develops, as the daily losses are small (1–2 µg).

Vitamin B\textsubscript{12} consists of a small group of compounds, the cobalamins, which are composed of a planar group with a central cobalt atom (corrin ring) and a nucleotide set at right angles. Vitamin B\textsubscript{12} was first crystallized as cyanocobalamin, but the main natural cobalamins have deoxyadenosyl-, methyl- and hydroxocobalamin groups attached to the cobalt atom. Deoxyadenosylcobalamin is a coenzyme for the conversion of methylmalonyl CoA to succinyl CoA. Measurement of methylmalonic acid was used as a test for vitamin B\textsubscript{12} deficiency but it is no longer carried out routinely.

**Absorption and transport**

Vitamin B\textsubscript{12} is liberated from protein complexes in food by gastric enzymes and then binds to a vitamin B\textsubscript{12}-binding protein (‘R’ binder), which is related to plasma transcobalamin I (TCI) and is derived from saliva. Vitamin B\textsubscript{12} is released from the ‘R’ binder by pancreatic enzymes and then becomes bound to intrinsic factor.

Intrinsic factor is a glycoprotein with a molecular weight of 45 000. It is secreted by gastric parietal cells along with H\textsuperscript{+} ions. It combines with vitamin B\textsubscript{12} and carries it to a specific receptor on the surface of the mucosa of the ileum, cubilin. Vitamin B\textsubscript{12} enters the ileal cells and intrinsic factor remains in the lumen and is excreted. Vitamin B\textsubscript{12} is transported from the enterocytes to the bone marrow and other tissues by the glycoprotein transcobalamin II (TCII). Vitamin B\textsubscript{12} bound to TCII is known as holotranscobalamin or ‘active B\textsubscript{12}’, as this is the form of vitamin B\textsubscript{12} that is taken up by cells. Although TCII is the essential carrier protein for vitamin B\textsubscript{12}, the amount of B\textsubscript{12} on TCII is low. Vitamin B\textsubscript{12} in plasma is mainly bound to TCI (70–90%). About 1% of an oral dose of B\textsubscript{12} is absorbed ‘passively’ without the need for intrinsic factor.

**Vitamin B\textsubscript{12} deficiency**

There are a number of causes of B\textsubscript{12} deficiency and abnormal B\textsubscript{12} metabolism (**Box 16.5**). The most common cause of vitamin B\textsubscript{12} deficiency in adults is pernicious anaemia. Malabsorption of vitamin B\textsubscript{12} because of pancreatitis, coeliac disease or treatment with metformin is mild and
does not usually result in significant vitamin $B_{12}$ deficiency.

**Box 16.5**

**Vitamin $B_{12}$ deficiency and abnormal $B_{12}$ utilization: further causes**

**Low dietary intake**
- Veganism

**Impaired absorption**

**Stomach**
- Pernicious anaemia
- Gastrectomy
- Congenital deficiency of intrinsic factor

**Small bowel**
- Ileal disease or resection
- Bacterial overgrowth
- Tropical sprue
- Fish tapeworm (*Diphyllobothrium latum*)

**Abnormal utilization**
- Congenital transcobalamin II deficiency
- Nitrous oxide (inactivates $B_{12}$)

*See text.

**Pernicious anaemia**

Pernicious anaemia (PA) is an autoimmune disorder in which there is atrophic gastritis with loss of parietal cells in the gastric mucosa and consequent failure of intrinsic factor production and vitamin $B_{12}$ malabsorption.

**Pathogenesis**

This disease is common in the elderly, about 1 in 8000 of the population aged over 60 years being affected in the UK. It can be seen in all races and is more common in females than males. There is an association with other autoimmune diseases, particularly thyroid disease,
Addison's disease and vitiligo. Approximately 50% of all patients with PA have thyroid antibodies. There is a higher incidence of gastric carcinoma with PA (1–3%) than in the general population.

Parietal cell antibodies are present in the serum in 90% of patients with PA — and also in 10% of normal individuals. Conversely, intrinsic factor antibodies, although found in only 50% of patients with PA, are specific for this diagnosis.

**Pathology**

Autoimmune gastritis (see pp. 377–378) affecting the fundus is present, with plasma cell and lymphoid infiltration. The parietal and chief cells are replaced by mucin-secreting cells. There is achlorhydria and absent secretion of intrinsic factor. The histological abnormality can be improved by corticosteroid therapy, which supports an autoimmune basis for the disease.

**Clinical features**

The onset of PA is insidious, with progressively increasing symptoms of anaemia. Patients are sometimes said to have a lemon-yellow colour owing to a combination of pallor and mild jaundice, caused by excess breakdown of haemoglobin. A red, sore tongue (glossitis) and angular stomatitis are sometimes present.

The neurological changes, if left untreated for a long time, can be irreversible. These neurological abnormalities occur only with very low levels of serum $\text{B}_{12}$ (<60 ng/L or 50 pmol/L) and occasionally are seen in patients who are not clinically anaemic. The classical neurological features are those of a polyneuropathy progressively involving the peripheral nerves and the posterior and eventually the lateral columns of the spinal cord (subacute combined degeneration; see p. 886). Patients present with symmetrical paraesthesiae in the fingers and toes, early loss of vibration sense and proprioception, and progressive weakness and ataxia. Paraplegia may result. Dementia, psychiatric problems, hallucinations, delusions and optic atrophy may occur from vitamin $\text{B}_{12}$ deficiency.

**Investigations**

- **Haematological findings** show the features of a megaloblastic anaemia, as described on page 527.
- **Bone marrow** shows the typical features of megaloblastic erythropoiesis (see Fig. 16.10), although it is frequently not sampled in cases of straightforward macrocytic anaemia and a low serum vitamin $\text{B}_{12}$.
- **Serum bilirubin** and lactate dehydrogenase (LDH) may be raised as a result of ineffective erythropoiesis. Normally, a minor fraction of serum bilirubin results from premature breakdown of newly formed red cells in the bone marrow. In many megaloblastic anaemias, where the destruction of developing red cells is much increased, the serum bilirubin can be
increased.

• **Serum vitamin B\textsubscript{12}** is usually well below 160 ng/L, which is the lower end of the normal range. Serum vitamin B\textsubscript{12} can be assayed using radioisotope dilution or immunological assays.

• **Holotranscobalamin** is the ‘active’ fraction of cobalamin, and its measurement may be a better marker for vitamin B\textsubscript{12} deficiency than serum vitamin B\textsubscript{12}.

• **Serum methylmalonic acid (MMA) and homocysteine (HC)** are raised in B\textsubscript{12} deficiency but testing is only recommended in complex cases, such as those where there is a strong suspicion of vitamin B\textsubscript{12} deficiency but where the vitamin B\textsubscript{12} level is normal.

### Absorption tests

Vitamin B\textsubscript{12} absorption tests are no longer performed in the UK, as radioactive B\textsubscript{12} is not available.

### Gastrointestinal investigations

In PA, there is achlorhydria. Intubation studies can be performed to confirm this but are rarely carried out in routine practice. Endoscopy or barium meal examination of the stomach is performed only if gastric symptoms are present.

### Differential diagnosis

Vitamin B\textsubscript{12} deficiency must be differentiated from other causes of megaloblastic anaemia, principally folate deficiency, but usually this is quite clear from the blood levels of these two vitamins.

PA should be distinguished from other causes of vitamin B\textsubscript{12} deficiency by testing for intrinsic factor antibodies (Box 16.5). Patients negative for intrinsic factor antibodies with no other cause of vitamin B\textsubscript{12} deficiency may still have PA.

### Management

See below.

### Folic acid

Folic acid monoglutamate is not itself present in nature but occurs as polyglutamates. Folates are present in food as polyglutamates in the reduced dihydrofolate or tetrahydrofolate (THF) forms. Polyglutamates are broken down to monoglutamates in the upper gastrointestinal tract, and during the absorptive process these are converted to methyl THF monoglutamate, which is the main form in the serum. The methylation of homocysteine to methionine requires both methylcobalamin and methyl THF as coenzymes. This reaction is the first step in which methyl THF entering cells from the plasma is converted into folate polyglutamates. Intracellular
polyglutamates are the active forms of folate and act as coenzymes in the transfer of single carbon units in amino acid metabolism and DNA synthesis (Fig. 16.12).

**Dietary intake**
Folate is found in green vegetables, such as spinach and broccoli, and offal, such as liver and kidney. Cooking causes a loss of 60–90% of the folate. The minimal daily requirement is about 100 µg.

**Folate deficiency**
The causes of folate deficiency are shown in Box 16.6. The main cause is poor intake, which may occur alone or in combination with excessive utilization or malabsorption. The body's reserves of folate are about 10 mg. On a deficient diet, folate deficiency develops over the course of about 4 months, but folate deficiency may develop rapidly in patients who have both a poor intake and excess utilization of folate (e.g. patients in intensive care units).

---

**Box 16.6**

**Causes of folate deficiency**

**Nutritional (major cause)**

**Poor intake**
- Old age
- Poor social conditions
- Starvation
- Alcohol excess (also causes impaired utilization)

**Poor intake due to anorexia**
- Gastrointestinal disease, e.g. partial gastrectomy, coeliac disease, Crohn's disease
- Cancer

**Antifolate drugs**
- Anticonvulsants:
  - Phenytoin
  - Primidone
- Methotrexate
- Pyrimethamine
- Trimethoprim

**Excess utilization**

**Physiological**
• Pregnancy
• Lactation
• Prematurity

**Pathological**
• Haematological disease with excess red cell production, e.g. haemolysis
• Malignant disease with increased cell turnover
• Inflammatory disease
• Metabolic disease, e.g. homocystinuria
• Haemodialysis or peritoneal dialysis

**Malabsorption**
• Occurs in small bowel disease, but the effect is minor compared with that of anorexia

Folic acid supplements at the time of conception and in the first 12 weeks of pregnancy reduce the incidence of neural tube defects. In the USA and Canada, mandatory fortification of grain products, such as bread, flour and rice, has substantially improved folate status and has been associated with a significant fall in neural tube defects. There is controversy about the role of folate supplementation in the reduction of cardiovascular and cerebrovascular disease by lowering homocysteine levels.

### Clinical features
Patients with folate deficiency may be asymptomatic or may present with symptoms of anaemia or of the underlying cause. Glossitis can occur. Unlike with B₁₂ deficiency, neuropathy does not occur.

### Investigations
The haematological findings are those of a megaloblastic anaemia, as discussed on page 527.

### Blood measurements
Serum folate reflects recent folate status and intake. It is usually measured using immunological methods; a level below 3 µg/L (7 nmol/L) is indicative of folate deficiency. The amount of folate in the red cells is a measure of tissue folate over the lifetime of red cells; a level below 150 µg/L (340 nmol/L) is consistent with folate deficiency, but measurement of the serum folate is usually sufficient to diagnose folate deficiency.

### Further investigations
In many cases of folate deficiency, the cause is not obvious from the clinical picture or dietary history. Occult gastrointestinal disease should then be suspected and appropriate
investigations, such as small bowel biopsy, should be performed.

Management and prevention of megaloblastic anaemia

Treatment depends on the type of deficiency. Blood transfusion is not usually indicated in chronic anaemia; indeed, it can be dangerous to transfuse elderly patients, as heart failure may be precipitated. Folic acid may produce a haematological response in vitamin B\textsubscript{12} deficiency but may aggravate the neuropathy. Large doses of folic acid alone should not be used to treat megaloblastic anaemia unless the serum vitamin B\textsubscript{12} level is known to be normal. In severely ill patients, it may be necessary to treat with both folic acid and vitamin B\textsubscript{12} while awaiting serum levels.

Management of vitamin B\textsubscript{12} deficiency

Hydroxocobalamin 1000 µg can be given intramuscularly to a total of 5–6 mg over the course of 2 weeks; 1000 µg is then necessary every 3 months for the rest of the patient's life.

Clinical improvement may occur within 48 hours and a reticulocytosis can be seen some 2–3 days after starting therapy, peaking at 5–7 days. Improvement of the polyneuropathy may occur over 6–12 months but longstanding spinal cord damage is irreversible. Hypokalaemia can occur and, if severe, supplements should be given. Iron deficiency often develops in the first few weeks of therapy. Hyperuricaemia also occurs but clinical gout is uncommon. In patients who have had a total gastrectomy or an ileal resection, vitamin B\textsubscript{12} should be monitored; if levels are low, prophylactic vitamin B\textsubscript{12} should be given. Vegans may require oral B\textsubscript{12} supplements.

Oral treatment with vitamin B\textsubscript{12} can also be used in patients but good compliance with treatment is required.

Management of folate deficiency

Folate deficiency can be corrected by giving 5 mg of folic acid daily; the same haematological response occurs as is seen after treatment of vitamin B\textsubscript{12} deficiency. Treatment should be given for about 4 months to replace body stores. Any underlying cause, such as coeliac disease, should be treated.

Prophylactic folic acid (400 µg daily) is recommended for all women planning a pregnancy and in early pregnancy to reduce neural tube defects.

Women who have had a child with a neural tube defect should take 5 mg folic acid daily before and during a subsequent pregnancy.

Prophylactic folic acid, in a dose of 5 mg daily or weekly, is also given in chronic haematological disorders where there is rapid cell turnover and to patients undergoing renal dialysis.
Macrocytosis without megaloblastic changes

A raised MCV with macrocytosis on the peripheral blood film can occur with a normoblastic rather than a megaloblastic bone marrow.

A common physiological cause of macrocytosis is pregnancy. Macrocytosis may also occur in the newborn. Common pathological causes are:

- alcohol excess
- liver disease
- reticulocytosis (e.g. due to haemolysis)
- hypothyroidism
- some haematological disorders (e.g. aplastic anaemia, myelodysplasia, pure red cell aplasia, multiple myeloma)
- drugs (e.g. hydroxycarbamide, azathioprine)
- cold agglutinins due to autoagglutination of red cells (see p. 544) (the MCV decreases to normal with warming of the sample to 37°C).

In all these conditions, normal levels of vitamin B₁₂ and folate will be found. The exact mechanisms in each case are uncertain, but in some there is increased lipid deposition in the red cell membrane.

An increased number of reticulocytes also leads to a raised MCV because they are large cells.

High alcohol consumption is a frequent cause of a raised MCV, and in such patients the MCV can be used as a surrogate marker for monitoring excessive alcohol consumption. A full-blown megaloblastic anaemia can also occur in people who use alcohol to excess; this is due to a toxic effect of alcohol on erythropoiesis and/or to dietary folate deficiency.

Further reading

Anaemia Due to Marrow Failure (Aplastic Anaemia)

Aplastic anaemia is defined as pancytopenia with hypocellularity (aplasia) of the bone marrow; there are no leukaemic, cancerous or other abnormal cells in the peripheral blood or bone marrow. It is usually an acquired condition but may rarely be inherited.

Aplastic anaemia is due to a reduction in the number of pluripotential stem cells (see Fig. 16.1), together with a fault in those remaining or an immune reaction against them so that they are unable to repopulate the bone marrow. Failure of only one cell line may also occur, resulting in isolated deficiencies such as the absence of red cell precursors in pure red cell aplasia. Evolution to myelodysplasia, paroxysmal nocturnal haemoglobinuria (PNH) or acute myeloid leukaemia occurs in some cases, probably owing to the emergence of an abnormal
A list of causes of aplasia is given in **Box 16.7**. Immune mechanisms are probably responsible for most cases of idiopathic acquired aplastic anaemia and play a part in at least the persistence of many secondary cases. Activated cytotoxic T cells in blood and bone marrow are responsible for the bone marrow failure.

### Box 16.7

**Causes of aplastic anaemia**

**Primary**
- Inherited, e.g. Fanconi’s anaemia
- Idiopathic acquired (67% of cases)

**Secondary**
- Chemicals, e.g. benzene, toluene, glue sniffing
- Drugs:
  - e.g. Chemotherapeutic
  - Antibiotics, e.g. chloramphenicol, gold, penicillamine, phenytoin, carbamazepine, carbimazole, azathioprine
- Insecticides
- Ionizing radiation
- Infections:
  - Viral, e.g. hepatitis, Epstein–Barr virus, human immunodeficiency virus (HIV), erythrovirus
  - Other, e.g. tuberculosis
- Paroxysmal nocturnal haemoglobinuria
- Miscellaneous, e.g. pregnancy

Many drugs may cause marrow aplasia, including cytotoxic drugs such as busulfan and doxorubicin, which are expected to cause transient aplasia as a consequence of their therapeutic use. However, some individuals develop aplasia due to sensitivity to non-cytotoxic drugs such as chloramphenicol, gold, carbimazole, chlorpromazine, phenytoin, ribavirin, tolbutamide, NSAIDs, and many others that have been reported to cause occasional cases of aplasia.

Inherited aplastic anaemias are rare. Multiple gene mutations have been identified. Several are tumour suppressor genes and have been seen in one-third of aplastic anaemias. Fanconi’s
anaemia is inherited as an autosomal recessive condition and is associated with skeletal, skin, eye, renal and central nervous system abnormalities. It usually presents between the ages of 5 and 10 years.

**Clinical features**

The clinical manifestations of marrow failure from any cause are anaemia, bleeding and infection. Bleeding is often the predominant initial presentation of aplastic anaemia with bruising and minimal trauma or blood blisters in the mouth. Physical findings include ecchymoses, bleeding gums and epistaxis. Mouth infections are common. Lymphadenopathy and hepatosplenomegaly are rare in aplastic anaemia.

**Investigations**

- Pancytopenia.
- The virtual absence of reticulocytes.
- A hypocellular or aplastic bone marrow with increased fat spaces (*Fig. 16.13*).

![FIGURE 16.13](image)

**Differential diagnosis**

Aplastic anaemia must be differentiated from other causes of pancytopenia (*Box 16.8*). A bone marrow trephine is essential for assessment of the bone marrow cellularity.
Box 16.8

Causes of pancytopenia

- Aplastic anaemia (see Box 16.7)
- Drugs
- Megaloblastic anaemia
- Bone marrow infiltration or replacement:
  - Hodgkin's and non-Hodgkin's lymphoma
  - Acute leukaemia
  - Myeloma
  - Secondary carcinoma: myelofibrosis
- Hypersplenism
- Systemic lupus erythematosus
- Disseminated tuberculosis
- Paroxysmal nocturnal haemoglobinuria
- Overwhelming sepsis

Management and prognosis

The treatment of aplastic anaemia depends on the underlying cause and the likelihood of spontaneous recovery of blood counts. Careful attention to supportive care is essential while awaiting bone marrow recovery and, in some cases, specific treatment can be used to accelerate marrow recovery.

The main danger is infection and stringent measures should be undertaken to avoid this (see also pp. 604–605). Any suspicion of infection in a severely neutropenic patient (neutrophil count of <0.5 $\times 10^9$/L) should lead to the immediate institution of broad-spectrum parenteral antibiotics. Supportive care, including transfusions of red cells and platelets, should be given as necessary. The cause of the aplastic anaemia must be eliminated if possible.

The course of aplastic anaemia can be variable, ranging from a rapid spontaneous remission to a persistent, increasingly severe pancytopenia, which may lead to death through haemorrhage or infection. The most reliable determinants for the prognosis are the number of neutrophils, reticulocytes and platelets, and the cellularity of the bone marrow.

A bad prognosis (i.e. severe aplastic anaemia) is associated with the presence of two of the following three features:
- neutrophil count of $<0.5 \times 10^9$/L
- platelet count of $<20 \times 10^9$/L
- reticulocyte count of $<40 \times 10^9$/L.

**Haemopoietic stem cells** are the treatment of choice for patients with severe aplastic
anaemia under the age of 40 who have a human leucocyte antigen (HLA)-identical sibling donor, where it gives a 75–90% chance of long-term survival.

Immunosuppressive therapy is recommended for:

- patients with severe disease over the age of 40
- younger patients with severe disease who do not have an HLA-identical sibling donor
- patients who do not have severe disease but who are transfusion-dependent.

The standard immunosuppressive treatment is antithymocyte globulin (ATG) and ciclosporin, which results in response rates of 60–80% and 5-year survival rates of 75–85%.

Stem cell transplantation using matched unrelated donors is an option for patients under the age of 50 who have no matched sibling donor, and who have failed to respond to immunosuppression with ATG and ciclosporin; the results are improving (5-year survival of 65–73%). The main problems are graft rejection, graft-versus-host disease and viral infections.

Levels of haemopoietic growth factors (see Fig. 16.1) are normal or increased in most patients with aplastic anaemia, and are ineffective as primary treatment.

Steroids should not be used to treat severe aplastic anaemia except for serum sickness due to ATG. They are also used to treat children with congenital pure red cell aplasia (Diamond–Blackfan syndrome).

**Adult pure red cell aplasia** is associated with a thymoma in 5–15% of cases and thymectomy occasionally induces a remission. It may also be associated with autoimmune disease or be idiopathic. Steroids, cyclophosphamide, azathioprine and ciclosporin are effective treatments in some cases.

---

**Haemolytic Anaemias: an Introduction**

Haemolytic anaemias are caused by increased destruction of red cells. The red cell normally survives about 120 days, but in haemolytic anaemias the red cell survival times are considerably shortened.

Breakdown of normal red cells occurs in the macrophages of the bone marrow, liver and spleen (see Fig. 16.5).

**Consequences of haemolysis (Fig. 16.14)**

Shortening of red cell survival does not always cause anaemia, as there is a compensatory increase in red cell production by the bone marrow. If the red cell loss can be contained within the marrow’s capacity for increased output, then a haemolytic state can exist without anaemia (*compensated haemolytic disease*). The bone marrow can increase its output by 6–8 times by
increasing the proportion of cells committed to erythropoiesis (erythroid hyperplasia) and by expanding the volume of active marrow. In addition, immature red cells (reticulocytes) are released prematurely. These cells are larger than mature cells and stain with a light blue tinge on a peripheral blood film (the description of this appearance on the blood film is polychromasia) due to the presence of residual ribosomal RNA. Reticulocytes may be counted accurately as a percentage of all red cells on a blood film using a supravital stain for residual RNA (e.g. new methylene blue).

![Haemolysis diagram](image)

**FIGURE 16.14** Haemolysis: diagnostic and haematological features. DCT, direct Coombs’ test; DIC, disseminated intravascular coagulation; G6PD, glucose-6-phosphate dehydrogenase; LDH, lactate dehydrogenase; NSAIDs, non-steroidal anti-inflammatory drugs.

**Sites of haemolysis**

**Extravascular haemolysis**
In most haemolytic conditions, red cell destruction is extravascular. The red cells are removed from the circulation by macrophages in the reticuloendothelial system, particularly the spleen.

**Intravascular haemolysis**
When red cells are rapidly destroyed within the circulation, haemoglobin is liberated. This is
initially bound to plasma haptoglobins but these soon become saturated.

Excess free plasma haemoglobin is filtered by the renal glomerulus and enters the urine, although small amounts are reabsorbed by the renal tubules. In the renal tubular cell, haemoglobin is broken down and becomes deposited in the cells as haemosiderin. This can be detected in the spun sediment of urine using Perls' reaction. Some of the free plasma haemoglobin is oxidized to methaemoglobin, which dissociates into ferrihaem and globin. Plasma haemopexin binds ferrihaem, but if its binding capacity is exceeded, ferrihaem becomes attached to albumin, forming methaemalbumin. On spectrophotometry of the plasma, methaemalbumin forms a characteristic band; this is the basis of Schumm's test.

The liver plays a major role in removing haemoglobin bound to haptoglobin and haemopexin, and any remaining free haemoglobin.

Evidence for haemolysis
Increased red cell breakdown is accompanied by increased red cell production. This is shown in Figure 16.14.

Demonstration of shortened red cell lifespan
Red cell survival can be estimated from $^{51}$Cr-labelled red cells given intravenously but this is rarely performed.

Intravascular haemolysis
This is suggested by raised levels of plasma haemoglobin, haemosiderinuria, very low or absent haptoglobins, and the presence of methaemalbumin (positive Schumm's test).

Various laboratory studies will be necessary to determine the exact type of haemolytic anaemia present. The causes of haemolytic anaemias are shown in Box 16.9.

**Inherited Haemolytic Anaemia**

**Red cell membrane defects**

The normal red cell membrane consists of a lipid bilayer crossed by integral proteins with an underlying lattice of proteins (or cytoskeleton), including spectrin, actin, ankyrin and protein 4.1, attached to the integral proteins (*Fig. 16.15*).
Hereditary spherocytosis

Hereditary spherocytosis (HS) is the most common inherited haemolytic anaemia in Northern Europeans, affecting 1 in 5000. It is inherited in an autosomal dominant manner, but in 25% of patients neither parent is affected and it is presumed that HS has occurred by spontaneous mutation or is truly recessive. In the absence of a family history, the most important differential diagnosis is that of autoimmune haemolytic anaemia, which can usually be excluded by a negative direct antiglobulin test. HS is caused by defects in the red cell membrane, resulting in the cells losing part of the cell membrane as they pass through the spleen, possibly because the lipid bilayer is inadequately supported by the membrane skeleton. The best-characterized defect is a deficiency in the structural protein spectrin, but quantitative defects in other membrane proteins have been identified (Fig. 16.15), with ankyrin defects being the most common. The abnormal red cell membrane in HS is associated functionally with an increased permeability to sodium, and this requires an increased rate of active transport of sodium out of the cells, which is dependent on adenosine triphosphate (ATP) produced by glycolysis. The surface-to-volume ratio decreases and the cells become spherocytic. Spherocytes are more rigid and less deformable than normal red cells. They are unable to pass through the splenic microcirculation so they have a shortened lifespan.

**FIGURE 16.15** Hereditary spherocytosis (HS) and hereditary elliptocytosis (HE): red cell membrane showing the sites of the principal defects. Vertical interactions producing HS: (a) ankyrin mutation, HS (Ank+) producing deficiency (45% of cases); (b) HS band 3 deficiency (20%); (c) β spectrin deficiency, HS (Sp+) (<20%); (d) abnormal spectrin/protein 4.1 binding, HS (Sp–4.1); (e) protein 4.2 (pallidin) deficiency (Japanese). These produce various autosomal dominant and recessive forms of the disease. Horizontal interactions producing HE: α spectrin (80%), protein 4.1 (15%), β spectrin (5%).

Clinical features

The condition may present with jaundice at birth. However, the onset of jaundice can be delayed for many years; some patients may go through life with no symptoms and are detected only during family studies. The patient may eventually develop anaemia, splenomegaly and
ulcers on the leg. As in many haemolytic anaemias, the course of the disease may be interrupted by aplastic, haemolytic and megaloblastic crises. Aplastic anaemia usually occurs after infections, particularly with erythrovirus (parvovirus), whereas megaloblastic anaemia is the result of folate depletion caused by hyperactivity of the bone marrow. Chronic haemolysis leads to the formation of pigment gallstones (see pp. 490–491).

**Investigations**

- **Anaemia.** This is usually mild but occasionally can be severe.
- **Blood film.** This shows spherocytes (*Fig. 16.16*) and reticulocytes.

\*FIGURE 16.16 Spherocytes (arrowed). This blood film also shows reticulocytes, polychromasia and a nucleated erythroblast.*

- **Haemolysis.** This is evident (e.g. the serum bilirubin and urinary urobilinogen will be raised).
- **Osmotic fragility.** When red cells are placed in solutions of increasing hypotonicity, they take in water, swell and eventually lyse. Spherocytes tolerate hypotonic solutions less well than do normal biconcave red cells. Osmotic fragility tests are infrequently carried out in routine practice but may be useful to confirm a suspicion of spherocytosis on a blood film.
- **Direct antiglobulin (Coombs') test.** This is negative in hereditary spherocytosis, virtually ruling out autoimmune haemolytic anaemia, in which spherocytes are also commonly present.

**Management**

Splenectomy is indicated in hereditary spherocytosis to relieve symptoms due to anaemia or splenomegaly, reverse growth failure and prevent recurrent gallstones. It is best to postpone splenectomy until after childhood, as sudden overwhelming fatal infections, usually due to encapsulated organisms such as pneumococci, may occur (see p. 553). Splenectomy should be preceded by appropriate immunization and followed by life-long penicillin prophylaxis (see
In addition to the well-known risk of bacterial infection, there is also a significant risk of adverse arterial and venous thromboembolic events after splenectomy and this needs to be taken into account when deciding whether to proceed to splenectomy.

Following splenectomy, the spherocytes persist but the Hb usually returns to normal, as the red cells are no longer destroyed.

Hereditary elliptocytosis

This disorder of the red cell membrane is inherited in an autosomal dominant manner and has a prevalence of 1 in 2500 in Caucasians. The red cells are elliptical due to deficiencies of protein 4.1 or the spectrin/actin/4.1 complex, which leads to weakness of the horizontal protein interaction and to the membrane defect (see Fig. 16.15). Clinically, it is a similar condition to HS but milder. Only a minority of patients have anaemia and only occasional patients require splenectomy.

Rarely, hereditary spherocytosis or elliptocytosis may be inherited in a homozygous fashion, giving rise to a severe haemolytic anaemia sometimes necessitating splenectomy in early childhood.

Hereditary stomatocytosis

Stomatocytes are red cells in which the pale central area appears slit-like. Their presence in large numbers may occur in a hereditary haemolytic anaemia associated with a membrane defect, but excess alcohol intake is also a common cause. Although these hereditary conditions are very rare, a correct diagnosis is required – splenectomy is contraindicated, as it may result in fatal thromboembolic events.

Haemoglobin abnormalities

In early embryonic life, haemoglobins Gower 1, Gower 2 and Portland predominate. Later, fetal haemoglobin (HbF), which has two α and two γ chains, is produced (Fig. 16.17). There is increasing synthesis of β chains from 13 weeks' gestation and at term there is 80% HbF and 20% HbA. The haemoglobin switch from HbF to HbA occurs after birth, when the genes for γ chain production are further suppressed and there is rapid increase in the synthesis of β chains. BCL IIA, a zinc finger protein, is one of a number of proteins that suppress γ gene expression. There is little HbF produced (normally <1%) from 6 months after birth. The δ chain is synthesized just before birth and HbA₂ (α₂δ₂) remains at a level of about 2% throughout adult life (Box 16.10).
Globin chains are synthesized in the same way as any protein. A normal individual has four α-globin chain genes (Fig. 16.17), with two α-globin genes on each haploid genome (genes derived from one parent). These are situated close together on chromosome 16. The genes controlling the production of ε, γ, δ and β chains are close together on chromosome 11. The
globin genes are arranged on chromosomes 16 and 11 in the order in which they are expressed and combine to give different haemoglobins. Normal haemoglobin synthesis is discussed on page 519.

**Further reading**

**Haemoglobinopathies**

Abnormalities occur in:
• globin chain production (e.g. thalassaemia)
• structure of the globin chain (e.g. sickle cell disease)
• combined defects of globin chain production and structure, e.g. sickle cell β-thalassaemia.

The thalassaemias

The thalassaemias affect people throughout the world (Fig. 16.18) and at least 60 000 severely affected individuals are born every year. Normally, there is balanced (1:1) production of α and β chains. The defective synthesis of globin chains in thalassaemia leads to ‘imbalanced’ globin chain production, causing precipitation of globin chains within the red cell precursors and resulting in ineffective erythropoiesis. Precipitation of globin chains in mature red cells leads to haemolysis.

![Figure 16.18](image)

**Figure 16.18** Major haemoglobin abnormalities: geographical distribution.

Beta-thalassaemia

In homozygous β-thalassaemia, either no normal β chains are produced (β0) or β-chain production is very reduced (β+). There is an excess of α chains, which precipitate in erythroblasts and red cells, causing ineffective erythropoiesis and haemolysis. The excess α chains combine with whatever β, δ and γ chains are produced, resulting in increased quantities of HbA2 and HbF and, at best, small amounts of HbA. In heterozygous β-thalassaemia, there is usually asymptomatic microcytosis with or without mild anaemia. Box 16.11 shows the findings in the homozygote and heterozygote for the common types of β-thalassaemia.

*Hb Lepore is a cross-fusion product of δ and β globin genes.

**Genetics**

The molecular errors accounting for over 200 genetic defects leading to β-thalassaemia have been characterized. Unlike in α-thalassaemia, the defects are mainly point mutations rather than gene deletions. The mutations result in defects in transcription, RNA splicing and modification, translation via frame shifts and nonsense codons producing highly unstable β-globin, which cannot be utilized.

**Clinical syndromes**

Clinically, β-thalassaemia can be divided into the following:

• thalassaemia minor (or trait), the symptomless heterozygous carrier state

• thalassaemia intermedia, a moderate anaemia not requiring regular transfusions (with a number of different genotypes)

• thalassaemia major (generally homozygous β-thalassaemia), a severe anaemia requiring regular transfusions.

**Thalassaemia minor (trait)**

This common carrier state (heterozygous β-thalassaemia) is asymptomatic. Anaemia is mild or absent. The red cells are hypochromic and microcytic with a low MCV and MCH, and the condition may be confused with iron deficiency. However, the two are easily distinguished, as in thalassaemia trait the serum ferritin and the iron stores are normal (see *Box 16.4*). The RDW is usually normal (see p. 517). Hb electrophoresis usually shows a raised HbA₂ and
often a raised HbF (Fig. 16.19). Iron should not be given to these patients unless they also have proven coincidental iron deficiency.

**Thalassaemia intermedia**

Thalassaemia intermedia patients include those who are symptomatic with moderate anaemia (Hb 70–100 g/L) and do not require regular transfusions.

Thalassaemia intermedia may be due to a combination of homozygous mild β+- and α-thalassaemia, where there is reduced α-chain precipitation, thus helping to reduce the degree of globin imbalance and having a consequent reduction in ineffective erythropoiesis and haemolysis. The inheritance of hereditary persistence of HbF with homozygous β-thalassaemia also results in a milder clinical picture than unmodified β-thalassaemia major because the excess α chains are partially removed by the increased production of γ chains.

Patients may have splenomegaly and bone deformities. Recurrent leg ulcers, gallstones and infections are also seen. It should be noted that these patients may be iron-overloaded despite a lack of regular blood transfusions. This is caused by excessive iron absorption, which results from the underlying dyserythropoiesis (see description of iron absorption, pp. 523–524).

**Thalassaemia major**

Most children affected by homozygous β-thalassaemia present during the first year of life with:

- failure to thrive and recurrent bacterial infections
- severe anaemia from 3 to 6 months, when the switch from γ- to β-chain production should
normally occur
• extramedullary haemopoiesis that soon leads to hepatosplenomegaly and bone expansion, giving rise to the classical thalassaemic facies (Fig. 16.20A).

Skull X-rays in these children show the characteristic ‘hair-on-end’ appearance of bony trabeculation as a result of expansion of the bone marrow into cortical bone (Fig. 16.20B). The expansion of the bone marrow is also shown in an X-ray of the hand (Fig. 16.20C).

The classic features of untreated thalassaemia major are generally only observed in patients from countries without good blood transfusion support.
The aims of treatment are to suppress ineffective erythro-poiesis, prevent bony deformities and allow normal activity and development.

- **Long-term folic acid** supplements are required.

- **Regular transfusions** should be given to keep the Hb above 100 g/L. Blood transfusions may be required every 4–6 weeks.

- If transfusion requirements increase, **splenectomy** may help, although this is usually delayed until after the age of 6 years because of the risk of infection. Prophylaxis against infection is required for patients undergoing splenectomy (see p. 553).

- **Iron overload**, caused by repeated transfusions (transfusion haemosiderosis), may lead to damage to the endocrine glands, liver, pancreas and myocardium by the time patients reach adolescence. Among these complications of iron overload, cardiomyopathy and associated cardiac tachyarrhythmias are the leading causes of morbidity and mortality. Magnetic resonance imaging (MRI; myocardial T2-relaxation time) is useful for monitoring iron overload in thalassaemia; both the heart and the liver can be monitored. The standard iron-chelating agent remains desferrioxamine, although it has to be administered parenterally. Desferrioxamine is given as an overnight subcutaneous infusion on 5–7 nights each week. Ascorbic acid 200 mg daily is given, as it increases the urinary excretion of iron in response to desferrioxamine. Often, young children have a very high standard of chelation, as it is organized by their parents. However, when the children become adults and take on this role themselves, they often rebel and chelation with desferrioxamine may become problematic. Deferiprone, an oral iron chelator, has been available for some years; results on a once-daily oral iron chelator, deferasirox, indicate that it is safe, similar in effectiveness to desferrioxamine and is being increasingly used.

- **Intensive treatment with desferrioxamine** has been reported to reverse damage to the heart in patients with severe iron overload, but excessive doses of desferrioxamine may cause cataracts, retinal damage and nerve deafness. Infection with *Yersinia enterocolitica* occurs in iron-loaded patients treated with desferrioxamine. Iron overload should be periodically assessed by measuring the serum ferritin and by assessing hepatic iron stores by MRI.

- **Bone marrow transplantation** has been used in young patients with HLA-matched siblings. It has been successful in patients in good clinical condition with a 3-year mortality of <5%, but there is a high mortality (>50%) in patients in poor condition with iron overload and liver dysfunction.

- **Prenatal diagnosis and gene therapy** are discussed on pages 116–117.

- **Testing of patients' partners** should be carried out. If both partners have β-thalassaemia trait, there is a 1 in 4 chance of such pregnancy resulting in a child having β-thalassaemia major. Therefore, couples in this situation must be offered prenatal diagnosis and counselling (see pp. 116–117).
Alpha-thalassaemia

Genetics

In contrast to β-thalassaemia, α-thalassaemia is often caused by gene deletions, although mutations of the α-globin genes may also occur. The gene for α-globin chains is duplicated on both chromosomes 16; that is, a normal person has a total of four α-globin genes. Deletion of one α-chain gene (α+) or both α-chain genes (α0) on each chromosome 16 may occur (Box 16.12). The former is the most common of these abnormalities.

- **Four-gene deletion** (deletion of both genes on both chromosomes). There is no α-chain synthesis and only Hb Barts (γ4) is present. Hb Barts cannot carry oxygen and is incompatible with life (see Boxes 16.10 and 16.12). Infants are either stillborn at 28–40 weeks or die very shortly after birth. They are pale and oedematous, and have enormous livers and spleens – a condition called hydrops fetalis.

- **Three-gene deletion**. The severe reduction in α-chain synthesis results in HbH disease, which is common in parts of Asia. HbH has four β chains, although patients with HbH disease also have low levels of HbA and Hb Barts. HbA2 is normal or reduced. HbH does not transport oxygen and precipitates in erythroblasts and erythrocytes. There is moderate anaemia (Hb 70–100 g/L) and splenomegaly (thalassaemia intermedia). The patients are not usually transfusion-dependent.

- **Two-gene deletion** (α-thalassaemia trait). There is microcytosis with or without mild anaemia. HbH bodies may be seen on staining a blood film with brilliant cresyl blue.

- **One-gene deletion**. The blood picture is usually normal.

*The normal α-globin genotype is αα/αα (i.e. four α-globin genes present).
Globin chain synthesis studies for the detection of a reduced ratio of α to β chains may be necessary for the definitive diagnosis of α-thalassaemia trait.

Less commonly, α-thalassaemia may result from genetic defects other than deletions: for example, mutations in the stop codon producing an α chain with many extra amino acids (Hb Constant Spring). It has a more severe clinical course than HbH, with severe anaemia often precipitated by infection.

Further reading

Sickle syndromes

Sickle cell haemoglobin (HbS) results from a single-base mutation of adenine to thymine, which produces a substitution of valine for glutamic acid at the sixth codon of the β-globin chain (α₂β₂⁶glu→val). In the homozygous state (sickle cell anaemia), both genes are abnormal (HbSS), whereas in the heterozygous state (sickle cell trait, HbAS), only one chromosome carries the gene. As the synthesis of HbF is normal, the disease usually does not manifest itself until the HbF decreases to adult levels at about 6 months of age.

The sickle gene is most common in Africans (up to 25% gene frequency in some populations) but is also found in India, the Middle East and Southern Europe.

Pathogenesis

Deoxygenated HbS molecules are insoluble and polymerize. The flexibility of the cells is decreased and they become rigid and take up their characteristic sickle appearance (*Fig. 16.21*). This process is initially reversible but, with repeated sickling, the cells eventually lose their membrane flexibility and become irreversibly sickled. This is due to dehydration, partly caused by potassium leaving the red cells via a calcium-activated potassium channel called the Gardos channel. These irreversibly sickled cells are dehydrated and dense, and will not return to normal when oxygenated. Sickling can produce:

• a shortened red cell survival

• impaired passage of cells through the microcirculation, leading to obstruction of small vessels and tissue infarction.
Sickle cell anaemia

Clinical features

Vaso-occlusive crises
An early presentation may be acute pain in the hands and feet (dactylitis) owing to vaso-occlusion of the small vessels. Severe pain in other bones, such as the femur, humerus, vertebrae, ribs and pelvis, occurs in older children and adults. These attacks vary greatly in frequency from patient to patient, and sometimes in the same patient from year to year; however, as a generalization, a patient with moderately severe sickle cell anaemia may have around three hospital admissions a year from painful vaso-occlusive crises. Fever often accompanies the pain.

Acute chest syndrome
This occurs in up to 30%, and pulmonary hypertension and chronic lung disease are the most common causes of death in adults with sickle cell disease. The acute chest syndrome is caused by infection, fat embolism from necrotic bone marrow or pulmonary infarction due to sequestration of sickle cells. It comprises shortness of breath, chest pain, hypoxia and new chest X-ray changes due to consolidation. The presentation may be gradual or very rapid, the
latter leading to death in a few hours. Management is with pain relief, high-flow supplemental oxygen and antibiotics (cefotaxime and clarithromycin), which should be started immediately. Exchange transfusion will reduce the amount of HbS to <20% if there is no improvement. Ventilation (continuous positive airways pressure, or CPAP) may be necessary. Infections can be due to *Chlamydia* and mycoplasma, as well as *Streptococcus pneumoniae*.

**Pulmonary hypertension**

Pulmonary hypertension (defined as a mean pulmonary artery pressure >25 mmHg by right heart catheterization) is a known consequence of sickle cell anaemia, occurring in approximately 10% of patients. Its mechanism is not understood but contributory factors probably include sickle cell vasculopathy, damage from repeated chest crises, and repeated thromboembolism and intravascular haemolysis with consequent effects on reactive oxygen species and levels of scavenging nitric oxide. Development of pulmonary hypertension raises the risk of hypoxaemia and worsening sickle cell crises, and is an independent risk factor for mortality in patients with sickle cell anaemia. Diagnosis of pulmonary hypertension in patients with sickle cell anaemia should prompt consideration of therapies to reduce levels of HbS (see below) and also referral to a pulmonary hypertension specialist.

**Anaemia**

Chronic haemolysis produces a stable haemoglobin level, usually in the 60–80 g/L range, but an acute fall in the haemoglobin level can occur owing to:
- splenic sequestration
- bone marrow aplasia
- further haemolysis due to drugs, acute infection or associated glucose-6-phosphate dehydrogenase (G6PD) deficiency.

**Splenic sequestration**

Vaso-occlusion produces an acute painful enlargement of the spleen. There is splenic pooling of red cells and hypovolaemia, leading in some to circulatory collapse and death. The condition supervenes in childhood before multiple infarctions have occurred. The latter eventually lead to a fibrotic, non-functioning spleen. Liver sequestration can also occur.

**Bone marrow aplasia**

This most commonly follows infection with erythrovirus B19, which invades proliferating erythroid progenitors. There is a rapid fall in haemoglobin with no reticulocytes in the peripheral blood because of the failure of erythropoiesis in the marrow.

**Long-term problems**

- **Growth and development.** Young children are short but regain their height by adulthood. However, they remain below the normal weight. Sexual maturation is often delayed and may
require hormone therapy.

- **Bones.** Bones are a common site for vaso-occlusive episodes, leading to chronic infarcts. Avascular necrosis of hips and shoulders, compression of vertebrae, and shortening of bones in the hands and feet occur. These episodes are the common cause for the painful crisis. Osteomyelitis is more frequent in sickle cell disease and is caused by *Staphylococcus aureus, Staph. pneumoniae* and salmonella (see p. 718). Occasionally, hip joint replacement may be required.

- **Infections.** Infections are common in tissues susceptible to vaso-occlusion, such as bones, lungs and kidneys.

- **Leg ulcers.** These occur spontaneously (vaso-occlusive episodes) or following trauma, and are usually found over the medial or lateral malleoli. They often become infected and are quite resistant to treatment; sometimes blood transfusion may facilitate ulcer healing.

- **Cardiac problems.** Cardiac problems occur, with cardiomegaly, arrhythmias and iron overload cardiomyopathy. Myocardial infarctions are caused by thrombotic episodes, which are not secondary to atheroma.

- **Neurological complications.** These occur in 25% of patients and include transient ischaemic attacks, fits, cerebral infarction, cerebral haemorrhage and coma. About 11% of patients under 20 years of age suffer strokes. The most common finding is obstruction of a distal intracranial internal carotid artery or a proximal middle cerebral artery. About 10% of children without neurological signs or symptoms have abnormal blood-flow velocity indicative of clinically significant arterial stenosis; such patients have a very high risk of stroke. It has been demonstrated that if children with stenotic cranial artery lesions, as demonstrated on transcranial Doppler ultrasonography, are maintained on a regular programme of transfusion that is designed to suppress erythropoiesis, so that no more than 30% of the circulating red cells are their own, about 90% of strokes in such children could be prevented.

- **Cholelithiasis.** Pigment stones occur as a result of chronic haemolysis.

- **Liver.** Chronic hepatomegaly and liver dysfunction are caused by trapping of sickle cells.

- **Renal.** Chronic tubulointerstitial nephritis occurs (see pp. 768–769).

- **Priapism.** An unwanted painful erection occurs from vaso-occlusion and can be recurrent. This requires urgent treatment, as it may result in impotence. Treatment is with an α-adrenergic blocking drug, analgesia and hydration.

- **Eye.** Background retinopathy, proliferative retinopathy, vitreous haemorrhages and retinal detachments all occur. Regular yearly eye checks are required.

- **Pregnancy.** Impaired placental blood flow causes spontaneous abortion, intrauterine growth retardation, pre-eclampsia and fetal death. Painful episodes, infections and severe anaemia occur in the mother.
Investigations

- **Blood count.** The level of Hb is in the range 60–80 g/L with a high reticulocyte count (10–20%).
- **Blood films.** These can show features of hyposplenism (see Fig. 16.26) and sickling (Fig. 16.21).
- **Sickle solubility test.** A mixture of HbS in a reducing solution such as sodium dithionite gives a turbid appearance because of precipitation of HbS, whereas normal Hb gives a clear solution. A number of commercial kits, such as Sickledex, are available for rapid screening for the presence of HbS: for example, before surgery in appropriate ethnic groups and in the Accident and Emergency department.
- **Hb electrophoresis** (see Fig. 16.19). This is always needed to confirm the diagnosis. There is no HbA, 80–95% HbSS and 2–20% HbF.
- **Patents.** The parents of the affected child will show features of sickle cell trait.

Management

Precipitating factors (see above) should be avoided or treated quickly. The complications that require inpatient management are shown in Box 16.13.

---

**Box 16.13**

**Complications of sickle cell disease requiring inpatient management**

- Pain – uncontrolled by non-opiate analgesia
- Swollen, painful joints
- Acute sickle chest syndrome or pneumonia
- Mesenteric sickling and bowel ischaemia
- Splenic or hepatic sequestration
- Central nervous system deficit
- Cholecystitis (pigment stones)
- Cardiac arrhythmias
- Renal papillary necrosis resulting in colic or severe haematuria
- Hyphaema and retinal detachment
- Priapism

Acute painful attacks require supportive therapy with intravenous fluids, and adequate analgesia. Oxygen and antibiotics are only given if specifically indicated. Crises can be
extremely painful and require strong, usually narcotic, analgesia. Morphine is the drug of choice. Milder pain can sometimes be relieved by codeine, paracetamol and NSAIDs (Box 16.14). Use of incentive spirometry is recommended for patients hospitalized for a vaso-occlusive crisis.

Box 16.14

Management of acute painful crisis in opioid-naive adults with sickle cell disease

Morphine/diamorphine
- 0.1 mg/kg i.v./s.c. every 20 min until pain controlled
- Then 0.05–0.1 mg/kg i.v./s.c. (or oral morphine) every 2–4 h

Patient-controlled analgesia (PCA)
(Example for adults >50 kg)

Diamorphine/morphine
- Continuous infusion: 0–10 mg/h
- PCA bolus dose: 2–10 mg
- Dose duration: 1 min
- Lockout time: 20–30 min

Adjuvant oral analgesia
- Paracetamol 1 g 6-hourly
- ± Ibuprofen\(^a\) 400 mg 8-hourly
- Or diclofenac\(^a\) 50 mg 8-hourly

Laxatives (all patients)
For example:
- Lactulose 10 mL × 2 daily
- Senna 2–4 tablets daily
- Sodium docusate 100 mg × 2 daily
- Macrogol 1 sachet daily
- Lubiprostone

Other adjuvants

Antipruritics
- Hydroxyzine 25 mg × 2 as required

Antiemetics
• Prochlorperazine 5–10 mg × 3 as required
• Cyclizine 50 mg × 3 as required

**Anxiolytic**
• Haloperidol 1–3 mg oral/i.m. × 2 as required

*Caution advised with NSAIDs in renal impairment.*

(Adapted from Rees DC, Olujohungbe AD, Parker NE et al. Guidelines for the management of the acute painful crisis in sickle cell disease. *British Journal of Haematology* 2003; 120(5):744–752.)

Infection prophylaxis is with penicillin 500 mg daily and vaccination with polyvalent pneumococcal and *Haemophilus influenzae* type b vaccine (see p. 553). Folic acid is given to all patients with haemolysis.

**Anaemia**

Blood transfusions should only be given when there are clear indications. Patients with steady state anaemia, those having minor surgery or those having painful episodes without complications should not be transfused. Transfusions should be given for acute chest syndrome and acute anaemia due to acute splenic sequestration or an aplastic crisis, aiming for an Hb of 100 g/L and HbS <30%. Before elective operations, transfusions given to increase the Hb to 100 g/L reduce the risk of perioperative complications. During pregnancy, repeated transfusions may be used to reduce the proportion of circulating HbS to <30% to prevent sickling. Following a stroke, there is a 90% chance of further episodes, which can be reduced by regular transfusion to keep HbS below 30%. Children with narrow intracerebral blood vessels detected by transcranial Doppler scans are at high risk of stroke, which has been shown to be reduced by 90% with regular transfusions to keep the HbS below 30%. Exchange transfusions may be necessary in patients with severe or recurrent crises, or before emergency surgery. Red cells for transfusion should be matched for Rhesus (Rh) and Kell blood groups to minimize the risk of alloimmunization. Ideally, patients requiring long-term transfusion, such as those with sickle cell anaemia and thalassaemia, should undergo molecular blood group typing before their first transfusion.

**Hydroxycarbamide** (hydroxyurea) has been widely used as therapy for sickle cell anaemia. It acts, at least in part, by increasing HbF concentrations. Hydroxycarbamide has been shown in trials to reduce the episodes of pain, the acute chest syndrome and the need for blood transfusions. Thus selected patients – for example, those who have three or more sickle cell-associated, moderate to severe vaso-occlusive crises in a 12-month period – should be offered hydroxycarbamide treatment.

**Stem cell transplantation** has been used to treat sickle cell anaemia, although in fewer numbers than for thalassaemia. Children and adolescents younger than 16 years of age who have severe complications (strokes, recurrent chest syndrome or refractory pain) and have an
HLA-matched donor are the best candidates for transplantation.

**Counselling**

A multidisciplinary team should be involved, with regular clinic appointments to build up relationships. Adolescents require careful counselling over psychosocial issues and drug and birth control.

**Prognosis**

Some patients with HbSS die in the first few years of life from either infection or episodes of sequestration. However, there is marked individual variation in the severity of the disease and some patients have a relatively normal lifespan with few complications.

**Sickle cell trait**

These individuals have no symptoms unless extreme circumstances cause anoxia, such as flying in non-pressurized aircraft. Sickle cell trait gives some protection against *Plasmodium falciparum* malaria (see pp. 298–299), and consequently the sickle gene has been seen as an example of a balanced polymorphism (where the advantage of the malaria protection in the heterozygote is balanced by the mortality of the homozygous condition). Typically, there is 60% HbA and 40% HbS. It should be emphasized that, unlike with thalassaemia trait, the blood count and film of a person with sickle cell trait are normal. The diagnosis is made by a positive sickle test or by Hb electrophoresis (see *Fig. 16.19*).

**Other structural globin chain defects**

There are very many Hb variants and most are not associated with any clinical manifestations. However, some Hb variants may interact with HbS; for example, compound heterozygosity for HbC and HbS gives rise to HbSC disease. The clinical course of HbSC disease is generally somewhat milder than that of HbSS disease, but there is an increased likelihood of thrombosis, which may lead to thrombosis in pregnancy and to retinopathy.

**Combined defects of globin chain production and structure**

Abnormalities of Hb structure (e.g. HbS, C) can occur in combination with thalassaemia. The combination of β-thalassaemia trait and sickle cell trait (sickle cell β-thalassaemia) resembles sickle cell anaemia (HbSS) clinically.

HbE (α₂β₂26glu → lys) is the most common Hb variant in South-east Asia, and the second most prevalent haemoglobin variant worldwide. HbE heterozygotes are asymptomatic; the haemoglobin level is normal but red cells are microcytic. Homozygous HbE causes a mild microcytic anaemia, but the combination of heterozygosity for HbE and β-thalassaemia produces a variable anaemia, which can be as severe as β-thalassaemia major.
Prenatal screening and diagnosis of severe haemoglobin abnormalities

Of the offspring of parents who both have either β-thalassaemia or sickle cell trait, 25% will have β-thalassaemia major or sickle cell anaemia, respectively. Recognition of these heterozygous states in parent and family counselling provides a basis for antenatal screening and diagnosis (see pp. 116–117).

Pregnant women with either sickle cell trait or thalassaemia trait must be identified at antenatal booking either by selective screening of high-risk groups on the basis of ethnic origin or by universal screening of all pregnant women. Beta-thalassaemia trait can always be detected by a low MCV and MCH, and confirmed by haemoglobin electrophoresis. However, sickle cell trait is undetectable from a blood count and the laboratory needs a specific request to screen for sickle cell trait. Clearly, universal antenatal screening, as practised in the UK, avoids such problems.

If a pregnant woman is found to have a haemoglobin defect, her partner should be tested. Antenatal diagnosis is offered if both are affected, as there is a risk of a severe fetal Hb defect, particularly β-thalassaemia major. Fetal DNA analysis can be carried out using amniotic fluid, chorionic villus or fetal blood samples. Abortion is offered if the fetus is found to be severely affected. Chorionic villus biopsy has the advantage that it can be carried out in the first trimester, thus avoiding the need for second-trimester abortions.

Metabolic disorders of the red cell

Red cell metabolism

The mature red cell has no nucleus, mitochondria or ribosomes and is therefore unable to synthesize proteins. Red cells have only limited enzyme systems but they maintain the viability and function of the cells. In particular, energy is required in the form of ATP for maintenance of the flexibility of the membrane and the biconcave shape of the cells to allow passage through small vessels, and for regulation of the sodium and potassium pumps to ensure osmotic equilibrium. In addition, it is essential for Hb to be maintained in the reduced state.

The enzyme systems responsible for producing energy and reducing power (Fig. 16.22) are:

- the glycolytic (Embden–Meyerhof) pathway, in which glucose is metabolized to pyruvate and lactic acid with production of ATP.
the hexose monophosphate (pentose phosphate) pathway, which provides reducing power for the red cell in the form of NADPH (the reduced form of nicotinamide adenine dinucleotide phosphate).

About 90% of glucose is metabolized by the former and 10% by the latter. The hexose monophosphate shunt maintains glutathione (GSH) in a reduced state. Glutathione is necessary to combat oxidative stress to the red cell, and failure of this mechanism may result in:

- rigidity due to cross-linking of spectrin, which decreases membrane flexibility (see Fig.)
16.15) and causes ‘leakiness’ of the red cell membrane

- oxidation of the Hb molecule, producing methaemoglobin and precipitation of globin chains as Heinz bodies localized on the inside of the membrane; these bodies are removed from circulating red cells by the spleen.

2,3-BPG is formed from a side-arm of the glycolytic pathway (Fig. 16.22). It binds to the central part of the Hb tetramer, fixing it in the low-affinity state (see Fig. 16.4). A decreased affinity with a shift in the oxygen dissociation curve to the right enables more oxygen to be delivered to the tissues.

In addition to the G6PD, pyruvate kinase and pyrimidine 5’ nucleotidase deficiencies described below, there are a number of rare enzyme deficiencies that need specialist investigation.

**Glucose-6-phosphate dehydrogenase deficiency**

The enzyme glucose-6-phosphate dehydrogenase (G6PD) holds a vital position in the hexose monophosphate shunt (Fig. 16.22), oxidizing glucose-6-phosphate to 6-phosphoglycerate with the reduction of NADP to NADPH. The reaction is necessary in red cells where it is the only source of NADPH, which is used via glutathione to protect the red cell from oxidative damage. G6PD deficiency is a common condition that presents with a haemolytic anaemia and affects millions of people throughout the world, particularly in Africa, around the Mediterranean, and in the Middle East (around 20%) and South-east Asia (up to 40% in some regions).

The gene for G6PD is localized to chromosome Xq28 near the factor VIII gene. The deficiency is therefore more common in males than in females. However, female heterozygotes can also have clinical problems due to Lyonization (see p. 109), whereby, because of random X-chromosome inactivation, female heterozygotes have two populations of red cells: a normal one and a G6PD-deficient one.

There are over 400 structural types of G6PD, and mutations are mostly single amino acid substitutions (missense point mutations). The World Health Organization (WHO) has classified variants by the degree of enzyme deficiency and severity of haemolysis. The most common types with normal activity are called type B+, which is present in almost all Caucasians and about 70% of black Africans, and type A+, which is present in about 20% of black Africans. There are many variants with reduced activity but only two are common. In the African or A− type, the degree of deficiency is mild and more marked in older cells. Haemolysis is self-limiting, as the young red cells newly produced by the bone marrow have nearly normal enzyme activity. However, in the Mediterranean type, both young and old red cells have very low enzyme activity. After an oxidant shock, the Hb level may fall precipitously; death may follow unless the condition is recognized and the patient is transfused urgently.

**Clinical syndromes**

- Acute drug-induced haemolysis (Box 16.15) – usually dose-related.
**Box 16.15**

**Drugs causing haemolysis in glucose-6-phosphate dehydrogenase deficiency**

**Analgesics, such as:**
- Aspirin
- Phenacetin (withdrawn in the UK)

**Antimalarials, such as:**
- Primaquine
- Pyrimethamine
- Quinine
- Chloroquine
- Pamaquin

**Antibacterials, such as:**
- Most sulfonamides
- Nitrofurantoin
- Chloramphenicol
- Quinolones

**Miscellaneous drugs, such as:**
- Dapsone
- Vitamin K
- Probenecid
- Quinidine
- Dimercaprol
- Phenylhydrazine
- Methylene blue

- Favism (ingestion of fava beans).
- Chronic haemolytic anaemia.
- Neonatal jaundice.
- Infections and acute illnesses – also precipitate haemolysis in patients with G6PD deficiency.
  
  Mothballs containing naphthalene can also cause haemolysis.

  The clinical features are due to rapid intravascular haemolysis with symptoms of anaemia, jaundice and haemoglobinuria.
**Investigations**

- **Blood count** is normal between attacks.
- **During an attack**, the blood film may show irregularly contracted cells, bite cells (cells with an indentation in the membrane), blister cells (cells in which the Hb appears to have become partially detached from the cell membrane; *Fig. 16.23*), Heinz bodies (red cell inclusions composed of denatured haemoglobin, best seen on films stained with methyl violet) and reticulocytosis.

![Blister cells (arrowed) in G6PD deficiency.](image)

**FIGURE 16.23** ‘Blister’ cells (arrowed) in G6PD deficiency.

- **Haemolysis** is evident (see p. 532).
- **Several screening tests**, such as demonstration of the decreased ability of G6PD-deficient cells to reduce dyes, can be used to detect G6PD deficiency. The level of the enzyme may also be directly assayed. There are two diagnostic problems. Immediately after an attack, the screening tests may be normal (because the oldest red cells with least 6GPD activity are destroyed selectively). The diagnosis of heterozygous females may be difficult because the enzyme level may range from very low to normal, depending on Lyonization. However, the risk of clinically significant haemolysis is minimal in patients with borderline G6PD activity.

**Management**

- Any offending drugs should be stopped.
- Underlying infection should be treated.
- Blood transfusion may be life-saving.
- Splenectomy is not usually helpful.

**Pyruvate kinase deficiency**
This is the most common defect of red cell metabolism after G6PD deficiency; it affects thousands rather than millions of people worldwide. The site of the defect is shown in Figure 16.22. Production of ATP is reduced, causing rigid red cells. Homozygotes have haemolytic anaemia and splenomegaly. It is inherited as an autosomal recessive condition.

### Investigations

- **Anaemia** of variable severity is present (Hb 50–100 g/L). The oxygen dissociation curve is shifted to the right as a result of the rise in intracellular 2,3-BPG, and this reduces the severity of symptoms due to anaemia.
- **Blood films** show distorted (‘prickle’) cells and a reticulocytosis.
- **Pyruvate kinase activity** is low (affected homozygotes have levels of 5–20%).

### Management

Blood transfusions may be necessary during infections and pregnancy. Splenectomy may improve the clinical condition and is usually advised for patients requiring frequent transfusions.

### Pyrimidine 5’ nucleotidase deficiency

This autosomal recessive disorder produces a haemolytic anaemia with basophilic stippling of the red cells. The enzyme degrades pyrimidine nucleotides to cytidine and uridine (pentose phosphate shunt), which in turn leads to the degradation of RNA in the reticulocytes. Lack of the enzyme results in accumulation of partially degraded RNA, which shows as basophilic stippling in mature red cells. The enzyme is also inhibited by lead (see p. 77), and thus basophilic stippling is seen in lead poisoning. The hereditary form can be diagnosed by measuring the enzyme in erythrocytes. A screening test using the ultraviolet absorption spectrum of red cells is available.

### Further reading

### Acquired Haemolytic Anaemia

These anaemias may be divided into those due to immune, non-immune or other causes (see Box 16.9).

### Aetiology
Causes of immune destruction of red cells

- Autoantibodies.
- Drug-induced antibodies.
- Alloantibodies.

Causes of non-immune destruction of red cells

- Acquired membrane defects (e.g. paroxysmal nocturnal haemoglobinuria; see p. 548).
- Mechanical factors (e.g. prosthetic heart valves or microangiopathic haemolytic anaemia; see p. 548).
- Secondary to systemic disease (e.g. renal and liver disease).

Miscellaneous causes

- Various toxic substances can disrupt the red cell membrane and cause haemolysis (e.g. arsenic, and toxins produced by *Clostridium perfringens (welchii)*).
- Malaria frequently causes anaemia owing to the combination of a reduction in red cell survival and reduced production of red cells.
- Hypersplenism (see p. 553) results in a reduced red cell survival, which may also contribute to the anaemia seen in malaria.
- Extensive burns result in denaturation of red cell membrane proteins and reduced red cell survival.
- Some drugs (e.g. dapsone, sulfasalazine) cause oxidative haemolysis with Heinz bodies.
- Some ingested chemicals (e.g. weedkillers such as sodium chlorate) can cause severe oxidative haemolysis leading to acute kidney injury.

Autoimmune haemolytic anaemias

Autoimmune haemolytic anaemias (AIHAs) are acquired disorders resulting from increased red cell destruction due to red cell autoantibodies. These anaemias are characterized by the presence of a positive direct antiglobulin (Coombs’) test, which detects the autoantibody on the surface of the patient's red cells (*Fig. 16.24*).
AIHA is divided into ‘warm’ and ‘cold’ types, depending on whether the antibody attaches better to the red cells at body temperature (37°C) or at lower temperatures. The major features and the causes of these two forms of AIHA are shown in Box 16.16. In warm AIHA, IgG antibodies predominate and the direct antiglobulin test is positive with IgG alone, IgG and complement, or complement only. In cold AIHA, the antibodies are usually IgM. They easily elute off red cells, leaving complement, which is detected as C3d.

**Immune destruction of red cells**

IgM or IgG red cell antibodies, which fully activate the complement cascade, cause lysis of red cells in the circulation (intravascular haemolysis).

IgG antibodies frequently do not activate complement and the coated red cells undergo extravascular haemolysis (Fig. 16.25). They either are completely phagocytosed in the spleen through an interaction with Fc receptors on macrophages, or they lose part of the cell membrane through partial phagocytosis and circulate as spherocytes until they become sequestered in the spleen. Some IgG antibodies partially activate complement, leading to deposition of C3b on the red cell surface, and this may enhance phagocytosis, as macrophages also have receptors for C3b.
Extravascular haemolysis. This is due to interaction of antibody-coated cells with cells in the reticuloendothelial system, predominantly in the spleen. (a) Spherocytosis results from partial phagocytosis. (b) Complete phagocytosis may occur and this is enhanced if there is complement as well as antibody on the cell surface. (c) Cells coated with complement only are ineffectively removed and circulate with C3d or C3b on their surface.

Non-complement-binding IgM antibodies are rare and have little or no effect on red cell survival. IgM antibodies, which partially rather than fully activate complement, cause adherence of red cells to C3b receptors on macrophages, particularly in the liver, although this is an ineffective mechanism of haemolysis. Most of the red cells are released from the macrophages when C3b is cleaved to C3d and then circulate with C3d on their surface.

‘Warm’ autoimmune haemolytic anaemias

Clinical features

These anaemias may occur at all ages and in both sexes, although they are most frequent in middle-aged females. They can present as a short episode of anaemia and jaundice but they often remit and relapse, and may progress to an intermittent chronic pattern. The spleen may be palpable. Infections or folate deficiency may provoke a profound fall in the haemoglobin level. Autoimmune haemolytic anaemias are primary or secondary. The most common underlying cause is a lymphoproliferative disorder (Box 16.16).

Investigations

- **Haemolytic anaemia** is evident (see pp. 533–543).
- **Spherocytosis** is present as a result of red cell damage.
- **Direct antiglobulin test** is positive, with either IgG alone (67%), IgG and complement (20%) or complement alone (13%) being found on the surface of the red cells.
Autoantibodies may have specificity for the Rh blood group system (e.g. for the e antigen).

Autoimmune thrombocytopenia and/or neutropenia may also be present (Evans syndrome; see p. 569).

Abdominal CT scan should be carried out to detect abdominal lymphoma.

Management and prognosis

Corticosteroids (e.g. prednisolone in doses of 1 mg/kg daily) are effective in inducing a remission in about 80% of patients. Steroids reduce both production of the red cell autoantibodies and destruction of antibody-coated cells. Splenectomy is the most effective second-line therapy, but many patients prefer to avoid splenectomy because of the lack of a guarantee of a successful outcome, its potential complications and the need to take antibiotic prophylaxis (see p. 553). Other immunosuppressive drugs, such as azathioprine and rituximab, may be effective in patients who fail to respond to steroids and splenectomy. Blood transfusion may be necessary if there is severe anaemia, although compatibility testing is complicated by the presence of red cell autoantibodies.

‘Cold’ autoimmune haemolytic anaemias

Low titres of IgM cold agglutinins reacting at 4°C are normally present in plasma and are harmless. At low temperatures, these antibodies can attach to red cells and cause their agglutination in the cold peripheries of the body. In addition, activation of complement may cause intravascular haemolysis when the cells return to the higher temperatures in the core of the body.

After certain infections (such as those caused by Mycoplasma, cytomegalovirus or Epstein-Barr virus (EBV)), increased production of polyclonal cold agglutinins may occur, producing a mild to moderate transient haemolysis.

Chronic cold haemagglutinin disease

Chronic cold haemagglutinin disease (CHAD) usually occurs in the elderly with a gradual onset of haemolytic anaemia owing to the production of monoclonal IgM cold agglutinins. After exposure to cold, the patient develops an acrocyanosis similar to Raynaud’s as a result of red cell autoagglutination.

Investigations

Red cells agglutinate in the cold or at room temperature. Agglutination is sometimes seen in the sample tube after cooling but is more easily observed on the peripheral blood film made at room temperature. The agglutination is reversible after warming the sample. The agglutination may cause a spurious increase in the MCV (see p. 517).

Cold agglutinin test demonstrates a markedly elevated titre in CHAD to >1 : 512.
• **Direct antiglobulin test** is positive with complement (C3d) alone.

• **Monoclonal IgM antibodies** have specificity for the Ii blood group system, usually for the I antigen but occasionally for the i antigen.

### Management

Any underlying cause should be treated, if possible. Patients should avoid exposure to cold. Steroids, alkylating agents (chemotherapy) and splenectomy are usually ineffective. Treatment with anti-CD20 (rituximab) has been successful in some cases. Blood transfusion may be necessary, and if so, the patient should be in a warm environment; compatibility testing may be difficult due to the cold agglutinin.

### Paroxysmal cold haemoglobinuria

Paroxysmal cold haemoglobinuria (PCH) is a rare condition associated with common childhood infections, such as measles, mumps and chickenpox. Intravascular haemolysis is associated with polyclonal IgG complement-fixing antibodies. These antibodies are biphasic, reacting with red cells in the cold in the peripheral circulation, with lysis occurring due to complement activation when the cells return to the central circulation. The antibodies have specificity for the P red cell antigen. The lytic reaction is demonstrated *in vitro* by incubating the patient's red cells and serum at 4°C and then warming the mixture to 37°C (Donath–Landsteiner test). Haemolysis is self-limiting but red cell transfusions may be necessary.

### Drug-induced immune haemolytic anaemia

Drug-induced haemolytic anaemias are rare, although over 100 drugs have been reported to cause immune haemolytic anaemia. The interaction between a drug and red cell membrane may produce three types of antibodies:

• **Antibodies to the drug** only, e.g. quinidine, rifampicin. Immune complexes attach to red cells and may cause acute and severe intravascular haemolysis, sometimes associated with kidney injury. The haemolysis usually resolves quickly once the drug is withdrawn.

• **Antibodies to the cell membrane** only, e.g. methyldopa, fludarabine. There is extravascular haemolysis and the clinical course tends to be more protracted.

• **Antibodies to part-drug, part-cell membrane**, e.g. penicillin. This develops only in patients receiving large doses of penicillin. The haemolysis typically develops over 7–10 days, and recovery is gradual after drug withdrawal.

  Confirmation of the diagnosis of drug-induced immune haemolytic anaemia requires:

• A temporal association between administration of a drug and haemolytic anaemia.

• Recovery after withdrawal of the drug.

• A positive direct antiglobulin test.
Drug-dependent red cell antibodies. These are detectable in the first and third mechanisms described above. In the second, the antibodies are not drug-dependent and are indistinguishable from autoantibodies.

**Alloimmune haemolytic anaemia**

Antibodies produced in one individual react with the red cells of another. This situation occurs in haemolytic disease of the newborn, in haemolytic transfusion reactions (see p. 557), and after allogeneic bone marrow, renal, liver, cardiac or intestinal transplantation when donor lymphocytes transferred in the allograft (‘passenger lymphocytes’) may produce red cell antibodies against the recipient and cause haemolytic anaemia.

**Haemolytic disease of the newborn**

Haemolytic disease of the newborn (HDN) is caused by fetomaternal incompatibility for red cell antigens. Maternal alloantibodies against fetal red cell antigens pass from the maternal circulation via the placenta into the fetus, where they destroy the fetal red cells. Only IgG antibodies are capable of transplacental passage from mother to fetus.

The most common type of HDN is that due to ABO incompatibility, where the mother is usually group O and the fetus group A.

HDN due to ABO incompatibility is usually mild and exchange transfusion is rarely needed. HDN due to RhD incompatibility has become much less common in developed countries following the introduction of anti-D prophylaxis (see below). HDN may be caused by antibodies against antigens in many blood group systems (e.g. other Rh antigens such as c and E, and Kell, Duffy and Kidd; see p. 554).

Sensitization occurs as a result of passage of fetal red cells into the maternal circulation (which most readily occurs at the time of delivery), so that first pregnancies are rarely affected. However, sensitization may occur at other times – for example, after a miscarriage, ectopic pregnancy or blood transfusion – or be due to episodes during pregnancy that cause transplacental bleeding, such as amniocentesis, chorionic villus sampling and threatened miscarriage.

**Clinical features**

These vary from a mild haemolytic anaemia of the newborn to intrauterine death from 18 weeks' gestation with the characteristic appearance of hydrops fetalis (hepatosplenomegaly, oedema and cardiac failure).

Kernicterus occurs owing to severe jaundice in the neonatal period, when the unconjugated (lipid-soluble) bilirubin exceeds 250 µmol/L and bile pigment deposition occurs in the basal ganglia. This can result in permanent brain damage, choreoathetosis and spasticity. In mild cases, it may present as deafness.
Investigations

**Routine antenatal serology**
All mothers should have their ABO and RhD groups determined and tested for atypical antibodies after attending the antenatal booking clinic. These tests should be repeated at 28 weeks' gestation.

If an antibody is detected, its blood group specificity should be determined and the mother should be retested at least monthly. A rising antibody titre of IgG antibodies or a history of HDN in a previous pregnancy is an indication for referral to a fetal medicine unit.

**Antenatal assessment and treatment**
If a clinically significant antibody capable of causing HDN, such as anti-D, anti-c or anti-K, is detected, the father's phenotype provides useful information for predicting the likelihood of the fetus carrying the relevant red cell antigen. If the father is heterozygous, the genotype of the fetus can be determined from fetal DNA obtained by amniocentesis, chorionic villus sampling or fetal blood sampling. Soluble fetal DNA in maternal plasma can also be used for RhD typing, avoiding an invasive procedure.

The severity of anaemia is assessed by Doppler flow velocity of the fetal middle cerebral artery; measurement of bile pigments in the amniotic fluid is no longer routinely used. If the infant appears to have severe anaemia on non-invasive monitoring, ultrasound-guided fetal blood sampling is used to confirm this directly; if necessary, an intravascular fetal transfusion of red cells is given.

**Birth of an affected infant**
A sample of cord blood is obtained at birth. This shows:
- anaemia with a high reticulocyte count
- a positive direct antiglobulin test
- a raised serum bilirubin.

**Postnatal management**
In mild cases, phototherapy may be used to convert bilirubin to water-soluble biliverdin. Biliverdin can be excreted by the kidneys and this therefore reduces the chance of kernicterus. In more severely affected cases, exchange transfusion may be necessary to replace the infant's red cells and to remove bilirubin. Indications for exchange transfusion include:
- a cord Hb of <120 g/L (normal cord Hb is 136–196 g/L)
- a cord bilirubin of >60 µmol/L
- a later serum bilirubin of >300 µmol/L
- a rapidly rising serum bilirubin level.
Further exchange transfusions may be necessary to remove the unconjugated bilirubin.

The blood used for exchange transfusions should be ABO-compatible with the mother and infant, lack the antigen against which the maternal antibody is directed, be fresh (no more than 5 days from the day of collection) and be cytomegalovirus (CMV)-seronegative to prevent transmission of CMV.

**Prevention of RhD immunization in the mother**

Anti-D should be given after delivery when all of the following conditions are fulfilled:

- The mother is RhD-negative.
- The fetus is RhD-positive.
- There is no maternal anti-D detectable in the mother's serum; that is, the mother is not already immunized.

The dose is 500 IU of IgG anti-D intramuscularly within 72 hours of delivery. The Kleihauer test is used to assess the number of fetal cells in the maternal circulation. A blood film prepared from maternal blood is treated with acid, which elutes HbA. HbF is resistant to this treatment and can be seen when the film is stained with eosin. If large numbers of fetal red cells are present in the maternal circulation, a higher or additional dose of anti-D will be necessary.

It may be necessary to give prophylaxis to RhD-negative women at other times when sensitization may occur, such as after an ectopic pregnancy, threatened miscarriage or termination of pregnancy. The dose of anti-D is 250 IU before 20 weeks' gestation and 500 IU after 20 weeks. A **Kleihauer test** should be carried out after 20 weeks to determine whether more anti-D is required.

Of previously non-immunized RhD-negative women carrying RhD-positive fetuses, 1–2% became immunized by the time of delivery. Antenatal prophylaxis with anti-D has been shown to reduce the incidence of immunization during pregnancy, and its routine use has been implemented in the UK. It can be given as two doses of anti-D immunoglobulin of either 500 IU or 1500 IU (one at 28 weeks' gestation and one at 34 weeks) or as a single dose of 1500 IU either at 28 weeks' gestation or between 28 and 30 weeks. Monoclonal anti-D could, in principle, replace polyclonal anti-D, which is collected from RhD-negative women immunized in pregnancy and deliberately immunized RhD-negative males, but it is likely to be some years before trials have been completed to confirm its safety and effectiveness.

**Further reading**

**Non-immune haemolytic anaemia**
Paroxysmal nocturnal haemoglobinuria (PNH) is a rare form of haemolytic anaemia that results from the clonal expression of haemopoietic stem cells that have mutations in the X-linked gene PIG-A. These mutations cause impaired synthesis of glycosylphosphatidylinositol (GPI), which anchors many proteins, such as decay accelerating factor (DAF; CD55), to the cell surface, and membrane inhibitor of reactive lysis (MIRL; CD59) to cell membranes. CD55, CD59 and other proteins are involved in complement degradation (at the C3 and C5 levels), and in their absence, the haemolytic action of complement continues.

Clinical features

The major clinical signs are intravascular haemolysis, venous thrombosis and haemoglobinuria. Haemolysis may be precipitated by infection, iron therapy or surgery. Characteristically, only the urine voided at night and in the morning on waking is dark in colour, although the reason for this phenomenon is not clear. In severe cases, all urine samples are dark. Urinary iron loss may be sufficient to cause iron deficiency. Some patients present insidiously with signs of anaemia and recurrent abdominal pains.

Venous thrombotic episodes may occur at atypical sites and severe thromboses may be a feature: for example, in hepatic (Budd–Chiari syndrome), mesenteric or cerebral veins. The cause of the increased predisposition to thrombosis is not known, but may be due to complement-mediated activation of platelets deficient in CD55 and CD59. Another suggestion is that intravascular haemolysis, which releases haemoglobin in the plasma, lowers plasma nitric oxide, causing the symptoms and venous thrombosis.

Investigations

- **Intravascular haemolysis** is evident (see p. 533).
- **Flow cytometric analysis** of red cells with anti-CD55 and anti-CD59 is undertaken.
- **Bone marrow** is sometimes hypoplastic (or even aplastic) despite haemolysis.

Management and prognosis

PNH is a chronic disorder requiring supportive measures such as blood transfusions, which are necessary for patients with severe anaemia. However, treatment with **eculizumab** has revolutionized therapy. The drug is administered intravenously every 7 days for the first 5 weeks and then every 2 weeks thereafter. It is a recombinant humanized monoclonal antibody that prevents the cleavage of C5 (and therefore formation of the membrane attack complex). It reduces intravascular haemolysis, haemoglobinuria and the need for transfusion, and gives an improved quality of life. Eculizumab also reduces the risk of thrombosis, the leading cause of mortality in PNH. It is now also being used in pregnancy. The most serious risk of terminal complement blockade is infection with *Neisseria meningitidis*; thus vaccination against *N.*
*meningitidis* is recommended 2 weeks before commencing treatment.

Long-term anticoagulation may be necessary acutely for patients with recurrent thrombotic episodes. Its long-term value is unclear with the use of eculizumab. In patients with bone marrow failure, treatment options include immunosuppression with antilymphocyte globulin, ciclosporin or bone marrow transplantation. Eculizumab does not alleviate bone marrow failure. Bone marrow transplantation has been successfully carried out using either HLA-matched sibling donors in patients under the age of 50 or matched unrelated donors in patients under the age of 25.

The course of PNH is variable. PNH may transform into aplastic anaemia or acute leukaemia, but it may remain stable for many years and the PNH clone may even disappear, which must be taken into account if considering potentially dangerous treatments such as bone marrow transplantation. The median survival is 10–15 years.

Further reading

**Mechanical haemolytic anaemia**

Red cells may be injured by physical trauma in the circulation. Direct injury may cause immediate cell lysis or be followed by resealing of the cell membrane with the formation of distorted red cells or ‘fragments’. These cells may circulate for a short period before being destroyed prematurely in the reticuloendothelial system.

The causes of mechanical haemolytic anaemia include:

• damaged artificial heart valves
• march haemoglobinuria, where there is damage to red cells in the feet associated with prolonged marching or running
• microangiopathic haemolytic anaemia (MAHA), where fragmentation of red cells occurs in an abnormal microcirculation because of malignant hypertension, eclampsia, haemolytic uraemic syndrome, thrombotic thrombocytopenic purpura, vasculitis or disseminated intravascular coagulation.

**Myeloproliferative Neoplasms**

Myeloproliferative neoplasms are clonal stem cell disorders characterized by uncontrolled proliferation of one or more of the cell lines in the bone marrow, usually erythroid, myeloid and/or megakaryocyte lines. Myeloproliferative disorders include:

• polycythaemia vera (PV)
• essential thrombocythaemia (ET)
• myelofibrosis – all of these three have a *JAK-2* molecular lesion
• chronic myeloid leukaemia (CML), a genetic *BCR-ABL* lesion.
These disorders are grouped together, as there can be transition from one disease to another; for example, PV can lead to myelofibrosis. They may also transform to acute myeloid leukaemia. The non-leukaemic myeloproliferative neoplasms (PV, ET and myelofibrosis) will be discussed in this section. CML is described on pages 612–613.

Polycythaemia

Polycythaemia (or erythrocytosis) is defined as an increase in haemoglobin, packed cell volume (PCV) and red cell count. PCV is a more reliable indicator of polycythaemia than is Hb, which may be disproportionately low in iron deficiency. Relative erythrocytosis is where the red cell volume is normal but there is a decrease in the plasma volume (see Fig. 16.6).

Polycythaemia can be classified as primary polycythaemia (PV) or secondary polycythaemia. Secondary polycythaemia can be congenital or acquired. The latter is due to either an appropriate increase in erythropoietin in response to hypoxia, or an inappropriate increase in erythropoietin associated with ectopic production by tumours, such as a renal carcinoma. The causes of polycythaemia are given in Box 16.17.

---

### Box 16.17

**Causes of polycythaemia**

**Primary**
- Polycythaemia vera

**Congenital**
- Mutations in erythropoietin receptor
- High-oxygen-affinity haemoglobins
- Mutations in hypoxia-sensing pathways, e.g. Chuvash polycythaemia mutation in von Hippel–Lindau gene

**Secondary**

- Due to an appropriate (hypoxic) increase in erythropoietin
  - High altitude
  - Chronic lung disease
  - Cardiovascular disease (right-to-left shunt)
  - Sleep apnoea
  - Morbid obesity
  - Heavy smoking
- Due to an inappropriate increase in erythropoietin
  - Renal disease: renal cell carcinoma, Wilms’ tumour
  - Hepatocellular carcinoma
  - Adrenal tumours
  - Cerebellar haemangioblastoma
  - Massive uterine leiomyoma
  - Over-administration of erythropoietin
  - Treatment with androgen preparations

**Relative**
- Stress or spurious polycythaemia
- Dehydration
Primary polycythaemia: polycythaemia vera

Polycythaemia vera (PV) is a clonal stem cell disorder in which there is an excessive proliferation of erythroid, myeloid and/or megakaryocytic progenitor cells. Over 95% of patients with PV have acquired mutations of the gene Janus kinase 2 (JAK2), in the vast majority of cases a point mutation that causes the substitution of phenylalanine for valine at position 617 (JAK2V617F). JAK2 is a cytoplasmic tyrosine kinase that transduces signals, especially those triggered by haemopoietic growth factors such as erythropoietin, in normal and neoplastic cells. The significance of the discovery of the JAK2 mutation in myeloproliferative neoplasms is two-fold: first, and of immediate significance, is the clinical utility of the detection of JAK2 mutations for the diagnosis of PV, and second is the prospect of the development of new treatments for the myeloproliferative disorders based on targeting JAK2 activity.

Clinical features

The onset is insidious. PV usually presents in patients aged over 60 years with tiredness, itching, vertigo, headache and visual disturbance. It should be noted that these symptoms are also common in the normal population over the age of 60 and, consequently, PV is easily missed. Patients may also present with complications of the disease relating to thrombosis or haemorrhage. Increasingly, PV is detected on routine blood tests conducted for other reasons. Severe itching is common after a hot bath or when the patient is warm. Gout due to increased cell turnover may be a feature, and peptic ulceration occurs in a minority of patients. Thrombosis and haemorrhage are the major complications of PV.

The patient is usually plethoric and has a deep dusky cyanosis. Injection of the conjunctivae is commonly seen. The spleen is palpable in 70% and is useful in distinguishing PV from secondary polycythaemia. The liver is enlarged in 50% of patients.

Diagnosis

JAK2 mutation screening is routine in the investigation of polycythaemia and is fully incorporated into diagnostic criteria. Box 16.18 shows the revised WHO criteria for diagnosis in adults. The measurement of red cell and plasma volume is not routinely required. Measurement of serum ferritin can be useful to detect cases of iron-deficient PV. There may be a raised serum uric acid, leucocyte alkaline phosphatase and raised serum vitamin B\textsubscript{12} and vitamin B\textsubscript{12} binding protein (transcobalamin 1).
Polycythemia vera: modified from revised WHO criteria

**Major criteria**
- Haemoglobin >185 g/L in men, >165 g/L in women or other evidence of increased red cell volume
- Presence of JAK2 tyrosine kinase V617F or other functionally similar mutation such as JAK2 exon 12 mutation

**Minor criteria**
- Bone marrow biopsy, showing hypercellularity for age with trilineage growth (panmyelosis) with prominent erythroid, granulocytic and megakaryocytic proliferation
- Serum erythropoietin level below the reference range for normal
- Endogenous erythroid colony (EEC) formation in vitro

Diagnosis requires the presence of both major criteria and one minor criterion, or the presence of the first major criterion together with two minor criteria.

---

EEC testing is not routinely available but colony formation in the absence of exogenous erythropoietin in vitro is 100% specific and sensitive in patients without previous treatment.

---

**Management**

**Course and management**

Treatment is designed to maintain a normal blood count and to prevent the complications of the disease, particularly thromboses and haemorrhage. Treatment is aimed at keeping the PCV below 0.45 L/L and the platelet count below 400 × 10⁹/L.

There are three types of specific treatment:

- **Venesection.** During initial phases of treatment, the removal of 400–500 mL of blood weekly will successfully relieve many of the symptoms of PV. Iron deficiency eventually limits erythropoiesis and only infrequent venesection is required. Venesection is often used as the sole treatment with the aim of maintaining a PCV of <0.45 L/L.

- **Chemotherapy.** Continuous or intermittent treatment with hydroxycarbamide (hydroxyurea) is used in patients who do not tolerate venesection or have other poorly controlled features of the disease, such as thrombocytosis, symptomatic splenomegaly or thrombosis. Interferon-alpha is also effective; it is administered by subcutaneous injection. Low-dose intermittent
busulfan may be more convenient for elderly people but use must be weighed against the potential risk of long-term complications, such as the increased risk of leukaemia development with busulfan and related treatments.

- **Low-dose aspirin.** Aspirin 75 mg daily with the above treatments is routinely used for patients with PV in the absence of contraindications

- **Anagrelide.** This inhibits megakaryocyte differentiation and is useful for thrombocytosis.
  
  Iron replacement should be avoided in patients with iron-deficient PV, as this can result in a dangerous rebound polycythaemia.

**General measures**

- **Radioactive $^{32}$P.** This is only given to patients over 70 years because of the increased risk of transformation to acute leukaemia.

- **Allopurinol.** This can be given to block uric acid production. The pruritus is lessened by avoiding very hot baths.

- **H1-receptor antagonists.** These have largely proved unsuccessful in relieving distressing pruritus but **H2-receptor antagonists**, such as cimetidine, are occasionally effective.

- **Surgery.** Polycythaemia should be controlled before surgery. Patients with uncontrolled PV have a high operative risk. In an emergency, reduction of the haematocrit by venesection and appropriate fluid replacement must be carried out.

**Prognosis**

PV develops into myelofibrosis in 30% of cases and into acute myeloblastic leukaemia in 5% as part of the natural history of the disease.

**Secondary polycythaemias**

Many high-oxygen affinity haemoglobin mutants (HOAHMs) have been described that lead to increased oxygen affinity but decreased oxygen delivery to the tissues, resulting in compensatory polycythaemia. A congenital autosomal recessive disorder (Chuvash polycythaemia) is due to a defect in the oxygen-sensing erythropoietin production pathway caused by a mutation of the von Hippel–Lindau (VHL) gene, resulting in an increased production of erythropoietin.

The causes of secondary polycythaemias are shown in **Box 16.17**.

Serum erythropoietin (EPO) levels are normal or raised in secondary polycythaemia. Rarely, the discovery of a high EPO level may be the clue to the presence of an EPO-secreting tumour.

**Management**

The treatment is that of the precipitating factor; for example, renal or posterior fossa tumours
need to be resected if possible. The most common cause is heavy smoking, which can produce as much as 10% carboxyhaemoglobin, and this can produce polycythaemia because of a reduction in the oxygen-carrying capacity of the blood. Heavy smokers also often have respiratory disease.

Complications of secondary polycythaemia are distinct to those seen in PV, and although hyperviscosity symptoms and thromboembolic episodes can occur, management depends on the underlying cause. Complications due to myeloproliferative disease, such as progression to myelofibrosis or acute leukaemia, do not develop. Venesection may be symptomatically helpful in the certain patients with secondary polycythaemia, particularly if the PCV is above 0.54 L/L.

‘Relative’ or ‘apparent’ polycythaemia (Gaisböck syndrome)
This condition was originally thought to be stress-induced. The red cell volume is normal, but as the result of a decreased plasma volume, there is a relative polycythaemia. ‘Relative’ polycythaemia is more common than PV and occurs in middle-aged men, particularly in association with smoking, high alcohol intake, obesity and high blood pressure. The condition may present with cardiovascular problems, such as myocardial or cerebral ischaemia. For this reason, it may be justifiable to venesect selected patients; management also requires modification of lifestyle factors, such as smoking and alcohol.

Essential thrombocythaemia
Essential thrombocythaemia (ET) is a myeloproliferative disorder, closely related to PV, which is characterized by a persistently raised platelet count. Patients usually have normal Hb levels, although mild anaemia may occur. The WCC is elevated in some patients. At diagnosis, the platelet count will usually be >600 × 10^9/L, and may be as high as 2000 × 10^9/L, or rarely even higher. ET presents either symptomatically with thromboembolic or, less commonly, bleeding problems, or incidentally (e.g. at a routine medical check). Erythromelalgia, severe burning pain, erythema, and warmth of the extremities – primarily the feet and, to a lesser extent, the hands – may occur in some patients.

The diagnosis of ET is based on a sustained platelet count ≥450 × 10^9/L in the absence of a possible reactive cause for thrombocytosis (see below), and absence of other haematological malignancy associated with thrombocytosis (e.g. PV, myelofibrosis). In selected cases, a bone marrow biopsy is required; however, the requirement for this has been largely replaced by molecular tests. The JAK2 mutation test (see PV) is useful in that the gene is mutated in about half of all cases of ET, confirming a myeloproliferative neoplasm. For the remaining 50% of patients with a normal JAK2 gene, testing for mutations in calreticulin (CALR) or the thrombopoietin receptor (MPL) will be informative in most cases, abrogating the need for a bone marrow biopsy. As a generalization, a person with a very high platelet count (>1000 × 10^9/L), who is clinically normal with good health, will most likely prove to have ET. In a patient who has a lower platelet count (e.g. 600 × 10^9/L) and is in poor health, the diagnosis can be more difficult. Other disorders that may give rise to reactive high platelet counts include autoimmune rheumatic disorders and malignancy. Individuals who have been
splenectomized (for any reason, including trauma) sometimes have high platelet counts.

**Treatment**

Treatment is with hydroxycarbamide (hydroxyurea), anagrelide or busulfan to control the platelet count to <400 x 10^9/L.

Interferon-alpha is also effective; it is administered by subcutaneous injection. ET may eventually transform into PV, myelofibrosis or acute leukaemia, but the disease may not progress for many years. Aspirin is routinely used in patients with ET.

**Myelofibrosis**

Myelofibrosis is a very debilitating chronic myeloproliferative neoplasm. It may be primary or develop late in the course of essential thrombocythaemia or polycythaemia vera. There is clonal proliferation of stem cells and abnormal myeloid cells in the bone marrow, liver, spleen and other organs. Increased fibrosis in the bone marrow is caused by hyperplasia of abnormal megakaryocytes, which release fibroblast-stimulating factors such as platelet-derived growth factor.

**Clinical features**

The disease presents insidiously with lethargy, weakness and weight loss. Patients often complain of a ‘fullness’ in the upper abdomen due to splenomegaly, which is often massive. Severe pain related to respiration may indicate perisplenitis secondary to splenic infarction, and bone pain and attacks of gout can complicate the illness. Extramedullary haemopoiesis can develop, typically in the spleen but also affecting other organs. Bruising and bleeding occur because of thrombocytopenia or abnormal platelet function. Other physical signs include anaemia, fever and massive splenomegaly (for other causes, see p. 553).

**Investigations**

- **Anaemia** with leucoerythroblastic features is present (see p. 563). Poikilocytes and red cells with characteristic teardrop forms are seen. The WCC may be >100 x 10^9/L, and the differential WCC may be very similar to that seen in chronic myeloid leukaemia; later, leucopenia may also develop.

- **The platelet count** may be very high but, in later stages, thrombocytopenia occurs.

- **Bone marrow aspiration** is often unsuccessful and this gives a clue to the presence of the condition. A bone marrow trephine is necessary to show the markedly increased fibrosis. Increased numbers of megakaryocytes may be seen.

- **The Philadelphia chromosome** is absent; this helps to distinguish myelofibrosis from most cases of chronic myeloid leukaemia.

- **The JAK2 mutation** is present in approximately half of the cases, and the **CALR mutation** in
many of the cases without JAK2 mutation.

**Management**

This consists of general supportive measures, such as blood transfusion, analgesics and allopurinol. Treatment for myelofibrosis is often difficult but an estimation of prognosis from a prognostic scoring system is a good basis on which to start planning a treatment strategy for the individual patient. This may range from observation alone in those with the best prognosis to drug treatment or allogeneic stem cell transplantation, offering a hope of cure for younger patients. Historically, symptomatic splenomegaly was managed using hydroxycarbamide, radiotherapy and, in some cases, splenectomy. However, the latter is associated with very significant morbidity and mortality in patients with myelofibrosis and the two former are largely ineffective. A new and very promising development in the treatment of myelofibrosis is targeted therapy with JAK inhibitors. Ruxolitinib is the first such JAK inhibitor treatment in routine clinical use. Ruxolitinib results in substantial spleen reduction and improvement in symptoms in many patients with higher-risk myelofibrosis. Although ruxolitinib may improve life expectancy in patients with myelofibrosis, it does not, however, eradicate the disease and underlying fibrosis remains in the vast majority of patients.

**Prognosis**

Patients may survive for ≥10 years; median survival is 4–5 years. Death may occur in 10–20% of cases from transformation to acute myeloid leukaemia. The other most common causes of death are progression of myelofibrosis, cardiovascular disease and infection.

**Myelodysplasia**

Myelodysplasia (MDS) describes a group of acquired bone marrow disorders that are due to a defect in stem cells. They are characterized by increasing bone marrow failure with quantitative and qualitative abnormalities in at least one of the three myeloid cell lines (red cells, granulocyte/monocytes and platelets). The natural history of MDS is variable, but there is a high morbidity and mortality owing to bone marrow failure, and transformation into acute myeloblastic leukaemia occurs in about 30% of cases. WHO classification of the myelodysplastic syndrome is shown in Box 16.19.

**Clinical features and investigations**

MDS occurs mainly in the elderly, and presents with symptoms of anaemia, infection or bleeding due to pancytopenia. MDS should be suspected in patients with otherwise unexplained cytopenias or macrocytosis. Serial blood counts show evidence of increasing bone marrow failure with anaemia, neutropenia, monocytosis and thrombocytopenia, either alone or in combination. By contrast, in chronic myelomonocytic leukaemias, monocytes are >1 × 10^9/L and the WCC is raised, in some cases markedly so (>100 × 10^9/L).

The bone marrow cellularity can be increased, normal or reduced, irrespective of the pancytopenia. Dyserythropoiesis is usually present, and granulocyte precursors and megakaryocytes may also have abnormal morphology. The percentage of bone marrow blast cells is important for classification and prognostic risk stratification in MDS. Ring sideroblasts are present in some types. Cytogenetic abnormalities are common and are important for prognostic stratification. **Box 16.19** shows the classification and the clinical presentation.

Somatic point mutations are commonly seen. A poor survival rate is seen in those carrying mutations in \( TP53, E2H2, ETV6, RUNX1 \) and \( ASXL1 \).

**Management**

MDS is a heterogeneous disease and management is dependent on clinical features and predicted prognosis; the latter can be estimated using international prognostic scoring systems that incorporate blood counts, bone marrow blast percentage and cytogenetics. Patients with lower-risk disease are usually managed conservatively with supportive care.

Patients with higher-risk disease should be considered for allogeneic transplantation, if
eligible. Treatment options include the following:

- **Supportive care** is the mainstay for all patients with MDS and symptomatic low blood counts. Supportive care includes blood transfusion, and the prevention and treatment of MDS-associated bleeding and infection.

- **Iron chelation** should be considered for patients with good prognostic MDS who develop secondary iron overload (transfused with more than 20 units of red cells or serum ferritin >1000 µg/L).

- **Erythropoietin** can be used in selected patients with low-risk MDS, symptomatic anaemia and inappropriately low endogenous erythropoietin levels.

- **Hypomethylating agents** (e.g. azacitidine) is useful in selected patients.

- **Immunosuppressive agents**, such as ciclosporin and antithymocyte globulin, can be used in selected patients, including patients with a hypocellular bone marrow. **Intensive chemotherapy** schedules used for acute myeloblastic leukaemia (see pp. 610–611) may be tried in selected patients with high-risk MDS and higher numbers of bone marrow blasts, but the remission rate is less than for acute myeloblastic leukaemia, and prolonged pancytopenia may occur owing to poor haemopoietic regeneration caused by the defect in stem cells.

- **Lenalidomide** (a thalidomide analogue) has been proven to be remarkably successful in the treatment of early-stage MDS with a chromosome 5q deletion (the 5q− syndrome). Avoid use in women of child-bearing age.

- **Allogeneic stem cell transplantation** offers the hope of cure for carefully selected MDS patients who have an HLA-identical sibling or an unrelated HLA-matched donor. Due to the potential morbidity and mortality associated with allogeneic stem cell transplantation, this procedure is usually restricted to patients without major co-morbidities who have higher-risk MDS and in whom the risk–benefit balance is clear.

The Spleen

The spleen is the largest lymphoid organ in the body and is situated in the left hypochondrium. There are two anatomical components:

- the red pulp, consisting of sinuses lined by endothelial macrophages and cords (spaces)
- the white pulp, which has a structure similar to that of lymphoid follicles.

Blood enters via the splenic artery and is delivered to the red and white pulp. During the flow, the blood is ‘skimmed’, with leucocytes and plasma preferentially passing to white pulp. Some red cells pass rapidly through into the venous system while others are held up in the red pulp.

Function

Sequestration and phagocytosis

Normal red cells, which are flexible, pass through the red pulp into the venous system without difficulty. Old or abnormal cells are damaged by the hypoxia, low glucose and low pH found in the sinuses of the red pulp and are therefore removed by phagocytosis along with other circulating foreign matter. Howell–Jolly and Heinz bodies and sideroblastic granules have their particles removed by ‘pitting’ and are then returned to the circulation. IgG-coated red cells are removed through their Fc receptors by macrophages.

Extramedullary haemopoiesis

Pluripotential stem cells are present in the spleen and proliferate during severe haematological stress, such as in haemolytic anaemia, thalassaemia major and myelofibrosis.

Immunological function

About 25% of the body's T lymphocytes and 15% of B lymphocytes are present in the spleen. The spleen shares the function of production of antibodies with other lymphoid tissues.

Blood pooling

Up to one-third of the platelets are sequestrated in the spleen and can be rapidly mobilized. Enlarged spleens pool a significant percentage (up to 40%) of the red cell mass.

Splenomegaly

The spleen enlarges from under the left costal margin inferiorly and medially. It is dull to percussion and it may be possible to palpate a notch along its leading edge, which further differentiates the mass from an enlarged left kidney. The spleen typically measures 11 cm in its longest dimension. An enlarged spleen is only palpable if it is 1.5–2 times the size of a normal
spleen. Ultrasound or CT scanning may be used to confirm splenomegaly and may also provide other useful information, such as the presence of abdominal lymphadenopathy.

### Aetiology

A clinically palpable spleen can have many causes:

- **Infection**:  
  - acute, e.g. septic shock, infective endocarditis, typhoid, infectious mononucleosis  
  - chronic, e.g. tuberculosis, brucellosis  
  - parasitic, e.g. malaria, kala-azar and schistosomiasis.
- **Inflammation**: rheumatoid arthritis, sarcoidosis, SLE.
- **Haematological factors**: haemolytic anaemia, haemoglobinopathies and the leukaemias, lymphomas and myeloproliferative disorders.
- **Portal hypertension**: liver disease.
- **Miscellaneous**: storage diseases (e.g. Gaucher's disease), amyloidosis, primary and secondary neoplasias, tropical splenomegaly.

  **Massive splenomegaly** is seen in myelofibrosis, chronic myeloid leukaemia, chronic malaria, kala-azar or, rarely, Gaucher's disease.

### Hypersplenism

This can result from splenomegaly due to any cause. It is commonly seen with splenomegaly due to haematological disorders, portal hypertension, rheumatoid arthritis (Felty syndrome) and lymphoma. Hypersplenism produces:

- pancytopenia
- haemolysis due to sequestration and destruction of red cells in the spleen
- increased plasma volume.

### Management

This is often dependent on the underlying cause, but splenectomy is sometimes required for severe anaemia or thrombocytopenia.

### Problems after splenectomy

Splenectomy is performed mainly for:

- trauma
- immune thrombocytopenic purpura (see pp. 569–570)
- haemolytic anaemias (see p. 534)
• hypersplenism.

An immediate problem is an increased platelet count (usually 600–1000 × 10^9/L) for 2–3 weeks. Thromboembolic phenomena may occur. In the longer term, there is an increased risk of overwhelming infections, particularly pneumococcal infections.

**Prophylaxis against infection after splenectomy or splenic dysfunction**

See **Box 16.20** for prophylactic measures. All patients should be educated about the risk of infection and the importance of its early recognition and treatment. They should be given an information leaflet and should carry a card or bracelet to alert health professionals to their risk of overwhelming infection.

---

**Box 16.20**

**Prophylaxis against infection after splenectomy or splenic dysfunction**

**Vaccinate 2–3 weeks before elective splenectomy**

- A 23-valent unconjugated pneumococcal polysaccharide vaccine repeated every 5 years
- Meningococcal group C conjugate vaccine*
- Annual influenza vaccine
- *Haemophilus influenzae* type b (Hib) vaccine
- Long-term penicillin V 500 mg 12-hourly (if sensitive, use erythromycin)
- Meningococcal polysaccharide vaccine (ACWY) for travellers to Africa/Saudi Arabia, e.g. during Hajj and Umrah pilgrimages

*Men B vaccination is now available.

---

**Post-splenectomy haematological features**

- *Thrombocytosis* persists in about 30% of cases.
- *The WCC* is usually normal but there may be a mild lymphocytosis and monocytosis.
- *Abnormalities in red cell morphology* are the most prominent changes and include Howell–Jolly bodies (contain basophilic nuclear remnants), Pappenheimer bodies (contain sideroblastic granules), target cells and irregular contracted red cells (*Fig. 16.26*). Pitted red cells can be counted.
Splenic atrophy

This is seen in sickle cell disease due to infarction. Hyposplenism is also seen in a wide range of non-haematological diseases, including coeliac disease, dermatitis herpetiformis and, occasionally, ulcerative colitis. Post-splenectomy haematological features are seen.

Blood Transfusion

The cells and proteins in the blood express antigens that are controlled by polymorphic genes; that is, a specific antigen may be present in some individuals but not in others. A blood transfusion may immunize the recipient against donor antigens that the recipient lacks (alloimmunization), and repeated transfusions increase the risk. Similarly, the transplacental passage of fetal blood cells during pregnancy may alloimmunize the mother against fetal antigens inherited from the father. Antibodies stimulated by blood transfusion or pregnancy, such as Rh antibodies, are termed *immune antibodies* and are usually IgG, in contrast to *naturally occurring antibodies*, such as ABO antibodies, which are made in response to environmental antigens present in food and bacteria, and which are usually IgM.

Blood Groups

The blood groups are determined by antigens on the surface of red cells; more than 300 blood groups are recognized. The ABO and Rh systems are the two major blood groups, but incompatibilities involving many other blood groups (e.g. Kell, Duffy, Kidd) may cause
haemolytic transfusion reactions and/or haemolytic disease of the newborn (HDN).

**ABO system**

This blood group system involves naturally occurring IgM anti-A and anti-B antibodies, which are capable of producing rapid and severe intravascular haemolysis of incompatible red cells.

The ABO system is under the control of a pair of allelic genes, \( H \) and \( h \), and also three allelic genes, \( A, B \) and \( O \), producing the genotypes and phenotypes shown in Box 16.21. The A, B and H antigens are very similar in structure; differences in the terminal sugars determine their specificity. The \( H \) gene codes for enzyme H, which attaches fucose to the basic glycoprotein backbone to form H substance; this is the precursor for A and B antigens (Fig. 16.27).

**FIGURE 16.27** Sugar chains in the ABO blood group system.

The \( A \) and \( B \) genes control specific enzymes responsible for the addition to H substance of \( N \)-acetylglactosamine for group A and d-galactose for group B. The \( O \) gene is amorphic and does not transform H substance; therefore O is not antigenic. The A, B and H antigens are present on most body cells. These antigens are also found in soluble form in tissue fluids, such as saliva and gastric juice, in the 80% of the population who possess secretor genes.
**Rh system**

There is a high frequency of development of IgG RhD antibodies in RhD-negative individuals after exposure to RhD-positive red cells. The antibodies formed cause HDN and haemolytic transfusion reactions.

This system is coded by allelic genes: C and c, E and e, and D and no D, which is signified as d. They are inherited as triplets on each chromosome 1, one from each pair of genes (i.e. CDE/cde). RhD-negative individuals have no D protein in the red cell membrane, which explains why it is so immunogenic when RhD-negative individuals are exposed to RhD antigen through transfusion or pregnancy. In Caucasians, the RhD-negative phenotype almost always results from a complete deletion of the RhD gene; in black Africans, it can also result from an inactive gene containing stop codons in the reading frame.

**Procedure for Blood Transfusion**

The safety of blood transfusion depends on meticulous attention to detail at each stage leading to and during the transfusion. Avoidance of simple errors involving patient and blood sample identification at the time of collection of the sample for compatibility testing and at the time of transfusion would avoid most serious haemolytic transfusion reactions, almost all of which involve the ABO system.

**Pre-transfusion compatibility testing**

**Blood grouping**

The ABO and RhD groups of the patient are determined.

**Antibody screening**

The patient's serum or plasma is screened for atypical antibodies that may cause a significant reduction in the survival of the transfused red cells. The patient's serum or plasma is tested against red cells from at least two group O donors, expressing a wide range of red cell antigens, for detection of IgM red cell alloantibodies (using a direct agglutination test of cells suspended in saline) and IgG antibodies (using an indirect antiglobulin test, see p. 544). About 10% of patients have a positive antibody screening result; in this case, further testing is carried out using a comprehensive panel of typed red cells to determine the blood group specificity of the antibody (clinically significant red cell antibodies are detected in about 20% of patients with positive antibody screens).

**Selection of donor blood and crossmatching**

**Selection procedures**

Donor blood of the same ABO and RhD group as the patient is selected. Matching for additional blood groups is carried out for patients with clinically significant red cell
antibodies (see below), and for patients who are likely to be multitransfused and are at high risk of developing antibodies, e.g. sickle cell disease; many hospitals routinely provide Kell-negative blood for women of child-bearing age to minimize the risk of alloimmunization and subsequent HDN.

Crossmatching procedures

Patients without atypical red cell antibodies

The full crossmatch involves testing the patient's serum or plasma against the donor red cells suspended in saline in a direct agglutination test, and also using an indirect antiglobulin test. In many hospitals, this serological crossmatch has been omitted, as a negative antibody screen makes it highly unlikely that there will be any incompatibility with the donor units. A greater risk is that of a transfusion error involving the collection of the patient sample or a mix-up of samples in the laboratory. Laboratories can use their information system to check the records of the patient and authorize the release of the donor units if a number of criteria are met (computer or electronic crossmatching), including the following:

• The system is automated for ABO and RhD grouping and antibody screening, including positive sample identification and electronic transfer of results.
• The patient's serum or plasma does not contain clinically significant red cell antibodies.
• The release of ABO-incompatible blood must be prevented by conformation of laboratory computer software to the following requirements:
  – The issue of blood is not allowed if the patient has only been grouped once.
  – The issue of blood is not allowed if the current group does not match the historical record.
  – The system must not allow the reservation and release of units that are ABO-incompatible with the patient.

Electronic issue can be extended to issue of previously unallocated blood at blood fridges remote from the main laboratory (‘remote blood issue’). This is only possible using blood fridges that are electronically linked to the blood transfusion laboratory information system. The printing of compatibility labels for the blood and its collection are under electronic control, applying the same rules as electronic issue from the main laboratory. Issue of blood using this process reduces the time it takes to provide blood for patients needing it urgently, particularly at hospitals without a blood transfusion laboratory, because transport of blood from the central laboratory is not required. There are good examples of centralized transfusion services in cities such as Pittsburgh and Seattle in the USA, and this model is likely to be increasingly employed in other developed countries, including the UK.

Patients with atypical red cell antibodies

Donor blood should be selected that lacks the relevant red cell antigen(s), as well as being of the same ABO and RhD group as the patient. A full crossmatch should always be carried out.
Several other systems for blood grouping, antibody screening and crossmatching are available to hospital transfusion laboratories. They do not depend on agglutination of red cells in suspension, but rather on the differential passage of agglutinated and unagglutinated red cells through a column of dextran gel matrix (e.g. DiaMed and Ortho Biovue systems), or on the capture of antibodies by red cells immobilized on the surface of a microplate well (e.g. Capture-R solid phase system).

**Blood ordering**

Increasingly, hospitals are using electronic systems for blood ordering; some include algorithms for the appropriate use of blood, and ‘alerts’ if there is non-compliance with agreed blood count triggers for transfusion.

**Elective surgery**

Many hospitals have guidelines for the ordering of blood for elective surgery (maximum surgical blood ordering schedules). These are aimed at reducing unnecessary crossmatching and the amount of blood that eventually becomes outdated. Many operations in which blood is required only occasionally for unexpectedly high blood loss can be classified as ‘group and save’; this means that, where the antibody screen is negative, blood is not reserved in advance but can be made available quickly if necessary – that is, in a few minutes – using the electronic crossmatch procedure. If a patient has atypical antibodies, compatible blood should always be reserved in advance; this may take several days if the patient has multiple or unusual antibodies.

**Emergencies**

There may be insufficient time for full pre-transfusion testing. The options include:

- Blood required immediately – 2 units of O RhD-negative blood (‘emergency stock’) are used, to allow additional time for the laboratory to group the patient.
- Blood required in 10–15 min – blood of the same ABO and RhD groups as the patient is used (‘group compatible blood’).
- Blood required in 45 min – most laboratories will be able to provide fully crossmatched blood within this time.

**Complications of Blood Transfusion**

Reporting schemes under the term ‘haemovigilance’ have been established in many countries, including the Serious Hazards of Transfusion (SHOT) scheme in the UK, which produced its first report in the UK in 1997. Figure 16.28 shows the reports to SHOT up to 2013, which indicate that ‘incorrect blood component transfused’ is the most frequent type of serious incident, and is the second most frequent cause of mortality and serious morbidity after transfusion-related acute lung injury (TRALI). Errors in clinical areas, either in the collection
of the blood sample for compatibility testing, the collection of blood from the fridge and/or the administration of blood (59%), were the most common source of error in 2012, and laboratory errors accounted for the remainder (41%). Death or serious morbidity can also be attributed to other complications of blood transfusion (Box 16.22), including transfusion-associated circulatory overload (TACO), transfusion-associated graft-versus-host disease (TA-GvHD) and bacterial infection of blood components.

**FIGURE 16.28** Overview of 13,141 cases reported to the Serious Hazards of Transfusion (SHOT) scheme between 1996 and 2013. The adverse events are divided into pathological reactions that may not be preventable, those that are probably or possibly preventable, and those caused by error. Those reported in 2013 are indicated in pink at the right-hand side of each bar. (From: PHB Bolton-Maggs (ed), D Poles, A W At and D Thomas on behalf of the Serious Hazards of Transfusion Steering Group. The 2013 SHOT Annual Report (2014), with permission.)

**Box 16.22**

**Complications of blood transfusion**

**Immunological**

**Alloimmunization and incompatibility**
• Red cells:
  – Immediate haemolytic transfusion reactions
  – Delayed haemolytic transfusion reactions
• Leucocytes and platelets:
  – Non-haemolytic (febrile) transfusion reactions
  – Transfusion-related acute lung injury (TRALI)
  – Poor survival of transfused platelets and granulocytes
  – Post-transfusion purpura
  – Transfusion-associated graft-versus-host disease (TA-GvHD)
• Plasma proteins:
  – Urticarial and anaphylactic reactions

Non-immunological

Transmission of infection
• Viruses:
  – HAV, HBV, HCV, HEV
  – HIV
  – CMV, HTLV-1, WNV
• Parasites:
  – Malaria, trypanosomiasis, toxoplasmosis
• Bacteria
• Prions

Transfusion-associated circulatory overload (TACO)

Iron overload
• Due to multiple transfusions: see p. 537

Bleeding and electrolyte changes
• May be caused by massive transfusion of stored blood

  CMV, cytomegalovirus; HAV/HBV/HCV/HEV, hepatitis A/B/C/E virus; HIV, human immunodeficiency virus; HTLV-1, human T-cell leukaemia virus 1; WNV, West Nile virus.

Prevention of wrong blood transfusions

The serious consequences of such failures emphasize the need for meticulous checks at all stages in the procedure of blood transfusion. Written procedures and good training of staff are essential, and regular audit to ensure compliance is also required. New approaches are being used, including the use of barcode patient identification and new technology at the bedside. Handheld devices can be used to prompt staff through the key steps and check that the barcode on the patient’s wristband matches the barcode on the unit of blood (Box 16.23).
Box 16.23

Bedside checks for blood unit compatibility

- The traditional pre-transfusion bedside checking required two nurses and checks of multiple items of written documentation.
- With barcode technology, a handheld computer scans a barcode on the patient wristband, corresponding to full patient details.
- The computer checks that the patient details match those on the unit's compatibility label barcode after pre-transfusion testing.
- This label also contains the unique number of the unit, and is matched with the number of the unit at the top left of the bag, to ensure that the blood bank has attached the right compatibility label.

Immunological complications

Alloimmunization

Blood transfusion carries a risk of alloimmunization to the many ‘foreign’ antigens present on red cells, leucocytes, platelets and plasma proteins. Alloimmunization also occurs during pregnancy – to fetal antigens inherited from the father and not shared by the mother (see pp. 546–547).

Alloimmunization does not usually cause clinical problems with the first transfusion but these may occur with subsequent transfusions. There may also be delayed consequences of alloimmunization, such as HDN and rejection of tissue or organ transplants.

Incompatibility

This may result in poor survival of transfused cells, such as red cells and platelets, and also in harmful effects of the antigen–antibody reaction.

Red cell complications: haemolytic transfusion reaction (immediate)

This is the most serious and life-threatening complication of blood transfusion and is usually due to ABO incompatibility. There is complement activation by the antigen–antibody reaction, usually caused by IgM antibodies and leading to rigors, lumbar pain, dyspnoea, hypotension, haemoglobinuria and renal failure. The initial symptoms may occur a few minutes after starting the transfusion. Activation of coagulation also occurs and bleeding due to disseminated intravascular coagulation (DIC) is a bad prognostic sign. Emergency treatment for shock (see pp. 1156–1161) is needed to maintain the blood pressure and renal function.

Diagnosis
This is confirmed by finding evidence of haemolysis (e.g. haemoglobinuria), and incompatibility between donor and recipient. All documentation should be checked to detect errors such as:

- failure to check the identity of the patient when taking the sample for compatibility testing (i.e. sample from the wrong patient)
- mislabelling of the blood sample with the wrong patient's name
- simple labelling or handling errors in the laboratory
- errors in the collection of blood, leading to delivery of the wrong blood to the ward/theatre
- failure to perform proper identity checks before the blood is transfused (i.e. blood transfused to the wrong patient).

**Investigations**

To confirm where the error occurred, blood grouping should be carried out on:

- the patient's original sample (used for the compatibility testing)
- a new sample taken from the patient after the reaction
- the donor units.

At the first suspicion of any serious transfusion reaction, the transfusion should always be stopped and the donor units returned to the blood transfusion laboratory with a new blood sample from the patient to exclude a haemolytic transfusion reaction.

**Red cell complications: haemolytic transfusion reaction (delayed)**

This occurs in patients alloimmunized by previous transfusions or pregnancies. The antibody level is too low to be detected by pre-transfusion compatibility testing but a secondary immune response occurs after transfusion, resulting in destruction of the transfused cells, usually by IgG antibodies.

Haemolysis is usually extravascular, as the antibodies are IgG, and the patient may develop anaemia and jaundice about a week after the transfusion, although most of these episodes are clinically silent. The blood film shows spherocytosis and reticulocytosis. The direct antiglobulin test is positive and detection of the antibody is usually straightforward.

**Leucocyte complications: non-haemolytic (febrile) transfusion reactions**

Febrile reactions are a common complication of blood transfusion in patients who have previously been transfused or pregnant. The usual causes are the presence of leucocyte antibodies in an alloimmunized recipient, which act against donor leucocytes in red cell concentrates, leading to release of pyrogens, or the release of cytokines from donor leucocytes in platelet concentrates. Typical signs are flushing and tachycardia, fever (>38°C), chills and rigors. Aspirin may be used to reduce the fever, although it should not be given to patients with
thrombocytopenia. The routine introduction of leucocyte-depleted blood in the UK, to minimize the risk of transmission of variant Creutzfeldt–Jakob disease (vCJD) by blood transfusion (see below), has reduced the incidence of febrile reactions. Universal leucocyte depletion of all blood components is common in European countries, but the proportion of blood components that are leucocyte-depleted is variable across the USA.

Transfusion-related acute lung injury (TRALI)

Potent leucocyte antibodies in the plasma of donors, who are usually multiparous women, may cause TRALI, characterized by dyspnoea, fever, cough, and shadowing in the perihilar and lower lung fields on the chest X-ray. Prompt respiratory support is essential and mechanical ventilation is frequently necessary. TRALI usually resolves within 48–96 hours but the mortality was 13% in the 305 cases of TRALI reported to SHOT up to 2013. The avoidance of female plasma in the preparation of fresh frozen plasma (FFP) and pooled platelets and the testing of female plateletpheresis donors for leucocyte antibodies have been implemented in many developed countries to reduce the risk of TRALI and are lowering the number of reported cases.

Transfusion-associated graft-versus-host disease

Transfused donor lymphocytes that share an HLA haplotype with the patient are able to circulate, as they are not rejected; they may recognize the patient as ‘foreign’ and cause an acute GvHD reaction, including pancytopenia. It is usually fatal but no cases have occurred in the UK for many years, probably because of routine leucocyte depletion of blood components. However, certain groups of immunosuppressed patients at particular risk of TA-GvHD should receive irradiated blood to minimize the risk. Such patients include those with congenital or acquired immunodeficiencies: for example, individuals who have had treatment with purine analogue drugs, those who have undergone haemopoietic stem cell transplant, fetuses, and neonates who have received an intrauterine transfusion.

Platelet complications: post-transfusion purpura

See page 570.

Plasma protein complications: urticaria and anaphylaxis

Urticarial reactions are often attributed to plasma protein incompatibility but, in most cases, they are unexplained. They are common but rarely severe; stopping or slowing the transfusion and administering chlorphenamine 10 mg i.v. are usually sufficient treatment. Anaphylactic reactions (see pp. 143–144) occasionally occur; severe reactions are seen in patients lacking IgA, who produce anti-IgA that reacts with IgA in the transfused blood. The transfusion should be stopped, and adrenaline (epinephrine) 0.5 mg i.m. and chlor-
**phenamine** 10 mg i.v. should be given immediately; endotracheal intubation may be required. Patients who have had severe urticarial or anaphylactic reactions should receive washed red cells, autologous blood or blood from IgA-deficient donors for patients with IgA deficiency.

### Immunosuppression

Transfusions are known to have a favourable effect on the survival of subsequent renal allografts, due to transfusion-induced immunomodulation. The precise mechanism is unclear but may be associated with the transfusion of allogeneic leucocytes. Other possible clinical effects caused by transfusion-induced immunosuppression, such as an increase in postoperative infection and tumour recurrence, have been proposed but remain unproven.

### Non-immunological complications

### Transmission of infection

#### Viral transmission

Donor blood in the UK is currently tested for hepatitis B virus (HBV), hepatitis C virus (HCV), human immunodeficiency virus (HIV)-1 and human T-cell leukaemia virus 1 (HTLV-1). Cytomegalovirus (CMV)-seronegative tested blood is given to immunosuppressed patients who are susceptible to acquiring CMV. Blood services continue a vigilant search for new infectious agents (‘emerging’ infections) that may be transmitted by blood transfusion, and for methods to prevent their transmission, including donor screening, testing and pathogen inactivation. Donor questionnaires record recent travel to exclude possible risks of West Nile virus (WNV), the causal agent of meningoencephalitis, which has been transmitted by transfusion and transplantation in the USA.

The risk of transmission of viral infections by blood transfusion varies from country to country, depending on factors such as the underlying prevalence of transfusion-transmitted infections in the population and the measures taken to minimize the risk of transmission. Viral transmission via blood transfusion is still a major issue in the developing world. In the UK, the risk of transmission of HIV by blood transfusion is extremely low – <1 in 7 million units transfused. Prevention is based on self-exclusion of donors in ‘high-risk’ groups and testing of each donation for anti-HIV. The risk of transmission of HBV is <1 in 1.2 million units transfused. The incidence of HCV is <1 in 28 million units transfused since the introduction of testing of donor plasma for viral nucleic acid. A recent study found a high prevalence of HEV in the English population and in blood donors, but at present blood donations are not screened. Measures for inactivating viruses in plasma, such as coagulation factor concentrates or intravenous immunoglobulin, include treatment with solvents and detergents.

#### Bacterial transmission

Bacterial contamination of blood components is rare but it is one of the most frequent causes of
death associated with transfusion. Some organisms, such as *Yersinia enterocolitica*, can proliferate in red cell concentrates stored at 4°C, but platelet concentrates stored at 22°C are a more frequent cause of this problem. Measures to avoid bacterial contamination include strict donor arm cleansing, diversion of the initial blood collection to samples for testing rather than into the collection bag, and bacterial detection systems for platelet concentrates, which have been implemented in most developed countries, including the USA. They were implemented in England in 2011.

*Transfusion-transmitted syphilis* is very rare. Spirochaetes do not survive for more than 72 hours in blood stored at 4°C, and each donation is tested using the *Treponema pallidum haemagglutination assay* (TPHA).

**Variant Creutzfeldt–Jakob disease**

In the UK, there continues to be concern about the risk of transmitting the prion protein that causes vCJD (see p. 267) by transfusion; four transmissions of vCJD have occurred following a blood transfusion in the UK. A number of measures have been taken in the UK, including universal leucocyte depletion of blood components in 1999, because the prion protein was thought to be primarily associated with lymphocytes. Blood donors are excluded if they have had a blood transfusion since 1980. UK donor plasma is not used for the manufacture of blood products; imported plasma from the USA is used instead. For children under the age of 16 years, FFP is sourced from plasma (from unremunerated donors) imported from the USA, on the basis that exposure to bovine spongiform encephalitis (BSE) from food was eliminated by 1 January 1996. FFP for this group is treated with methylthioninium chloride (methylene blue) to inactivate viruses.

While stringent measures are being taken to minimize the risk of transfusion-transmitted infection, it may never be possible to guarantee that donor blood is absolutely ‘safe’. The current approach to the safety of blood components and plasma in the UK and other developed countries is cautious but it is not an absolute guarantee of safety. Clinicians should always consider the patient's requirement for transfusion carefully, and only transfuse if clinically appropriate (see below).

**Transfusion-associated circulatory overload**

See management of acute heart failure (pages 984–988).

**Iron overload**

See page 537.

**Strategies for the avoidance of unnecessary transfusion**

These include:

- Strict criteria for the use of blood components and blood products
• Stopping drug therapy (anticoagulants and antiplatelet drugs) that may potentiate bleeding in surgical patients
• The identification and treatment of anaemia prior to surgery and in pregnancy
• The use of antifibrinolytic drugs, e.g. tranexamic acid in major surgery
• The use of recombinant factor VIIa, which is licensed to treat patients with haemophilia with inhibitors, and is being given ‘off-licence’ to treat patients with severe bleeding, such as after surgery, trauma or intracerebral haemorrhage. However, there is little evidence of its effectiveness for this latter indication and concerns about its safety remain.

Artificial haemoglobin solutions and other blood substitutes suitable for clinical use have not yet been developed. They generally have a short intravascular half-life, and a recent meta-analysis found a significant risk of mortality and myocardial infarction.

**Autologous transfusion**

An alternative to using blood from volunteer donors is to use the patient's own blood. There are three types of autologous transfusion:

• **Predeposit.** The patient donates 2–5 units of blood at approximately weekly intervals before elective surgery.

• **Preoperative haemodilution.** Immediately before surgery, 1 or 2 units of blood are removed from the patient and then retransfused to replace operative losses.

• **Blood salvage.** Blood lost during or after surgery may be collected and retransfused. Several techniques of varying levels of sophistication are available. The operative site must be free of bacteria, bowel contents and tumour cells.

The use of predeposit autologous transfusion was largely driven by concerns about transfusion-transmitted infection, particularly in the USA. It has been abandoned in the UK, except for those rare patients in whom it is not possible to identify compatible blood because of multiple antibodies. There is little evidence that this approach reduces blood requirements, and blood is perceived as being ‘safe’. Blood salvage is increasingly being employed as a way of avoiding the use of donor blood. In developing countries, autologous blood and blood from relatives are commonly chosen because of a lack of donor blood.

**Blood, Blood Components and Blood Products**

Most blood collected from donors is processed as follows:

• **Blood components**, such as red cell and platelet concentrates, fresh frozen plasma (FFP) and cryoprecipitate, are prepared from a single donation of blood by simple separation methods such as centrifugation and are transfused without further processing. Platelet concentrates are also prepared by plateletpheresis (see below).

• **Blood products**, such as coagulation factor concentrates, albumin and immunoglobulin solutions, are prepared by complex processes using the plasma from many donors as the
starting material (UK donor plasma is not used; see above).

In most circumstances, it is preferable to transfuse only the blood component or product required by the patient ('component therapy') rather than using whole blood. This is the most effective way of using donor blood, which is a scarce resource, and reduces the risk of complications from transfusion of unnecessary components of the blood.

Patients should be provided with information about blood transfusion, wherever possible, and given the opportunity to ask questions: for example, about alternatives to transfusion. This discussion should be documented. Some patients, such as Jehovah's Witnesses, may refuse transfusion and need specialized management when they undergo surgery or receive medical treatments that usually require blood transfusion. The indications for transfusion have been summarized by the National Blood Transfusion Committee.

**Whole blood**

A unit of whole blood consists of 450 mL ± 10% of blood from a suitable donor plus 63 mL of anticoagulant, which is then leucocyte-depleted. Blood stored at 4°C is given a ‘shelf-life’ of 5 weeks in the UK (6 weeks in some other countries), when at least 70% of the transfused red cells should survive normally. Whole blood is now rarely used for transfusion; donated blood is processed into red cell concentrates and other blood components.

**Red cell concentrates**

Virtually all the plasma is removed and is replaced by about 100 mL of an optimal additive solution, such as SAG-M, which contains sodium chloride, adenine, glucose and mannitol. The mean volume is about 330 mL. The PCV is about 0.57 L/L but the viscosity is low, as there are no plasma proteins in the additive solution; this allows fast administration, if necessary.

Red cell concentrates are used to increase the oxygen-carrying capacity of patients with major haemorrhage (Fig. 16.29), and to treat non-bleeding patients with severe anaemia by maintaining the Hb above 70 g/L; a higher threshold – e.g. Hb of 9 g/L – is used for patients with severe cardiovascular disease. An algorithm for the management of major haemorrhage is available in the UK Blood Services Handbook for Transfusion Medicine.
**Washed red cell concentrates**

These are preparations of red cells suspended in saline, produced by cell separators that remove all but traces of plasma proteins. They are used in patients who have had severe recurrent urticarial or anaphylactic reactions.
Platelet concentrates
These are prepared either by centrifugation of whole blood or by plateletpheresis of blood from single donors using cell separators. They may be stored for up to 5 days at 22°C with agitation. They are used to treat bleeding in patients with severe thrombocytopenia, and prophylactically to prevent bleeding in patients with bone marrow failure when the platelet count is <10 × 10⁹/L.

Granulocyte concentrates
These are prepared from whole blood as ‘buffy coats’ or from blood from single donors using cell separators, and are used for patients with severe neutropenia when there is definite evidence of bacterial infection. The numbers of granulocytes collected may be increased by treating donors with G-CSF and steroids. The half-life of granulocytes is of the order of a few hours only and thus granulocytes need to be collected and transfused on a daily basis, making the practicalities of this treatment challenging.

Fresh frozen plasma
FFP is prepared by freezing the plasma from 1 unit of blood to −30°C to maintain the concentration of coagulation factors. The volume is approximately 200 mL. FFP contains all the coagulation factors present in fresh plasma and is used mostly for replacement of coagulation factors in acquired coagulation factor deficiencies, such as massive haemorrhage and DIC. It may be further treated by a pathogen-inactivation process – for example, methylene blue or solvent detergent – to minimize the risk of disease transmission. For children, see pages 558–559.

Prothrombin complex concentrates
These contain factors II, VII, IX and X, and have replaced FFP as the recommended treatment for rapid reversal of warfarin overdose in patients with an elevated INR and bleeding (see Box 16.38) because of their superior efficacy and lower risk of allergic reactions and volume overload.

Cryoprecipitate
This is obtained by allowing the frozen plasma from a single donation to thaw at 4–8°C and removing the supernatant. The volume is about 20 mL and it is stored at −30°C. It contains factor VIII : C, von Willebrand factor (VWF) and fibrinogen, and may be useful in DIC and other conditions where the fibrinogen level is very low. It is no longer used for the treatment of haemophilia A and von Willebrand’s disease because of the greater risk of virus transmission compared with virus-inactivated coagulation factor concentrates. Fibrinogen concentrates are now available, but are not yet approved for the treatment of patients with acquired disorders of haemostasis such as massive transfusion.

Specific coagulation factor concentrates
Specific factor concentrates are available for factors VII, VIII, IX, X, XI, XIII and VWF. These are freeze-dried preparations of the specific factor prepared from large pools of plasma. All products are produced from plasma sources at low risk of vCJD and are virus-inactivated during manufacture using either heat or chemicals. They are used for treating patients with inherited coagulation factor deficiencies, where recombinant coagulation factor concentrates are unavailable. If available, recombinant coagulation factor concentrates are the treatment of choice (see pp. 571–573).

**Albumin**

There are two preparations:

- **Human albumin solution 4.5%** contains 45 g/L albumin and 160 mmol/L sodium. It is available in 50, 100, 250 and 500 mL bottles.

- **Human albumin solution 20%** contains approximately 200 g/L albumin and 130 mmol/L sodium. It is available in 50 and 100 mL bottles.

  Human albumin solutions are generally considered to be inappropriate fluids for acute volume replacement or for the treatment of shock because they are no more effective in these situations than synthetic colloid solutions, such as polygelatins (Gelofusine) or hydroxyethyl starch (Haemaccel). However, albumin solutions are indicated for treatment of acute severe hypoalbuminaemia and as the replacement fluid for plasma exchange. The 20% albumin solution is particularly useful for patients with nephrotic syndrome or liver disease who are fluid-overloaded and resistant to diuretics. Albumin solutions should not be used to treat patients with malnutrition or chronic renal or liver disease who have a low serum albumin.

**Normal immunoglobulin**

This is prepared from normal plasma. It is used in patients with hypogammaglobulinaemia, to prevent infections, and in patients with, for example, immune thrombocytopenic purpura (see pp. 569–570).

**Specific immunoglobulins**

These are obtained from donors with high titres of antibodies. Many preparations are available, such as anti-D, anti-hepatitis B and anti-varicella zoster.

**Therapeutic use of haemopoietic stem cell transplantation**

The use of haemopoietic stem cells to regenerate the bone marrow of patients whose own, usually diseased, marrow has been ablated by radiation and/or chemotherapy is the first and, to date, the only routine ‘stem cell therapy’ in clinical practice. Haemopoietic stem cell transplantation (HSCT) is used in a range of haematological malignancies, and occasionally in other cancers and non-malignant disorders, such as sickle cell disease. It relies on the regenerative potential of transfused haemopoietic stem cells to repopulate the marrow niche that has been rendered temporarily or permanently hypoplastic by chemotherapy with or
without additional radiotherapy. Such procedures vary in the source of the stem cells and in the type and intensity of the preparatory conditioning regimen (Box 16.24).

## Box 16.24

**Sources of stem cells**

Bone marrow or peripheral blood stem cells
- Autologous – from patient
- Syngeneic – from identical twin
- Allogeneic
  - related or unrelated donor
  - full (10/10) or partial (8 or 9/10) HLA match
  - umbilical cord blood

### Autologous stem cell transplantation

Most anticancer drugs have a sigmoid dose–response relationship, which suggests that, up to a point, a higher dose of a cytotoxic drug will induce a greater response. However, increasing a cytotoxic drug dose is often not possible, owing to toxicity. For those chemotherapeutic agents with a dose-limiting toxicity of bone marrow failure, infusion of previously harvested haemopoietic stem cells is able to ‘rescue’ the haemopoietic system and permits the use of higher doses to overcome tumour drug resistance. Haemopoietic stem cells are collected either from the patient's bone marrow or, more commonly, from the peripheral blood by leucopheresis, following stem cell mobilization from the marrow niche by the administration of the growth factor G-CSF (see p. 517), with or without chemotherapy. These stem cells are stored by cryopreservation and then re-infused intravenously after an intensive chemotherapy regimen. This approach has been particularly effective in relapsed lymphomas, myeloma and germ cell tumours, and the large majority of HSCT procedures are carried out to treat these conditions. However, tumour contamination of the re-infused stem cells remains a reality. The infused stem cells take a period of 2–4 weeks to regenerate normal blood cell production, and therefore patients undergoing autologous HSCT experience a prolonged period of severe cytopenias and immunosuppression, with a consequent treatment-related mortality in the region of 1–5%.

### Allogeneic HSCT

#### Conventional myeloablative allogeneic HSCT

Conventional myeloablative allogeneic HSCT combines the cytotoxic effect of high-dose chemotherapy and/or radiotherapy with a potent immunotherapy effect. Historically, the transplantation of donor haemopoietic cells has been combined with myeloablative chemotherapy with or without radiotherapy, with the dual effects of treating the malignancy and
causing temporary immunosuppression that allows the graft ‘to take’. Donors are usually fully matched at the major HLA antigens. Thus siblings are more likely to be found to be potential donors (25% chance for each sibling) than unrelated volunteers, who have to be carefully selected by HLA-matching using large sample registries of potential donors. Allogeneic transplantation has been successfully used in a number of haemopoietic malignancies: most commonly, acute leukaemias. The engraftment of the donor immune system, with antitumour activity (graft-versus-tumour), is primarily responsible for the increased effectiveness of this approach. Complications include GvHD, an alloimmune reaction of the donor cells against normal host organs, which can affect 30–50% of transplant recipients and is potentially fatal in some cases. Immunosuppression, both from conditioning therapy and from the immunosuppressive drugs (ciclosporin or tacrolimus) given to prevent GvHD, results in a high incidence of opportunistic infection and viral reactivation, such as CMV. All patients receive prophylactic antibacterial, antifungal and antiviral drugs. Mortality from conventional allogeneic stem cell transplantation is therefore a major problem, with 15–40% at risk of dying from the procedure, depending on the age and status of the recipient and the degree of HLA compatibility of the donor. The use of donor lymphocyte infusions following allogeneic HSCT, while losing some of the specificity, has produced the strongest evidence for the efficacy of immunotherapy via graft-versus-tumour activity with clinical remissions observed, albeit with a risk of triggering GvHD.

**Non-myeloablative allogeneic HSCT**

The considerable toxicity associated with conventional myeloablative allogeneic HSCT limits use of the procedure to younger patients. This is problematic, as many haematological malignancies for which allogeneic HSCT is indicated primarily affect older patients. To address this problem, allogeneic HSCT approaches using ‘reduced-intensity conditioning’ have been developed since the turn of the century and are based on drugs such as fludarabine, which are primarily immunosuppressive rather than myelosuppressive. This maintains the anticancer ‘graft-versus-leukaemia’ effect of the transplant without the toxicity of conventional allogeneic stem cell transplantation. Treatment-related mortality is lower and the technique can be used successfully, particularly in the elderly and those with co-morbidities. GvHD remains an obstacle to success, however. Non-myeloablative allogeneic transplants are now more common than conventional myeloablative HSCT procedures.

**Further reading**

The White Cell

The five types of leucocytes found in peripheral blood are: neutrophils, eosinophils and basophils (which are all called granulocytes), and lymphocytes and monocytes (see also pp. 124–125). The development of these cells is shown in Figure 16.1.

Neutrophils

The earliest morphologically identifiable precursors of neutrophils in the bone marrow are myeloblasts, which are large cells constituting up to 3% of the nucleated cells in the marrow. The nucleus is large and contains 2–5 nucleoli. The cytoplasm is scanty and contains no granules. Promyelocytes are similar to myeloblasts but have some primary cytoplasmic granules, containing enzymes such as myeloperoxidase. Myelocytes are smaller cells without nucleoli but with more abundant cytoplasm and both primary and secondary granules. Indentation of the nucleus marks the change from myelocyte to metamyelocyte. The mature neutrophil is a smaller cell with a nucleus that has 2–5 lobes, with predominantly secondary granules in the cytoplasm, which contain lysozyme, collagenase and lactoferrin.

Peripheral blood neutrophils are equally distributed into a circulating pool and a marginating pool lying along the endothelium of blood vessels. In contrast to the prolonged maturation time of about 10 days for neutrophils in the bone marrow, their half-life in the peripheral blood is extremely short: only 6–8 hours. In response to stimuli (e.g. infection, corticosteroid therapy), neutrophils are released into the circulating pool from both the marginating pool and the marrow. Immature white cells are released from the marrow when a rapid response (within hours) occurs in acute infection (described as a ‘shift to the left’ on a blood film).

Function
The prime function of neutrophils is to ingest and kill bacteria, fungi and damaged cells. Neutrophils are attracted to sites of infection or inflammation by chemotaxins. Recognition of foreign or dead material is aided by the coating of particles with immunoglobulin and complement (opsonization), as neutrophils have Fc and C3b receptors (see pp. 124–125). The material is ingested into vacuoles, where it is subjected to enzymic destruction; this is either oxygen-dependent, with the generation of hydrogen peroxide (myeloperoxidase), or oxygen-independent (lysosomal enzymes and lactoferrin). Leucocyte alkaline phosphatase (LAP) is an enzyme found in leucocytes. It is raised when there is a neutrophilia due to an acute illness. It is also raised in polycythaemia and myelofibrosis, and reduced in chronic myeloid leukaemia.

**Neutrophil leucocytosis**

A rise in the number of circulating neutrophils to $>10 \times 10^9/L$ occurs in bacterial infections or is a result of tissue damage. This may also be seen in pregnancy, during exercise and after corticosteroid administration (Box 16.25). With any tissue necrosis, there is a release of various soluble factors, causing a leucocytosis. Interleukin 1 is also released in tissue necrosis and causes a pyrexia. The pyrexia and leucocytosis that accompany a myocardial infarction are a good example of this and may be wrongly attributed to infection.

**Box 16.25**

*Causes of a neutrophil leucocytosis*

- Bacterial infections
- Tissue necrosis, e.g. myocardial infarction, trauma
- Inflammation, e.g. gout, rheumatoid arthritis
- Drugs, e.g. corticosteroids, lithium, G-CSF
- Haematological:
  - Myeloproliferative disease
  - Leucoerythroblastosis (see text)
- Physiological, e.g. pregnancy, exercise
- Malignant disease, e.g. bronchial, breast, gastric
- Metabolic, e.g. renal failure, acidosis
- Congenital, e.g. leucocyte adhesion deficiency, hereditary neutrophilia
- Smoking
- Acute haemorrhage or haemolysis
  G-CSF, granulocyte colony stimulating factor.

A *leucoerythroblastic blood film* (an overproduction of white cells, with many immature cells and nucleated red cells) may occur in many types of severe acute illness (e.g. infection,
haemorrhage), tuberculosis, malignant infiltration of the bone marrow, and occasionally after haemorrhage, haemolysis and severe haemolytic or megaloblastic anaemia.

**Neutropenia and agranulocytosis**

Neutropenia is defined as a circulatory neutrophil count of $<1.5 \times 10^9$/L. The causes are given in Box 16.26. A virtual absence of neutrophils is called agranulocytosis. It is important to note that black patients may have somewhat lower neutrophil counts. Neutropenia caused by viruses is probably the most common type. Chemotherapy and radiotherapy predictably produce neutropenia; many other drugs have been known to produce an idiosyncratic cytopenia and a drug cause should always be considered.

**Box 16.26**

**Causes of neutropenia**

**Acquired**

- Viral infection
- Severe bacterial infection, e.g. typhoid
- Felty syndrome (rheumatoid arthritis-associated)
- Immune neutropenia – autoimmune, autoimmune neonatal neutropenia
- Pancytopenia from any cause, including drug-induced marrow aplasia (see p. 530)
- Drug-induced agranulocytosis, e.g. carbimazole
- Pure white cell aplasia

**Inherited**

- Ethnic (neutropenia is common in black races)
- Kostmann syndrome (severe infantile agranulocytosis) due to mutation in the elastane 2 ($ELA2$) gene
- Cyclical (genetic mutation in $ELA2$ gene with neutropenia every 2–3 weeks)
- Others, e.g. Schwachman–Diamond syndrome, dyskeratosis congenita, Chédiak–Higashi syndrome

**Clinical features**

Infections may be frequent, are often serious, and are more likely as the neutrophil count falls. An absolute neutrophil count of $<0.5 \times 10^9$/L is regarded as ‘severe’ neutropenia and may be associated with life-threatening infections, such as pneumonia and septicaemia. A characteristic glazed mucositis occurs in the mouth, and ulceration is common.
Investigations

The blood film shows marked neutropenia. The appearance of the bone marrow will indicate whether the neutropenia is due to depressed production or increased destruction of neutrophils. Neutrophil antibody studies are performed if an immune mechanism is suspected.

Management

Antibiotics should be given as necessary to patients with acute severe neutropenia (see pp. 604–605). Exposure to infections should be minimized. A neutropenic diet is instituted (see Box 17.21).

If the neutropenia seems likely to have been caused by a drug, all current drug therapy should be stopped. Recovery of the neutrophil count usually occurs after about 10 days. G-CSF (see p. 517) is used to decrease the period of neutropenia after chemotherapy and haemopoietic transplantation. It is also employed successfully in the treatment of chronic neutropenia.

Steroids and high-dose intravenous immunoglobulin are used to treat patients with severe autoimmune neutropenia and recurrent infections, and G-CSF has produced responses in some cases.

Eosinophils

Eosinophils are slightly larger than neutrophils and are characterized by a nucleus, usually with two lobes, and large cytoplasmic granules that stain deeply red. The eosinophil plays a part in allergic responses (see p. 125) and in the defence against infections with helminths and protozoa.

Eosinophilia is defined as >0.4 × 10⁹/L eosinophils in the peripheral blood. The causes of eosinophilia are listed in Box 16.27.

Box 16.27

Causes of eosinophilia

Parasitic infestations, such as:
- *Ascaris*
- Hookworm
- *Strongyloides*

Allergic disorders, such as:
- Hayfever (allergic rhinitis)
- Other hypersensitivity reactions, including drug reactions
Skin disorders, such as:
- Urticaria
- Pemphigus
- Eczema

Pulmonary disorders, such as:
- Bronchial asthma
- Tropical pulmonary eosinophilia
- Allergic bronchopulmonary aspergillosis
- Eosinophilic granulomatosis with polyangiitis

Malignant disorders, such as:
- Hodgkin's lymphoma
- T-cell non-Hodgkin's lymphoma
- Carcinoma
- Eosinophilic leukaemia
- Acute myeloid leukaemia
- Myeloproliferative diseases associated with PDGFR rearrangements

Miscellaneous disorders, such as:
- Hypereosinophilic syndrome
- Sarcoidosis
- Hypoadrenalism
- Eosinophilic gastroenteritis

**Basophils**

The nucleus of basophils is similar to that of neutrophils but the cytoplasm is filled with large, black granules. The granules contain histamine, heparin, and enzymes such as myeloperoxidase. The physiological role of the basophil is not known. Binding of IgE causes the cells to degranulate and release histamine and other contents involved in acute hypersensitivity reactions (see p. 142).

Basophils are usually few in number (<1 × 10⁹/L) but are significantly increased in some myeloproliferative disorders, such as chronic myeloid leukaemia.

**Monocytes**

Monocytes are slightly larger than neutrophils. The nucleus has a variable shape and may be round, indented or lobulated. The cytoplasm contains fewer granules than neutrophils. Monocytes are precursors of tissue macrophages and dendritic cells; they spend only a few
hours in the blood but can continue to proliferate in the tissues for many years.

A monocytosis (>0.8 × 10^9/L) may be seen in chronic bacterial infections, such as tuberculosis or infective endocarditis, chronic neutropenia and myelodyplasia, particularly chronic myelomonocytic leukaemia.

**Lymphocytes**

Lymphocytes form nearly half of circulating white cells. They descend from pluripotent stem cells (see Fig. 16.1). Circulating lymphocytes are small cells, a little larger than red cells, with a dark-staining central nucleus. There are two main types: T and B lymphocytes (see p. 121).

Lymphocytosis (lymphocyte count >5 × 10^9/L) occurs in response to viral infections, particularly EBV, CMV and HIV, and chronic infections such as tuberculosis and toxoplasmosis. It is also found in chronic lymphocytic leukaemia and in some lymphomas.

**Haemostasis and Thrombosis**

The integrity of the circulation is maintained by blood flowing through intact vessels lined by endothelial cells. Haemostasis is the host defence mechanism that protects this integrity after injury to the vessel wall and tissue injury.

**Haemostasis**

Haemostasis is a complex process that depends on interactions between the vessel wall, leucocytes, platelets, coagulation and fibrinolytic mechanisms. Haemostatic systems are normally quiescent but, following tissue injury, become rapidly activated. The formation of the haemostatic plug is shown in Figure 16.30.
FIGURE 16.30 Formation of the haemostatic plug: sequential interactions between the vessel wall, platelets and coagulation factors. A. Contact of platelets with collagen via the platelet receptor GP1b and factor von Willebrand factor (VWF) in plasma activates platelet prostaglandin synthesis, which stimulates release of adenosine diphosphate (ADP) from the dense bodies. Vasoconstriction of the vessel occurs as a reflex and by release of serotonin and thromboxane A₂ (TXA₂) from platelets. B. Release of ADP from platelets induces platelet aggregation and formation of the platelet plug. The coagulation pathway is stimulated, leading to the formation of fibrin. C. Fibrin strands are cross-linked by factor XIII and stabilize the haemostatic plug by binding platelets and red cells.
**Vessel wall**

The vessel wall is lined by endothelium, which, in normal conditions, prevents platelet adhesion and thrombus formation. This property is partly due to its negative charge but also to:

- thrombomodulin and heparan sulphate expression
- synthesis of prostacyclin (prostaglandin I$_2$, PGI$_2$) and nitric oxide (NO), which cause vasodilatation and inhibit platelet aggregation
- production of plasminogen activator.

Injury to vessels causes reflex vasoconstriction, while endothelial damage results in loss of antithrombotic properties, activation of platelets and coagulation, and inhibition of fibrinolysis (*Fig. 16.30*).

**Platelets**

**Platelet adhesion**

When the vessel wall is damaged, the escaping platelets come into contact with and adhere to collagen and subendothelial bound VWF. This adherence is mediated through glycoprotein Ib (GPIb). Glycoprotein IIb–IIIa is then exposed, forming a second binding site for VWF. Within seconds of adhesion to the vessel wall, platelets begin to undergo a shape change, from a disc to a sphere, spread along the subendothelium and release the contents of their cytoplasmic granules. These are the dense bodies (containing adenosine diphosphate (ADP) and serotonin) and the α-granules (containing platelet-derived growth factor, platelet factor 4, β-thromboglobulin, fibrinogen, VWF, fibronectin, thrombospondin and other factors).

**Platelet release**

The release of ADP leads to a conformational change in the fibrinogen receptor, the glycoprotein IIb–IIIa complex (GPIIb–IIIa), on the surfaces of adherent platelets, allowing it to bind to fibrinogen (see also *Fig. 16.39*).

**Platelet aggregation**

As fibrinogen is a dimer, it can form a direct bridge between platelets and so binds platelets into activated aggregates (platelet aggregation; *Fig. 16.30B*), and further platelet release of ADP occurs. A self-perpetuating cycle of events is set up, leading to formation of a platelet plug at the site of the injury.

**Coagulation**

After platelet aggregation and release of ADP, the exposed platelet membrane phospholipids are available for the assembly of coagulation factor enzyme complexes (tenase and prothrombinase); this platelet phospholipid activity has been called platelet factor 3 (PF-3). The presence of thrombin encourages fusion of platelets, and fibrin formation reinforces the stability of the platelet plug. Central to normal platelet function is platelet prostaglandin
synthesis, which is induced by platelet activation and leads to the formation of thromboxane A₂ (TXA₂) in platelets (Fig. 16.31). TXA₂ is a powerful vasoconstrictor and also lowers cyclic adenosine monophosphate (AMP) levels and initiates the platelet release reaction. Prostacyclin (PGI₂) is synthesized in vascular endothelial cells and opposes the actions of TXA₂. It produces vasodilatation and increases the level of cyclic AMP, preventing platelet aggregation on the normal vessel wall, as well as limiting the extent of the initial platelet plug after injury.

Coagulation and fibrinolysis

Coagulation involves a series of enzymatic reactions that lead to the conversion of soluble plasma fibrinogen to fibrin-based clot (Fig. 16.32). Roman numerals are used for most of the factors, but I and II are referred to as fibrinogen and prothrombin, respectively; III, IV and VI are redundant. The active forms are denoted by ‘a’. The coagulation factors are primarily synthesized in the liver and are either serine protease enzyme precursors (factors XI, X and IX, and thrombin) or co-factors (V and VIII), except for fibrinogen, which is polymerized to form fibrin.
FIGURE 16.32 Coagulation mechanism. The in vivo pathway begins with tissue factor–factor VIIa (VIIa, TF) complex activating factor X (Xa) and amplifying factor IX (IXa). Thrombin activates factor XI (Xla), as well as factor IXa, VIIIa, and Va and Xa complexes. TFPI, tissue factor pathway inhibitor.

Coagulation pathway

This enzymatic amplification system was traditionally divided into ‘extrinsic’ and ‘intrinsic’ pathways. This concept is useful for the interpretation of clinical laboratory tests, such as the prothrombin time (PT) and activated partial thromboplastin time (APTT) (see Fig. 16.36), but is unrepresentative and oversimplifies in vivo coagulation. Coagulation is initiated by tissue damage (Fig. 16.32):

• Tissue damage exposes tissue factor (TF), which binds to factor VII.
• The TF–factor VII complex directly converts factor X to active factor Xa, and some factor IX to factor IXa.
• In the presence of factor Xa, tissue factor pathway inhibitor (TFPI) inhibits further generation of factor Xa and factor IXa.
• Following inhibition by TFPI, the amount of factor Xa produced is insufficient to maintain coagulation. Further factor Xa, to allow haemostasis to progress to completion, can only be generated by the alternative factor IX/factor VIII pathway. However, enough thrombin exists at this point to activate factor VIII, which dramatically increases the activity of factor IXa (generated by TF–factor VIIa), so further activation of factor X can proceed. Without the amplification and consolidating action of factor VIII/factor IX, bleeding will ensue, as generation of factor Xa is insufficient to sustain haemostasis.
• Similarly, thrombin activates factor V, dramatically enhancing the conversion of prothrombin to thrombin by factor Xa.
• Thrombin hydrolyses the peptide bonds of fibrinogen, releasing fibrinopeptides A and B, and
allowing polymerization between fibrinogen molecules to form fibrin. At the same time, thrombin, in the presence of calcium ions, activates factor XIII, which stabilizes the fibrin clot by cross-linking adjacent fibrin molecules.

**Factor VIII**
Factor VIII consists of a molecule with coagulant activity (VIII : C) associated with VWF. Factor VIII increases the activity of factor IXa by approximately 200 000 fold. VWF functions to prevent premature factor VIII : C breakdown and locate it to areas of vascular injury. Factor VIII : C has a molecular weight of about 350 000.

**Von Willebrand factor**
VWF is a glycoprotein with a molecular weight of about 200 000, which readily forms multimers in the circulation with molecular weights of up to $20 \times 10^6$. It is synthesized by endothelial cells and megakaryocytes, and stored in platelet granules as well as the endothelial cells. The high-molecular-weight multimeric forms of VWF are the most biologically active (see p. 573 and Fig. 16.37).

**Physiological limitation of coagulation**
Without a physiological system to limit blood coagulation, dangerous thrombosis could ensue. The natural anticoagulant mechanism regulates and localizes thrombosis to the site of injury.

**Antithrombin**
Antithrombin (AT), a member of the serine protease inhibitor (serpin) superfamily, is a potent inhibitor of coagulation. It inactivates the serine proteases by forming stable complexes with them, and its action is greatly potentiated by heparin.

**Activated protein C**
This is generated from its vitamin K-dependent precursor, protein C, by thrombin; thrombin activation of protein C is greatly enhanced when thrombin is bound to thrombomodulin on endothelial cells (Fig. 16.33). Activated protein C inactivates factor V and factor VIII, reducing further thrombin generation.
**Protein S**
This is a co-factor for protein C, which acts by enhancing binding of activated protein C to the phospholipid surface. It circulates bound to C4b binding protein but some 30–40% remains unbound and active (free protein S).

**Other inhibitors**
Other natural inhibitors of coagulation include $\alpha_2$-macroglobulin, $\alpha_1$-antitrypsin and $\alpha_2$-antiplasmin.

**Fibrinolysis**
Fibrinolysis is a normal haemostatic response that helps to restore vessel patency after vascular damage. The principal component is the enzyme plasmin, which is generated from its inactive precursor plasminogen *(Fig. 16.34)*. This is achieved principally via tissue plasminogen activator (t-PA) released from endothelial cells. Some plasminogen activation may also be promoted by urokinase, produced in the kidneys. Other plasminogen activators (factor XII and prekallikrein) are of minor physiological importance.
Plasmin

Plasmin is a serine protease, which breaks down fibrinogen and fibrin into fragments X, Y, D and E, collectively known as fibrin (and fibrinogen) degradation products (FDPs). D-dimer is produced when cross-linked fibrin is degraded. Its presence in the plasma indicates that the coagulation mechanism has been activated.

Fibrinolytic system

This is activated by the presence of fibrin. Plasminogen is specifically adsorbed to fibrin and fibrinogen by lysine-binding sites. However, little plasminogen activation occurs in the absence of polymerized fibrin, as fibrin also has a specific binding site for plasminogen activators, whereas fibrinogen does not *(Fig. 16.35)*.
A. The conversion of plasminogen to plasmin by tissue plasminogen activator (t-PA) occurs most efficiently on the surface of fibrin, which has binding sites for both plasminogen and t-PA. B. Free plasmin in the blood is rapidly inactivated by α₂-antiplasmin. Plasmin generated on the fibrin surface is partially protected from inactivation. The lysine-binding sites on plasminogen are necessary for the interaction between plasmin(ogen) and fibrin, and between plasmin and α₂-antiplasmin.

**Tissue plasminogen activator**

This is inactivated by plasminogen activator inhibitor-1 (PAI-1). Activated protein C inactivates PAI-1 and therefore induces fibrinolysis (Fig. 16.33). Inactivators of plasmin, such as α₂-antiplasmin (Fig. 16.35) and thrombin-activatable fibrinolysis inhibitor (TAFI), also contribute to the regulation of fibrinolysis.

**Investigation of bleeding disorders**

Although the precise diagnosis of a bleeding disorder will depend on laboratory tests, much information is obtained from the history and physical examination.

**Is there a generalized haemostatic defect?**

Supportive evidence for a generalized haemostatic defect includes bleeding from multiple sites, spontaneous bleeding, and excessive bleeding after injury.

**Is the defect inherited or acquired?**

A family history of a bleeding disorder should be sought. Severe inherited defects usually become apparent in infancy, sometimes at the time of birth with prolonged bleeding from the umbilical cord, while mild inherited defects may only come to attention later in life: for example, with excessive bleeding after surgery, childbirth, dental extractions or trauma. Some defects are revealed by routine coagulation screens that are performed before surgical
procedures.

**Is the bleeding suggestive of a vascular/platelet defect or a coagulation defect?**

**Vascular/platelet bleeding**

This is characterized by easy bruising and spontaneous bleeding from small vessels. There is often bleeding into the skin. Purpura includes both petechiae, small skin haemorrhages varying from pinpoint size to a few millimetres in diameter and which do not blanch on pressure, and ecchymoses, larger areas of bleeding into the skin. Bleeding also occurs from mucous membranes, especially the nose and mouth.

**Coagulation disorders**

These are typically associated with bleeding after injury or surgery and, in more severe forms, haemarthroses and muscle haematomas. There is often a short delay between the precipitating event and overt haemorrhage or haematoma formation.

**Laboratory investigations**

**Blood count and film**

These show the number and morphology of platelets and any blood disorder, such as leukaemia or lymphoma. The normal range for the platelet count is 150–400 $\times 10^9$/L.

**Coagulation tests**

These are performed using blood collected into citrate, which neutralizes calcium ions and prevents clotting.

*The prothrombin time (PT)* (also see p. 579) is measured by adding tissue factor (thromboplastin) and calcium to the patient's plasma and measuring the length of time taken for the blood to clot. The normal PT is 12–16 s. When used to measure warfarin-based oral anticoagulation, the PT is expressed as the international normalized ratio, or INR (see p. 579). The PT measures VII, X, V, prothrombin and fibrinogen (the classic ‘extrinsic’ pathway) *(Fig. 16.36)*, and is prolonged in abnormalities of these factors. It may also be abnormal in liver disease, or if the patient is on oral anticoagulants, including warfarin and some of the new alternative oral anticoagulants.
**The activated partial thromboplastin time (APTT)** is also sometimes known as the PTT with kaolin (PTTK). It is measured by adding a surface activator (such as kaolin, micronized silica or ellagic acid), phospholipid (to mimic platelet membrane) and calcium to the patient's plasma. The normal APTT is 26–37 s and depends on the exact methodology. The APTT measures XII, XI, IX, VIII, X, V, prothrombin and fibrinogen (the classic ‘intrinsic’ pathway), and is prolonged in deficiencies of one or more of these factors. It is not dependent on factor VII.

**The thrombin time (TT)** is measured by adding thrombin to the patient's plasma. The normal TT is 12–14 s, and it is prolonged in fibrinogen deficiency, in qualitative defects of fibrinogen (dysfibrinogenaemia) or in the presence of inhibitors such as heparin or FDPs.

**Correction tests** can be used to differentiate prolonged times in the PT, APTT and TT due to various coagulation factor deficiencies and inhibitors of coagulation. Prolonged PT, APTT or TT due to coagulation factor deficiencies can be corrected by addition of normal plasma to the patient's plasma. Failure to correct after addition of normal plasma is suggestive of the presence of an inhibitor of coagulation.

**Factor assays** are used to confirm coagulation defects, especially where a single inherited disorder is suspected.

**Special tests of coagulation** will often be required to confirm the precise haemostatic defect. Such tests include estimation of fibrinogen and FDPs, platelet function tests such as platelet aggregation, and platelet granule contents.

**Bleeding time** measures platelet plug formation *in vivo*. A sphygmomanometer cuff is inflated to 40 mmHg and incisions in the forearm 1 mm deep and 1 cm long are made with a template.
Wounds are blotted every 30 s and the time taken for bleeding to stop is recorded (normally 3–10 min). Prolonged bleeding times are found in patients with platelet function defects, and when the platelet count is $<100 \times 10^9$/L. Nowadays, this test is very rarely done, as it can scar and is painful.

**Vascular Disorders**

The vascular disorders *(Box 16.28)* are characterized by easy bruising and bleeding into the skin. Bleeding from mucous membranes sometimes occurs but the bleeding is rarely severe. Laboratory investigations, including the bleeding time, are normal. The vascular disorders are described below.

---

**Box 16.28**

**Vascular disorders**

**Congenital**
- Hereditary haemorrhagic telangiectasia (Osler–Weber–Rendu disease)
- Connective tissue disorders (Ehlers–Danlos syndrome, osteogenesis imperfecta, pseudoxanthoma elasticum, Marfan syndrome)

**Acquired**

**Severe infections**
- Septicaemia
- Meningococcal infections
- Measles
- Typhoid

**Allergic disorders**
- Henoch–Schönlein purpura
- Autoimmune rheumatic disorders (systemic lupus erythematosus, rheumatoid arthritis)

**Drug-induced disorders**
- Steroids
- Sulphonamides

**Others**
- Senile purpura
- Easy bruising syndrome
- Scurvy
- Factitious purpura
Hereditary haemorrhagic telangiectasia
This is a rare disorder with autosomal dominant inheritance. In most cases, mutations occur in one of three genes – ENG, ALK1 or SMAD4 – that encode components of the TGF-β signalling pathway that is involved in blood vessel development. Dilatation of capillaries and small arterioles produces characteristic small, red spots that blanch on pressure in the skin and mucous membranes, particularly the nose and gastrointestinal tract. Recurrent epistaxis and chronic gastrointestinal bleeding are the major problems that cause chronic iron deficiency anaemia. Vascular malformations also occur in pulmonary, hepatic cerebral and spinal vasculature.

Easy bruising syndrome
This is a common benign disorder occurring in otherwise healthy women. It is characterized by bruises on the arms, legs and trunk with minor trauma, possibly because of skin vessel fragility. It may give rise to the suspicion of a serious bleeding disorder.

Senile purpura and purpura due to steroids
These are both due to atrophy of the vascular supporting tissue.

Purpura due to infections
This is mainly caused by damage to the vascular endothelium. The rash of meningococcal septicaemia is particularly characteristic (see pp. 281–282).

Henoch–Schönlein purpura
This occurs mainly in children (see p. 748). It is a type III hypersensitivity (immune complex) reaction that is often preceded by an acute upper respiratory tract infection. Purpura is seen mainly on the legs and buttocks. Abdominal pain, arthritis, haematuria and glomerulonephritis also occur. Recovery is usually spontaneous but some patients develop renal failure.

Episodes of inexplicable bleeding or bruising
These may represent abuse, either self-inflicted or caused by others. These various forms of artificial or factitious purpura may be expressions of emotional or psychiatric disturbances.

Platelet Disorders
Bleeding due to thrombocytopenia or abnormal platelet function is characterized by purpura and bleeding from mucous membranes. Bleeding is uncommon with platelet counts >50 × 10^9/L, and severe spontaneous bleeding is unusual with platelet counts >20 × 10^9/L (Box

**Thrombocytopenia**

This is caused by reduced platelet production in the bone marrow, excessive peripheral destruction of platelets or sequestration in an enlarged spleen (*Box 16.30*). The underlying cause may be revealed by history and examination but a bone marrow examination will show whether the numbers of megakaryocytes are reduced, normal or increased, and will provide essential information on morphology. Specific laboratory tests may be useful to confirm the presence of such conditions as paroxysmal nocturnal haemoglobinuria (PNH) or SLE.

**Box 16.30**

**Causes of thrombocytopenia**

**Impaired production**

- Selective megakaryocyte depression:
  - Rare congenital defects
  - Drugs, chemicals and viruses
- As part of a general bone marrow failure:
  - Cytotoxic drugs and chemicals
  - Radiation
  - Megaloblastic anaemia
  - Leukaemia
- Myelodysplastic syndromes
- Myeloma
• Myelofibrosis
• Solid tumour infiltration
• Aplastic anaemia
• HIV infection

**Excessive destruction or increased consumption**

• Immune
• Autoimmune – immune thrombocytopenic purpura
• Drug-induced, e.g. GP IIb/IIIa inhibitors, penicillins, thiazides
• Secondary immune (systemic lupus erythematosus, chronic lymphocytic leukaemia, viruses, drugs, e.g. heparin, bivalirudin)
• Alloimmune neonatal thrombocytopenia
• Post-transfusion purpura
• Disseminated intravascular coagulation
• Thrombotic thrombocytopenic purpura

**Sequestration**

• Splenomegaly
• Hypersplenism

**Dilutional**

• Massive transfusion

In patients with thrombocytopenia due to failure of production, no specific treatment may be necessary but the underlying condition should be treated if possible. Where the platelet count is very low or the risk of bleeding is very high, then platelet transfusion is indicated.

**Immune thrombocytopenic purpura**

In immune thrombocytopenic purpura (ITP), thrombocytopenia is due to immune destruction of platelets. The antibody-coated platelets are removed following binding to Fc receptors on macrophages.

**ITP in children**

This occurs most commonly in the 2–6-year age group. ITP has an acute onset with mucocutaneous bleeding and there may be a history of a recent viral infection, including varicella zoster or measles. Although bleeding may be severe, life-threatening haemorrhage is rare (approximately 1%). Bone marrow examination is not usually performed unless treatment becomes necessary on clinical grounds.
**ITP in adults**

The presentation is usually less acute than in children. ITP is characteristically seen in women and may be associated with other autoimmune disorders such as SLE, thyroid disease and autoimmune haemolytic anaemia (*Evans syndrome*). It is also seen in patients with chronic lymphocytic leukaemia and solid tumours, and after infections with viruses such as HIV. Platelet autoantibodies are detected in about 60–70% of patients, and are presumed to be present, although not detectable, in the remaining patients; the antibodies often have specificity for platelet membrane glycoproteins IIb/IIIa and/or Ib.

**Clinical features**

Major haemorrhage is rare and is seen only in patients with severe thrombocytopenia. Easy bruising, purpura, epistaxis and menorrhagia are common. Physical examination is normal except for evidence of bleeding. Splenomegaly is rare.

**Investigations**

The only blood count abnormality is thrombocytopenia. Normal or increased numbers of megakaryocytes are found in the bone marrow (if examination is performed), which is otherwise normal. The detection of platelet autoantibodies is not essential for confirmation of the diagnosis, which often depends on exclusion of other causes of excessive destruction of platelets.

**Management**

**Children**

Children do not usually require treatment. Where treatment is necessary on clinical grounds, corticosteroids, intravenous immunoglobulin (i.v. IgG) and anti-D are effective; i.v. IgG is effective in more than 80% of children and raises the count more rapidly than steroids. Treatment should be reserved for very serious bleeding or urgent surgery. Chronic ITP is rare and requires specialist management.

**Adults**

Patients with platelet counts $>30 \times 10^9/L$ generally require no treatment unless they are about to undergo a surgical procedure. Patients with even lower platelet counts may not require treatment unless they have spontaneous bruising or bleeding.

**First-line therapy**

This consists of oral corticosteroids 1 mg/kg body weight. Approximately 66% will respond to prednisolone but relapse is common when the dose is reduced. Only 33% of patients can expect a long-term response, and long-term remission is seen in only 10–20% of patients after
stopping prednisolone. Patients who fail to respond to corticosteroids or require high doses to maintain a safe platelet count should be considered for splenectomy.

Intravenous immunoglobulin (i.v. IgG) is effective. It raises the platelet count in 75%, and in 50% the platelet count will normalize. Responses are only transient (3–4 weeks) with little evidence of any lasting effect. However, i.v. IgG is very useful where a rapid rise in platelet count is desired: for example, before surgery.

**Second-line therapy**

Therapies include:

- **Splenectomy**, to which the majority of patients respond; two-thirds will achieve a normal platelet count. About 50% of patients who do not have a complete response can still expect some improvement in the platelet count.
- **Rituximab (anti-CD20)**, to which about 60% of patients respond, although only 15–20% have longlasting responses.
- **Thrombopoietin receptor agonists**, such as romiplostim and eltrombopag, which drive increased platelet production. They have been shown to increase platelet counts significantly in ITP on a long-term basis and are approved drugs for refractory ITP.
- **Platelet transfusions**, reserved for intracranial or other extreme haemorrhage, where emergency splenectomy may be justified.

---

### Other immune thrombocytopenias

**Drugs**

Drugs cause immune thrombocytopenia by the same mechanisms as those described for drug-induced immune haemolytic anaemia (see p. 546). The same drugs can be responsible for immune haemolytic anaemia, thrombocytopenia or neutropenia in different patients.

**Heparin-induced thrombocytopenia**

See pages 578–581.

**Neonatal alloimmune thrombocytopenia**

This condition is due to fetomaternal incompatibility for platelet-specific antigens, usually for human platelet alloantigen 1a (HPA-1a), and is the platelet equivalent of haemolytic disease of the newborn. The mother is HPA-1a-negative and produces antibodies that destroy the HPA-1a-positive fetal platelets. Thrombocytopenia is self-limiting after delivery, but platelet transfusions may be required initially to prevent or treat bleeding associated with severe thrombocytopenia; platelets are prepared from HPA-1a-negative volunteers or the mother herself. Severe bleeding, such as intracranial haemorrhage, may also occur in utero.

Antenatal treatment of the mother – usually with high-dose IgG and/or steroids – has been effective in preventing haemorrhage in severely affected cases.
Post-transfusion purpura

Post-transfusion purpura (PTP) is rare, occurring 7–10 days after a transfusion of platelet-containing blood components, usually red cells. PTP is associated with a platelet-specific alloantibody, usually anti-HPA-1a in an HPA-1a-negative individual. PTP always occurs in patients who have previously been immunized, either by blood transfusion or by pregnancy – hence it is more common in women. The cause of the destruction of the patient's own platelets is not well understood, but they may be destroyed as ‘bystanders’ during the acute immune response to HPA-1a. PTP is self-limiting, but intravenous IgG or plasma exchange may be required in severe bleeding.

Thrombotic thrombocytopenic purpura

Thrombotic thrombocytopenic purpura (TTP; see p. 750) is a rare but very serious condition, in which platelet consumption leads to profound thrombocytopenia. There is a characteristic symptom complex of florid purpura, fever, fluctuating cerebral dysfunction and microangiopathic haemolytic anaemia with red cell fragmentation, often accompanied by acute kidney injury. The coagulation screen is usually normal but lactate dehydrogenase (LDH) levels are markedly raised as a result of haemolysis. TTP arises due to endothelial damage and microvascular thrombosis. This occurs due to a reduction in ADAMTS-13 (a disintegrin-like and metalloproteinase domain with thrombospondin-type motifs), a protease that is normally responsible for regulating the size of VWF. ADAMTS-13 is needed to break down ultra-large von Willebrand factor multimers (UL VWFMs) into smaller, haemostatically active fragments that interact with platelets. Reduction in ADAMTS-13 results in the adhesion and aggregation of platelets to UL VWFMs and multiorgan microthrombi. In most sporadic cases, there is a true deficiency of the ADAMTS-13, associated with antibodies to ADAMTS-13. In some congenital cases, the deficiency is due to mutations in the ADAMTS-13 gene. Secondary causes of acute TTP include pregnancy, oral contraceptives, SLE, infection and drug treatment, including the use of ticlopidine and clopidogrel. Such cases may have a variable ADAMTS-13 activity at presentation, and may or may not have associated antibodies to ADAMTS-13.

Management

Plasma exchange is the mainstay of treatment. It provides a source of ADAMTS-13 and removes associated autoantibody in acute TTP. Cryoprecipitate and solvent-detergent FFP both contain ADAMTS-13. Pulsed intravenous methylprednisolone is given acutely; increasingly, rituximab is also a primary treatment of choice. Disease activity is monitored by measuring the platelet count and serum LDH. Platelet concentrates are contraindicated. The untreated condition has a mortality of up to 90% but modern management has reduced this figure to about 10%. Recurrent and relapsing TTP occurs, often associated with a persistent lack of ADAMTS-13. In secondary TTP cases, identifiable precipitating drugs should be stopped. Caplacizumab is a single-variable-domain immunoglobulin directed to the A1 region of the
von Willebrand factor. It inhibits the VWF interaction with glycoprotein 1b and has shown short-term benefit in a phase 2 study.

**Platelet function disorders**

Platelet function disorders (Box 16.31) are usually associated with excessive bruising and bleeding and, in some of the acquired forms, with thrombosis. The platelet count is often normal and the bleeding time is prolonged. The rare inherited defects of platelet function require more detailed investigations, such as platelet aggregation studies and factor VIII : C and VWF assays, if von Willebrand's disease is suspected.

---

**Box 16.31**

**Inherited and acquired types of platelet dysfunction**

**Inherited**

- **Glanzmann's thrombasthenia** – lack of platelet membrane glycoprotein IIb–IIIa complex, resulting in defective fibrinogen binding and failure of platelet aggregation
- **Bernard–Soulier syndrome** – lack of platelet membrane glycoprotein Ib–IX–V complex (the binding site for VWF), causing failure of platelet adhesion and moderate thrombocytopenia
- **Storage pool disease** – lack of the storage pool of platelet dense bodies, causing poor platelet function

**Acquired**

- Myeloproliferative disorders
- Renal and liver disease
- Paraproteinaemias
- Drug-induced, such as with NSAIDs (aspirin) or other platelet inhibitory drugs

---

If there is serious bleeding or if the patient is about to undergo surgery, drugs with antiplatelet activity should be withdrawn and any underlying condition should be corrected if possible.

Bleeding in renal disease is multifactorial, although platelet dysfunction is a major component. The degree of the defect of haemostasis is broadly proportional to the plasma urea concentration – platelet function is impaired by urea, guanidinosuccinic acid and other phenolic metabolites that accumulate in chronic kidney disease. Dialysis partially corrects platelet function. The haematocrit should be increased to >0.30 and the use of desmopressin may be helpful. Platelet transfusions may be required if these measures are unsuccessful or if the risk of bleeding is high.
Thrombocytosis

The platelet count may rise above $400 \times 10^9/L$ as a result of:

- splenectomy
- malignant disease
- inflammatory disorders, such as rheumatoid arthritis and inflammatory bowel disease
- major surgery and post haemorrhage
- myeloproliferative disorders
- iron deficiency.

Thus, thrombocytosis is part of the acute-phase reaction, although platelet numbers are also elevated following splenectomy because of the loss of a major site of platelet destruction.

**Essential thrombocythaemia**, a myeloproliferative neoplasm that is described on page 550, and other myeloproliferative conditions such as polycythaemia vera, myelofibrosis and chronic myeloid leukaemia may also be associated with a high platelet count.

A persistently elevated platelet count can lead to arterial or venous thrombosis. It is usual to treat the underlying cause of the thrombocytosis but sometimes a small dose of aspirin (75 mg) is also given. In myeloproliferative diseases, the primary risk is thrombosis and specific action is often taken to reduce the platelet count, usually with hydroxycarbamide (hydroxyurea). Paradoxically, there is also a risk of abnormal bleeding if the platelet count is very high.

Inherited Coagulation Disorders

Inherited coagulation disorders are uncommon and usually involve deficiency of one factor only. Acquired coagulation disorders occur more frequently and almost always involve several coagulation factors (see pp. 573–575).

In inherited coagulation disorders, deficiencies of all factors have been described. Those
leading to abnormal bleeding are rare, apart from haemophilia A (factor VIII deficiency), haemophilia B (factor IX deficiency) and von Willebrand's disease.

**Haemophilia A**

This is due to a lack of factor VIII. VWF is normal in haemophilia (*Fig. 16.37*). The prevalence of haemophilia A is about 1 in 5000 of the male population. It is inherited as an X-linked disorder. If a female carrier has a son, he has a 50% chance of having haemophilia; a daughter has a 50% chance of being a carrier. All daughters of men with haemophilia are carriers and the sons are normal.

![FIGURE 16.37 Synthesis of factor VIII and von Willebrand factor (VWF) in inherited coagulation disorders. A. Normal factor VIII synthesis. B. Haemophilia A, showing defective synthesis of factor VIIIc. C. Von Willebrand's disease, showing reduced synthesis of VWF.](image)

Although a large number of different genetic defects have been found in the factor VIII gene, a common gene inversion in intron 22 is causative in approximately 50% of families with severe disease. There is a high mutation rate, one-third of cases being apparently sporadic with no family history of haemophilia.

**Clinical features and investigations**

The clinical features depend on the level of factor VIII. The normal level of factor VIII is 50–150 IU/dL.

- **Levels of <1 IU/dL (severe haemophilia)** are associated with frequent spontaneous bleeding from early life, typically into joints and muscles. Without adequate treatment, such recurrent bleeding into joints leads to crippling joint deformity.
- **Levels of 1–5 IU/dL (moderate haemophilia)** are associated with severe bleeding following injury and occasional spontaneous bleeds.
Levels of >5 IU/dL (mild haemophilia) are usually associated with bleeding only after injury or surgery. Diagnosis in this group can often be delayed until quite late in life.

With treatment, life expectancy today is very good. The most common causes of death in people with haemophilia are cancer and heart disease, as for the general population, rather than bleeding, although cerebral haemorrhage is much more frequent than in the general population. The main laboratory features of haemophilia A are shown in Box 16.32. The abnormal findings are a prolonged APTT and a reduced level of factor VIII. The PT, bleeding time and VWF level are normal.

### Management

Bleeding is treated by administration of *factor VIII concentrate* by intravenous infusion to achieve normalization of levels. Factor VIII concentrate is available as plasma-derived and recombinant products. Recombinant products are the treatment of choice but economic constraints often limit availability, particularly in developing countries.

Many patients with severe haemophilia treat themselves at home with regular factor VIII infusions three or more times per week, to prevent recurrent bleeding into joints and subsequent joint damage. Such ‘prophylaxis’ is usually started in early childhood (around 2 years of age). Otherwise, patients at home may treat as and when they have a bleed: ‘on-demand’ treatment.

For surgery, levels should be kept to normal until healing has occurred; as factor VIII has a half-life of 12 hours, it is often administered twice daily to maintain the required level.

New bioengineered factor VIII products are now becoming available that have half lives approximately 1.5 times that of base factor VIII.

For those with milder haemophilia, *synthetic vasopressin* (desmopressin, an analogue of vasopressin) – intravenous, subcutaneous or intranasal – produces a 3–5-fold rise in factor VIII and VWF levels. It is very useful in patients with a baseline level of factor VIII >10 IU/dL. It avoids the complications associated with blood products and is useful for
treatinig and preventing bleeding in mild haemophilia.

People with haemophilia should be registered at comprehensive care centres (CCC), which take responsibility for their full medical care, including social and psychological support.

### Complications

Up to 30% of people with severe haemophilia will, during their lifetime, develop antibodies to factor VIII that inhibit its action. Such inhibitors usually develop after the first few treatment doses of factor VIII. Inhibitors are relatively rare in moderate and mild haemophilia, and are often associated with specific molecular defects.

Management of inhibitor patients is very difficult, as infused factor VIII is rapidly inactivated. Acute bleeding events require treatment with agents that can bypass factor VIII, such as recombinant factor VIIa or activated prothrombin complex concentrates.

In those recently identified as having developed an inhibitor, the long-term aim is to eradicate the inhibitory antibody. This is done using immune tolerance induction strategies, sometimes with additional immunosuppression. This is successful in around 80% of cases.

Although a historical legacy of plasma-derived concentrates, the risk of viral transmission has been virtually eliminated (see p. 558). Although many died as a consequence of HIV and hepatitis C infection, a considerable number of patients remain that have HIV and/or hepatitis C infection.

### Carrier detection and antenatal diagnosis

Owing to Lyonization early in embryonic life (i.e. random inactivation of one chromosome; see p. 109), some female carriers may have low levels of factor VIII while others will have normal levels. Carrier detection is, therefore, definitively carried out using molecular genetic testing/mutation analysis. Antenatal diagnosis may be carried out by molecular analysis of chorionic villus biopsy at 11–12 weeks' gestation if selective termination is being considered, or by third trimester amniocentesis if not.

### Haemophilia B (Christmas disease)

Haemophilia B is caused by a deficiency of factor IX. The inheritance and clinical features are identical to those of haemophilia A, but the incidence is only about 1 in 30,000 males. It has been identified as the type of haemophilia affecting the Russian royal family. The half-life of factor IX is longer at 18 hours. Haemophilia B is treated with factor IX concentrates, recombinant factor IX being generally available, and prophylactic doses are given twice a week. New bioengineered factor IX concentrates have half-lives 3–5 times that of regular factor IX. Desmopressin is ineffective. Gene therapy has shown promise in potential management of severe haemophilia B.

### Von Willebrand's disease
In von Willebrand's disease (VWD), there is defective platelet function, as well as factor VIII deficiency. Both these defects are due to a deficiency or abnormality of VWF (Fig. 16.37). VWF plays a role in platelet adhesion to damaged subendothelium, as well as stabilizing factor VIII in plasma (see p. 565).

The VWF gene is located on chromosome 12 and numerous mutations of the gene have been identified. VWD has been classified into three types:

- **Type 1** is partial quantitative deficiency of VWF and significant type 1 VWD is usually inherited as an autosomal dominant.
- **Type 2** is due to a qualitative abnormality of VWF, and it too is usually inherited as an autosomal dominant.
- **Type 3** is recessively inherited and patients have virtually complete deficiency of VWF. Their parents are often phenotypically normal.

Many subtypes of VWD are described, particularly type 2 variants, which reflect the specific qualitative changes in the VWF protein.

### Clinical features

These are very variable. Type 1 and type 2 patients usually have relatively mild clinical features. Bleeding follows minor trauma or surgery, and epistaxis and menorrhagia often occur. Haemarthroses are rare. Type 3 patients have more severe bleeding but rarely experience the joint and muscle bleeds seen in haemophilia A.

Characteristic laboratory findings are shown in Box 16.32. These also include defective platelet aggregation with ristocetin.

### Management

Management depends on the severity of the condition and may be similar to that of mild haemophilia, including the use of desmopressin where possible. Some plasma-derived factor VIII concentrates contain intact VWF and are the current mainstay of replacement therapy. Recombinant VWF is in late-stage clinical trial. These specific products are used to treat bleeding or to cover surgery in patients who require replacement therapy, such as those with type 3 (severe) VWD and those who do not respond adequately to desmopressin. Cryoprecipitate can be used as a source of VWF but should be avoided if possible, since it is not virus-inactivated.

### Further reading

Acquired Coagulation Disorders

**Vitamin K deficiency**

Vitamin K is necessary for the γ-carboxylation of glutamic acid residues on coagulation factors II, VII, IX and X, and on proteins C and S. Without it, these factors cannot bind calcium.

Deficiency of vitamin K (see also p. 197) may be due to:

- **inadequate stores**, as in haemorrhagic disease of the newborn and severe malnutrition, especially when combined with antibiotic treatment (see p. 197)
- **malabsorption of vitamin K**, a fat-soluble vitamin, which occurs in cholestatic jaundice owing to the lack of intraluminal bile salts
- **oral anticoagulant drugs**, many of which are vitamin K antagonists.

The PT and APTT are prolonged *(Box 16.32)* and there may be bruising, haematuria and gastrointestinal or cerebral bleeding. Minor bleeding is treated with phytonadione (vitamin K₃) 10 mg intravenously. Some correction of the PT is usual within 6 hours but it may not return to normal for 2 days.

Newborn babies have low levels of vitamin K and this may cause minor bleeding in the first week of life *(classical haemorrhagic disease of the newborn)*. Vitamin K deficiency also causes *late haemorrhagic disease of the newborn*, which occurs 2–26 weeks after birth and results in severe bleeding such as intracranial haemorrhage. Most infants with these syndromes have been exclusively breast-fed, and both conditions are prevented by administering 1 mg i.m. vitamin K to all neonates (see p. 197). Concerns about the safety of this are unfounded.

**Liver disease**

Liver disease may result in a number of defects in haemostasis:

- **Vitamin K deficiency**. This occurs owing to intrahepatic or extrahepatic cholestasis.
- **Reduced synthesis**. Reduced synthesis of coagulation factors may be the result of severe hepatocellular damage. The use of vitamin K does not improve the results of abnormal coagulation tests, but it is generally given to ensure that a treatable cause of failure of haemostasis has not been missed.
- **Thrombocytopenia**. This results from hypersplenism due to splenomegaly associated with portal hypertension, or from folic acid deficiency.
- **Functional abnormalities**. Functional abnormalities of platelets and fibrinogen are found in many patients with liver failure.
- **Disseminated intravascular coagulation**. DIC (see below) occurs in acute hepatic failure.

**Disseminated intravascular coagulation**

Disseminated intravascular coagulation (DIC) never occurs in isolation. Recognition that the
patient has a clinical disorder (Box 16.33) that may result in DIC is the key to investigation and management. DIC arises because of systemic activation of coagulation either by release of procoagulant material, such as tissue factor, or via cytokine pathways as part of the inflammatory response. Such systemic activation leads to widespread generation of fibrin and deposition in blood vessels, leading to thrombosis and multiorgan failure. Due to the widespread coagulation activation there is consumption of platelets and coagulation factors and secondary activation of fibrinolysis, leading to production of fibrin degradation products (FDPs and D-dimer). These further contribute to the coagulation defect by inhibiting fibrin polymerization (Fig. 16.38). The consequences of these changes are a mixture of initial thrombosis, followed by a bleeding tendency due to consumption of coagulation factors and dysregulated fibrinolytic activation.

---

Box 16.33

Causes of disseminated intravascular coagulation

- Malignant disease
- Septicaemia (e.g. Gram-negative, including meningococcal)
- Haemolytic transfusion reactions
- Obstetric causes (e.g. abruptio placentae, amniotic fluid embolism, pre-eclampsia)
- Trauma, burns, surgery
- Other infections (e.g. falciparum malaria)
- Liver disease
- Snake bite
Clinical features

The underlying disorder is usually obvious. The patient is often acutely ill and shocked. The clinical presentation of DIC varies from no bleeding at all to profound haemostatic failure with widespread haemorrhage. Bleeding may occur from the mouth, nose and venepuncture sites, and there may be widespread ecchymoses.

Thrombotic events occur as a result of vessel occlusion by fibrin and platelets. Any organ may be involved but the skin, brain and kidneys are most often affected.

Investigations

The diagnosis needs to encompass both clinical and laboratory aspects. It is often suggested by the underlying condition of the patient. If the patient has an underlying disorder known to be compatible with overt DIC, the ISTH scoring system is a useful diagnostic tool. This scoring system provides an objective assessment (Box 16.34).

<td>&lt;1 g/L = 1</td>
</tr>
</tbody>
</table>

**Calculate score:**

>5 compatible with overt DIC: repeat score daily,

<5 suggestive of non-overt DIC: repeat next 1–2 days

In severe cases with haemorrhage:

- The PT, APTT and TT are usually very prolonged and the fibrinogen level is markedly reduced.
- High levels of FDPs, including D-dimer, are found, owing to the intense fibrinolytic activity stimulated by the presence of fibrin in the circulation.
- There is severe thrombocytopenia.
- The blood film may show fragmented red blood cells.

**Management**

The cornerstone of management is treatment of the underlying condition and intensive support to manage hypoxia, acidosis and organ failure. In those that are not bleeding, this is often all that is necessary. Transfusions of platelet concentrates, FFP, cryoprecipitate and red cell concentrates is indicated in patients who are bleeding or to cover interventions. Transfusion of blood components on the basis of coagulation tests alone is not required. Inhibitors of fibrinolysis, such as tranexamic acid, should not be used in DIC, as dangerous fibrin deposition may result. In those cases with a dominant thrombotic component, the cautious use of unfractionated heparin should be considered. In critically ill, non-bleeding patients with DIC, thromboprophylactic doses of heparin are recommended.

**Excessive fibrinolysis**

Excessive fibrinolysis occurs in certain malignancies, such as acute promyelocytic leukaemia, and also during surgery involving tumours of the prostate, breast, pancreas and uterus owing to release of tissue plasminogen activators.

**Primary hyperfibrinolysis** is very rare but activation of fibrinolysis occurs in DIC as a
secondary event in response to intravascular deposition of fibrin.

The clinical picture is similar to that of DIC, with widespread bleeding. Laboratory investigations are also similar, with a prolonged PT, APTT and TT, a low fibrinogen level and increased FDPs, although fragmented red cells and thrombocytopenia are not seen because disseminated coagulation with widespread fibrin deposition is not present.

If the diagnosis is certain, fibrinolytic inhibitors, such as tranexamic acid, can be given but evidence for efficacy is lacking.

### Massive transfusion

Few platelets and reduced levels of clotting factors are found in stored blood, although there are adequate amounts of the other coagulation factors. During massive transfusion (defined as transfusion of a volume of blood equal to the patient's own blood volume within 24 hours, e.g. >10 units in an adult), the platelet count and PT and APTT should be checked at intervals.

Transfusion of platelet concentrates, FFP and cryoprecipitate should be given if thrombocytopenia or defective coagulation is thought to be contributing to continued blood loss. Other problems of massive transfusion are described on page 1157.

### Inhibitors of coagulation

**Factor VIII autoantibodies** arise occasionally in patients without haemophilia but with autoimmune disorders such as SLE, in elderly patients, with malignant disease and sometimes after childbirth. There can be severe bleeding. Immediate bleeding problems are managed with concentrates that bypass factor VIII activity (e.g. recombinant factor VIIa or activated prothrombin complex concentrates; see p. 572). Longer-term therapy is to eliminate the autoantibody using immunosuppression, such as steroids, cyclophosphamide or rituximab.

**Lupus anticoagulant antibodies** (see p. 695) are autoantibodies directed against phospholipids (antiphospholipid antibodies) and lead to prolongation of phospholipid-dependent coagulation tests, particularly the APTT; they do not inhibit coagulation factor activity.

### Further reading

**Thrombosis**
A thrombus is defined as a solid mass formed in the circulation from the constituents of the blood during life. Fragments of thrombi (emboli) may break off and block vessels downstream. Thromboembolic disease is much more common than abnormal bleeding; nearly half of adult deaths in England and Wales are due to coronary artery thrombosis, cerebral artery thrombosis or pulmonary embolism.

A thrombus results from a complex series of events involving coagulation factors, platelets, red blood cells and the vessel wall.

### Arterial thrombosis

This usually occurs in association with atheroma, which tends to form at areas of turbulent blood flow, such as the bifurcation of arteries. Platelets adhere to the damaged vascular endothelium and aggregate in response to ADP and TXA₂ to form a ‘white thrombus’. The growth of the platelet thrombus is limited at its margins by PGI₂ and nitric oxide (NO). Plaque rupture leads to the exposure of blood containing factor VIIa to tissue factor within the plaque, which may trigger blood coagulation and lead to thrombus formation. This results in complete occlusion of the vessel or embolization that produces distal obstruction. The risk factors for arterial thrombosis are related to the development of atherosclerosis (see p. 992).

Arterial thrombi may also form in the heart, as mural thrombi in the left ventricle after myocardial infarction, in the left atrium in mitral valve disease, or on the surfaces of prosthetic valves.

### Venous thrombosis

Unlike arterial thrombosis, venous thrombosis often occurs in normal vessels. Major causes are stasis and hypercoagulability. The majority of venous thrombi occur in the deep veins of the leg, originating around the valves as ‘red thrombi’ consisting mainly of red cells and fibrin. The propagating thrombus is formed of fibrin and platelets, and is particularly liable to embolize. Chronic venous obstruction following thrombosis in the deep veins of the leg frequently results in a permanently swollen limb and may lead to ulceration (post-phlebitic syndrome).

Risk factors for venous thrombosis are shown in Box 16.35. Venous thrombosis may occur with changes in blood cells, such as polycythaemia and thrombocythaemia, and with coagulation abnormalities (thrombophilia; see below).

---

**Box 16.35**

**Risk factors for venous thromboembolism (VTE)**

**Patient factors**

- Age
• Body mass index (BMI) >30 kg/m²
• Varicose veins
• Continuous travel >3 h in preceding 4 weeks
• Immobility (bed rest ≥3 days)
• Pregnancy and puerperium
• Previous deep vein thrombosis or pulmonary embolism
• Thrombophilia
  – Antithrombin deficiency
  – Protein C or S deficiency
  – Factor V Leiden
  – Resistance to activated protein C (caused by factor V Leiden variant)
  – Prothrombin gene variant
  – Hyperhomocystinaemia
  – Antiphospholipid antibody/lupus anticoagulant
• Oestrogen therapy, including hormone replacement therapy (HRT)
• Dysfibrinogenaemia
• Plasminogen deficiency

**Disease or surgical procedure**
• Trauma or surgery, especially of pelvis, hip or lower limb
• Malignancy
• Cardiac or respiratory failure
• Recent myocardial infarction or stroke
• Acute medical illness/severe infection
• Inflammatory bowel disease
• Behçet's disease
• Nephrotic syndrome
• Myeloproliferative disorders
• Paroxysmal nocturnal haemoglobinuria
• Paraproteinaemia
• Sickle cell anaemia
• Central venous catheter *in situ*

The clinical features and diagnosis of venous thrombosis are discussed on page 1055.

**Thrombophilia**
Thrombophilia is a term describing inherited or acquired defects of haemostasis leading to a
predisposition to venous or arterial thrombosis. It occurs in people with:

- recurrent venous thrombosis
- venous thrombosis for the first time under the age of 40 years
- an unusual venous thrombosis, such as mesenteric or cerebral vein thrombosis
- unexplained neonatal thrombosis
- recurrent miscarriages
- arterial thrombosis in the absence of arterial disease.

**Coagulation abnormalities**

**Factor V Leiden**

Factor V Leiden differs from normal factor V by a single nucleotide substitution (Arg506Gln). This variation makes factor V less likely to be cleaved by activated protein C. As factor V is a co-factor for thrombin generation (see *Fig. 16.32*), impaired inactivation by activated protein C (see *Fig. 16.33*) results in a tendency to thrombosis. Factor V Leiden is found in 3–5% of healthy individuals in the Western world and in about 20–30% of patients with venous thrombosis. It is very rare in Chinese populations.

Factor V Leiden acts synergistically with other acquired thrombosis risk factors: for example, in those who are taking oral contraceptive pills or are pregnant. Thrombosis risk rises 35-fold in those on a combined oral contraceptive pill, although the absolute risk for thrombosis remains at significantly below 0.5% per year for any single individual.

**Prothrombin variant**

A mutation in the 3’ untranslated region of the prothrombin gene has been described (G20210A). This variant is associated with elevated levels of prothrombin and a 2–3-fold increase in the risk of venous thrombosis. There is an interaction with factor V Leiden and contraceptive pill use or pregnancy. The prevalence is 2% in Caucasian populations, and 6% in unselected patients with thrombosis.

**Antithrombin deficiency**

This deficiency can be inherited as an autosomal dominant. Many variations have been described that lead to a conformational change in the protein. It can also be acquired following trauma, with major surgery and with the contraceptive pill. Low levels are also seen in severe proteinuria (e.g. the nephrotic syndrome). Recurrent thrombotic episodes occur, starting at a young age in the inherited variety. Patients may be relatively resistant to heparin, as antithrombin is required for its action. Antithrombin concentrates are available.

**Protein C and S deficiencies**

These autosomal dominant conditions result in an increased risk of venous thrombosis, often before the age of 40 years. Homozygous protein C or S deficiency causes neonatal purpura
fulminans, which is fatal without immediate replacement therapy. Plasma-derived protein C concentrate is available.

**Antiphospholipid antibody**

See page 695.

**Homocysteine**

When elevated, this amino acid is associated with both arterial thrombosis and venous thromboembolism. The mechanism of vascular damage is unclear. Folate, vitamin B\textsubscript{12} and vitamin B\textsubscript{6} supplementation is often helpful in reducing levels.

### Investigations

**Haemostatic screening test**

- *Full blood count*, including platelet count.
- *Coagulation screen*, including a fibrinogen level. These tests will detect erythrocytosis, thrombocytosis, dysfibrinogenaemia and the possible presence of a lupus anticoagulant.

**Testing for specific causes of thrombophilia**

- *Assays* for naturally occurring anticoagulants, such as antithrombin, protein C and protein S.
- *Assay* for activated protein C resistance and molecular testing for factor V Leiden and the prothrombin variant.
- *Screening for a coagulation factor inhibitor*, including a lupus anticoagulant (and anticardiolipin antibodies) (see p. 695).

### Prevention and treatment of arterial thrombosis

Attempts to prevent or reduce arterial thrombosis are directed mainly at minimizing factors predisposing to atherosclerosis. Treatment of established arterial thrombosis includes the use of antiplatelet drugs and thrombolytic therapy.

**Antiplatelet drugs**

Platelet activation at the site of vascular damage is crucial to the development of arterial thrombosis, and this can be altered by the following drugs (Box 16.36):

- *Aspirin* irreversibly inhibits the enzyme cyclo-oxygenase (COX), resulting in reduced platelet production of TXA\textsubscript{2} (see Fig. 24.30). At the low doses used in cardiovascular disease prevention or treatment, there is selective inhibition of the isoform COX-1, found within platelets. This inhibition cannot be repaired and is effective for the life of the circulating platelet, which is about 1 week. It has been suggested that there may be significant
individual variability in the response to aspirin, although there is no clear reason for this. The term ‘aspirin resistance’ has been loosely applied when the clinical effects of aspirin are less than expected. No large body of clinical trial data is specifically available to correlate clinical events and laboratory findings with respect to aspirin response and so it is difficult to determine whether the breakthrough events experienced by patients treated with aspirin represent aspirin resistance or are related to more mundane issues, such as aspirin dose, drug interactions or drug non-compliance.

• **Dipyridamole**, which inhibits platelet phosphodiesterase, causing an increase in cyclic AMP with potentiation of the action of PGI₂, has been widely used as an antithrombotic agent but there is little evidence that it is effective.

• **Clopidogrel** irreversibly blockades the ADP (P2Y₁₂) receptor on platelet cell membranes, so affecting the ADP-dependent activation of the glycoprotein IIb/IIIa complex. It is similar to ticlopidine but has fewer side-effects. Trials support its use in acute coronary syndromes (see p. 999).

• **Prasugrel**, a novel thienopyridine, is like clopidogrel and is licensed for use in acute coronary syndromes (see p. 999).

• **Ticagrelor** is also a P2Y₁₂ platelet ADP receptor blocker but, unlike clopidogrel, is reversible and is not a prodrug, so having a faster onset of action than greater degree of platelet inhibition and consistency of effect. It is licensed for use in acute coronary syndromes.

• **Glycoprotein IIb/IIIa receptor antagonists** block the receptor on the platelet for fibrinogen and VWF (Fig. 16.39). Three classes have been described:
  – murine–human chimeric antibodies (e.g. abciximab)
  – synthetic peptides (e.g. eptifibatide)
  – synthetic non-peptides (e.g. tirofiban).

They have been used as an adjunct in invasive coronary artery intervention and as primary medical therapy in coronary heart disease. Excessive bleeding has been a problem.

• **Epoprostenol** is a prostacyclin that is used to inhibit platelet aggregation during renal dialysis (with or without heparin), and also in primary pulmonary hypertension.

• **Terutroban** is a thromboxane prostaglandin receptor antagonist that is being trialled in secondary prevention of cerebrovascular and cardiovascular disease as an alternative to aspirin.

---

### Box 16.36

**Drugs used in the treatment of thrombotic disorders**

**Antiplatelet**

• Aspirin
- Thromboxane synthase, e.g. dipyridamole
- GP IIb/IIIa inhibitors, e.g. abciximab, eptifibatide, tirofiban
- ADP receptor antagonists/P2Y$_{12}$ inhibitors, e.g. clopidogrel, prasugrel, ticagrelor
- Epoprostenol
- Thromboxane prostaglandin receptor antagonists, e.g. terutroban

**Thrombolytic**
- Streptokinase
- Tissue-type plasminogen activator (t-PA or alteplase)
- Reteplase (r-PA)
- Tenecteplase (TNK-tPA)

**Anticoagulant**
- Heparin:
  - Unfractionated (or standard)
  - Low-molecular-weight
- Hirudin-like, e.g. bivalirudin
- Fondaparinux
- Warfarin
- Xa inhibitors, e.g. apixaban, rivaroxaban, otamixaban, edoxaban, betrixaban
- Direct thrombin inhibitors, e.g. dabigatran

The indications for and results of antiplatelet therapy are discussed in the appropriate sections (see p. 999).

**Thrombolytic therapy**
**Streptokinase**

Streptokinase is a purified fraction of the filtrate obtained from cultures of haemolytic streptococci. It forms a complex with plasminogen, resulting in a conformational change, which activates other plasminogen molecules to form plasmin. Streptokinase is antigenic and the development of streptococcal antibodies precludes repeated use. Activation of plasminogen is indiscriminate, so that both fibrin in clots and free fibrinogen are lysed, leading to low fibrinogen levels and the risk of haemorrhage.

**Plasminogen activators**

Tissue-type plasminogen activators (alteplase (t-PA), tenecteplase (TNK-tPA)) are produced by recombinant technology. Reteplase (r-PA) is also a recombinant plasminogen activator. These agents are not antigenic and do not give allergic reactions. They are relatively fibrin-specific, and have relatively little systemic activity and short half-lives (around 5 min). The bleeding complications observed are similar in severity and frequency to those seen with streptokinase, suggesting that fibrin specificity does not confer protection against haemorrhage.

**Indications**

The use of thrombolytic therapy in myocardial infarction is discussed on page 1003. The combination of aspirin with thrombolytic therapy produces better results than thrombolytic therapy alone. The extent of the benefit depends on how quickly treatment is given. These agents are also used in cerebral infarction (see p. 836) and in massive pulmonary embolism where there is haemodynamic instability. The main risk of thrombolytic therapy is bleeding. Treatment should not be given to patients who have had recent bleeding, uncontrolled hypertension or a haemorrhagic stroke, or surgery or other invasive procedures within the previous 10 days.

**Prevention and management of venous thromboembolism**

Venous thromboembolism (VTE) is a common problem after surgery, particularly in high-risk patients such as the elderly, those with malignant disease and those with a history of previous thrombosis *(Box 16.37)*. The incidence is also high in patients confined to bed following trauma, myocardial infarction or other illnesses. The prevention and treatment of venous thrombosis includes the use of anticoagulants.

---

**Box 16.37**

**Indications for warfarin and target INR**

**Target INR 2.5**

- Pulmonary embolism
- Proximal and calf deep vein thrombosis
• Recurrence of venous thromboembolism when no longer on warfarin therapy
• Symptomatic inherited thrombophilia
• Atrial fibrillation
• Cardioversion
• Mural thrombus
• Cardiomyopathy
• Antiphospholipid syndrome
• Bioprosthetic heart valves

**Target INR 3.5**
• Recurrence of venous thromboembolism while on warfarin therapy
• Mechanical prosthetic heart valve

**Anticoagulants**

**Heparin (standard or unfractionated)**
Heparin is not a single substance but rather a mixture of polysaccharides. Commercially available unfractionated heparin consists of components with molecular weights varying from 5000 to 35 000, with an average of about 13 000. It was initially extracted from liver (hence its name) but is now prepared from porcine gastric mucosa. Heparin acts immediately, binding to antithrombin. This induces a conformational change that increases the inhibitory activity of antithrombin (at least 5000-fold) towards activated serine protease coagulation factors (thrombin, XIIa, XIa, Xa, IXa and VIIa).

**Low-molecular-weight heparins**
Low-molecular-weight (LMW) heparins are produced by enzymatic or chemical degradation of standard heparin, producing fractions with molecular weights in the range of 2000–8000. Potentiation of thrombin inhibition (anti-IIa activity) requires a minimum length of the heparin molecule with an approximate molecular weight of 5400, whereas the inhibition of factor Xa requires only a smaller heparin molecule with a molecular weight of about 1700. LMW heparins have the following properties:
• Bioavailability is better than that of unfractionated heparin.
• They have greater activity against factor Xa than against factor IIa, suggesting that they may produce an equivalent anticoagulant effect to standard heparin but have a lower risk of bleeding, although this has not generally been confirmed. In addition, LMW heparins cause less inhibition of platelet function.
• They have a longer half-life than standard heparin and so can be given as a once-daily subcutaneous injection instead of every 8–12 h.

• They produce little effect on tests of overall coagulation, such as the APTT at doses recommended for prophylaxis. They are not fully neutralized by protamine.

LMW heparins are excreted renally and therefore dose reductions are required in those with renal impairment.

LMW heparins are widely used for antithrombotic prophylaxis: for example, in high-risk surgical patients and for the treatment of established thrombosis (see pp. 1055–1056).

The main complication of all heparin treatment is bleeding. This is managed by stopping heparin. Very occasionally, it is necessary to neutralize unfractionated heparin with protamine. Other complications include osteoporosis with prolonged therapy and thrombocytopenia.

Heparin-induced thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is an uncommon complication of heparin therapy and usually occurs 5–14 days after first heparin exposure. It is due to an immune response directed against heparin/platelet factor 4 complexes. All forms of heparin have been implicated but the problem occurs less often with LMW heparins.

HIT is paradoxically associated with severe thrombosis; when it is diagnosed, all forms of heparin must be discontinued, including heparin flush. Unfortunately the diagnosis can be difficult to make because patients on heparin are often very sick and may be thrombocytopenic for many other reasons. Use of the ‘4Ts’ pre-test probability score can help diagnosis (based on degree of thrombocytopenia, timing of thrombocytopenia, presence of new thrombosis, and likelihood of an alternative diagnosis for the thrombocytopenia). Those with an intermediate or high risk score should have the diagnosis confirmed or refuted using an anti-enzyme-linked immunosorbent assay (anti-ELISA).

It is always necessary to continue some form of anticoagulation in patients with HIT and the choice lies between the heparinoid danaparoid and the direct thrombin inhibitor argatroban. The introduction of warfarin should be covered by one of these agents, as warfarin alone may exacerbate thrombosis as protein C levels fall.

Fondaparinux

This is a synthetic pentasaccharide that inhibits activated factor X, similar to the LMW heparins. It is used in acute coronary syndrome (see pp. 999–1000). A long-acting version, idraparinux, is also available and only needs to be given weekly. Neither binds to platelet factor 4 and so has no capacity to cause HIT.

Direct thrombin inhibitors

Hirudins bind directly to thrombin and are, effectively, irreversible inhibitors. Recombinant hirudins are no longer available.

Bivalirudin is a 20 amino acid synthetic analogue of hirudin. Compared with hirudin, it
appears to cause less bleeding, is a reversible thrombin inhibitor (as it is broken down by thrombin) and has a shorter half-life. It is used in percutaneous coronary interventions.

Argatroban is a small-molecule, direct thrombin inhibitor with a short half-life. It is licensed in the UK for treatment of HIT.

**Oral anticoagulants**

**Coumarins and indanediones**

These act by interfering with vitamin K metabolism. The coumarin warfarin is most commonly used because it has a low incidence of side-effects other than bleeding.

The dosage is controlled by prothrombin tests (PT). Thromboplastin reagents for PT testing are derived from a variety of sources and give different PT results for the same plasma.

It is standard practice to compare each thromboplastin with an international reference preparation so that it can be assigned an international sensitivity index (ISI). The *international normalized ratio (INR)* is the ratio of the patient's PT to a normal control when using the international reference preparation. Therapeutic ranges using the INR for warfarin in various conditions are shown in Box 16.37.

Each laboratory can use a chart adapted to the ISI of their thromboplastin to convert the patient's PT to the INR. Suitably selected control plasmas can also be employed to achieve the same objective. Adoption of this system means that PT tests on a given plasma sample using different thromboplastins result in the same INR and that anticoagulant control is comparable in different hospitals across the world.

**Contraindications**

Contraindications to the use of oral anticoagulants are seldom absolute and include:

- severe uncontrolled hypertension
- non-thromboembolic strokes
- peptic ulceration (unless cured by *Helicobacter pylori* eradication)
- severe liver and renal disease
- pre-existing haemostatic defects
- non-compliance.

Warfarin should be avoided in pregnancy because it is teratogenic in the first trimester and may be associated with fetal haemorrhage later in pregnancy. When anticoagulation is considered essential in pregnancy, self-administered subcutaneous heparin should be used as an alternative, although this may not be as effective for women with prosthetic cardiac valves. Specialist advice should be sought.

Many drugs interact with warfarin (see p. 24). More frequent PT testing should accompany changes in medication, which should be implemented with the full knowledge of the anticoagulant clinic.
**Increased anticoagulant effect due to warfarin**

An increased anticoagulant effect caused by warfarin is usually produced by one of the following mechanisms:

- drugs causing a reduction in the metabolism of warfarin, including tricyclic antidepressants, cimetidine, sulphonamides, phenothiazines and amiodarone
- drugs such as clofibrate and quinidine, which increase the sensitivity of hepatic receptors to warfarin
- drugs interfering with vitamin K absorption (such as broad-spectrum antibiotics and colestyramine), which also potentiate the action of warfarin
- displacement of warfarin from its binding site on serum albumin by drugs such as sulphonamides (this is not usually responsible for clinically relevant interactions)
- drugs that inhibit platelet function (such as aspirin), which increase the risk of bleeding
- alcohol excess, cardiac failure, liver or renal disease, hyperthyroidism and febrile illnesses, which result in potentiation of the effect of warfarin.

**Decreased anticoagulant effect due to warfarin**

A decreased anticoagulant effect due to warfarin is usually produced by drugs that increase the clearance of warfarin by induction of hepatic enzymes that metabolize warfarin, such as rifampicin and barbiturates.

**Anticoagulant-related bleeding**

Bleeding is the most serious side-effect of warfarin. Bleeding occurs in up to 4% of patients on oral anticoagulants per year, requires hospital admission in 2% and has a 0.25% morbidity associated with it. The benefit of anticoagulants must therefore be notably more than the risk of bleeding. Management of warfarin-related bleeding *(Box 16.38)* is dependent upon the INR and the degree of bleeding. Minor bleeding may be treated with cessation of warfarin alone, while serious bleeding will require additional use of vitamin K and factor concentrates.

---

**Box 16.38**

**Management of warfarin-related bleeding and excessive oral anticoagulation**

---
INR/Bleeding | Actions
---|---
INR >3.0 <6.0 (target INR 2.5) | 1. Reduce warfarin dose or stop
INR >4.0 <5.0 (target INR 3.5) | 2. Restart warfarin dose or stop
INR >5.0 <8.0, no bleeding | 1. Stop warfarin
2. Reduce maintenance warfarin dose and investigate cause of elevated INR
INR >8.0, no bleeding or minor bleeding | 1. Stop warfarin
2. Reduce maintenance warfarin dose and investigate cause of elevated INR
3. If no bleeding, give 1–5 mg of oral vitamin K
4. If minor bleeding, give 1–3 mg intravenous vitamin K
Major bleeding | 1. Stop warfarin
2. Give four-factor prothrombin complex concentrate 25–50 U/kg (FFP 15 mL/kg only if concentrate not available)
3. Give 5 mg of intravenous vitamin K

If unexpected bleeding occurs, investigate the possibility of a local anatomical cause.

**Direct oral anticoagulants (also called new/novel oral anticoagulants)**

A number of orally active direct thrombin (e.g. dabigatran) and Xa inhibitor drugs (e.g. rivaroxaban, apixaban, edoxaban) have been introduced for the treatment and prevention of venous and arterial thrombosis. These new direct oral anticoagulants have a much broader therapeutic window than warfarin, have fewer drug interactions (aside from stronger inducers and inhibitors of P-glycoprotein and CYP3A4) and offer the prospect of fixed drug dosing without the need to monitor coagulation.

**Monitoring**

The primary advantage of these drugs is that they do not require regular monitoring. Dose amendment is, however, recommended with some NOACs in relation to patient age, weight and renal/liver function. Although they may prolong routine clotting times, this is variable. In the rare event that any actual monitoring is required, specific drug levels must be measured.

**Indications**

Dabigatran, apixaban and rivaroxaban are licensed for prevention of thrombosis in hip and knee replacement surgery, prevention of stroke in atrial fibrillation, and treatment of VTE. These drugs have proved at least as effective as warfarin in large-scale clinical trials, and in some regimes are more effective than warfarin. All have at least similar safety profiles in terms of clinically significant bleeding rates; they do have higher rates of gastrointestinal haemorrhage but lower rates of intracranial haemorrhage than warfarin. Large-scale studies for other indications in various aspects of thrombosis treatment and prevention are being undertaken using such drugs, which are replacing warfarin in a significant number of patients. However, patients with significant hepatic dysfunction or renal impairment may not be good candidates for these drugs due to their hepatic and renal excretion.
Bleeding and reversal
Specific molecules (monoclonal antibody fragment against dabigatran or a factor Xa decoy for rivaroxaban and apixaban) are in clinical trials. Idarucizumab has recently obtained FDA approval as a reversal agent for dabigatran. If bleeding occurs with these new agents that requires anticoagulant reversal, this can be partially achieved using activated or traditional prothrombin complex concentrates. All agents have relatively short half-lives (<14 hours) and will leave the circulation relatively quickly. Care needs to be taken, however, in planning the timing of anticoagulant cessation prior to elective surgery.

Prophylaxis to prevent venous thromboembolism
Risk factors for VTE are well defined. Most hospitalized patients have one or more of these risk factors and VTE is common in hospitalized patients. The risk of developing deep vein thrombosis (DVT) after hip replacement surgery has been estimated to be as high as 50% when thromboprophylaxis is not used. Approximately 10% of hospital deaths may be due to pulmonary embolism (PE) and more people die from hospital-acquired venous thrombosis than the combined total of deaths from road traffic accidents, acquired immunodeficiency syndrome (AIDS) and breast cancer. PE is the most common preventable cause of hospital death.

Appropriate thromboprophylaxis is highly effective and cost-effective. Such prophylactic measures include early mobilization, elevation of the legs, and use of compression stockings, intermittent compression devices and anticoagulant drugs, such as LMW heparins and thrombin inhibitors. All patients, medical and surgical, admitted to hospital should be assessed for thrombotic risk and given appropriate thromboprophylaxis. National guidelines are available to guide appropriate management (Box 16.39).

- **Low-risk patients** (*Box 16.39*) require no specific measures other than early mobilization.
- **High-risk patients** based on risk assessment are most effectively managed using graduated compression stockings and LMW heparin subcutaneously daily.

---

**Box 16.39**

Risk assessment for deep vein thrombosis and pulmonary embolism for hospital patients (NICE CG92)

Patients who are at risk of VTE

**Medical patients**
- If mobility significantly reduced for ≥3 days or
- If expected to have ongoing reduced mobility due to normal state plus any VTE risk factor

**Surgical patients and patients with trauma**
- If total anaesthetic + surgical time >90 min or
- If surgery involves pelvis or lower limb and total anaesthetic + surgical time >60 min or
• If acute surgical admission with inflammatory or intra-abdominal condition or
• If expected to have significant reduction in mobility or
• If any VTE risk factor present

**VTE risk factors***

• Active cancer or cancer treatment
• Age >60 years
• Critical care admission
• Dehydration (usually associated with surgery)
• Known thrombophilia
• Obesity (BMI >30 kg/m²)
• One or more significant medical co-morbidities (e.g. heart disease, metabolic endocrine or respiratory pathologies, acute infectious diseases, inflammatory conditions)
• Personal history or first-degree relative with a history of VTE
• Use of HRT
• Use of oestrogen-containing contraceptive therapy
• Varicose veins with phlebitis

**Patients who are at risk of bleeding**

All patients who have any of the following:

• Active bleeding
• Acquired bleeding disorders (such as acute liver failure)
• Concurrent use of anticoagulants known to increase the risk of bleeding (such as warfarin with INR >2)
• Lumbar puncture/epidural/spinal anaesthesia within the previous 4 h or expected within the next 12 h
• Acute stroke
• Thrombocytopenia (platelets <75 × 10⁹/L
• Uncontrolled systolic hypertension (≥230/120 mmHg)
• Untreated inherited bleeding disorders (such as haemophilia or von Willebrand's disease)

---

*For women who are pregnant or have given birth within the previous 6 weeks, see recommendations 1.6.4–1.6.6 in NICE Clinical Guideline 92.

The antithrombin agents dabigatran and rivaroxaban are routinely used after lower limb joint replacement surgery. They are as effective as LMW heparins and, as they are given orally, can be used for extended periods out of hospital.
Management of established venous thromboembolism

- **The aim** of anticoagulant treatment is to prevent further thrombosis and pulmonary embolization while resolution of venous thrombi occurs by natural fibrinolytic activity. Anticoagulation is started with heparin, as it produces an immediate anticoagulant effect. Heparin should be administered for approximately 5 days, the time taken for simultaneously administered warfarin to produce an anticoagulant effect (INR 2.5).

- **LMW heparin** (e.g. tinzaparin 175 U/kg daily, dalteparin 200 U/kg daily, enoxaparin 1.5 mg/kg daily) is equally effective and as safe as unfractionated heparin in the immediate treatment of DVT and PE. This creates the opportunity for treatment of VTE without admission to hospital, in compliant patients without coexisting risk factors for haemorrhage.

- **Length of anticoagulation.** This is recommended for *at least* 6 weeks after precipitated isolated calf vein thrombosis and *at least* 3 months after precipitated proximal DVT or PE in patients who have temporary risk factors. For patients with idiopathic VTE or permanent risk factors, at least 3 months' anticoagulation is recommended and consideration should be given to indefinite anticoagulation.

- **Use of longer-term anticoagulation** in patients with previous thrombosis: it has been suggested that a lower INR might be safer and equally effective but the current view is that the target INR should be 2.0–3.0 where oral anticoagulation is used. Indefinite anticoagulation is considered appropriate for those with two or more episodes of VTE.

- **Outpatient anticoagulation** is best supervised in anticoagulant clinics. Patients are issued with national booklets for recording INR results and anticoagulant doses. Home monitoring is possible in well-motivated patients.

  Inferior vena cava (IVC) filters are an important tool for preventing PE in patients who have a contraindication to anticoagulation. Most are now retrievable, allowing removal once a temporary contraindication to anticoagulation has passed. Long-term use of an IVC filter is associated with a risk of thrombosis at and below the site of the filter.

  The role of thrombolytic therapy in the treatment of venous thrombosis is not established. It is used in patients with massive PE who are haemodynamically unstable and in patients with extensive deep venous thrombi.

  Thrombolytic therapy should be followed by anticoagulation with heparin for a few days and then by oral anticoagulants to prevent rethrombosis.

Introduction

The term ‘malignant disease’ encompasses a wide range of illnesses, including common ones such as lung, breast and colorectal cancer (see Box 17.43), as well as rare ones like the acute...
leukaemias. Malignant disease is widely prevalent and, in the West, almost one-third of the population will develop cancer at some time during their life. It is second only to cardiovascular disease as a cause of death. Although the mortality of cancer is high, many advances have been made, both in terms of treating the disease and in understanding its biology at the molecular level.

The Biology of Cancer

Most human neoplasms are clonal in origin: that is, they arise from a single population of precursor or cancer stem cells. This process is typically initiated by genetic aberrations within this precursor cell that may be inherited (germline) or acquired (somatic). Cancer becomes increasingly common as we get older, and can be related to a time-dependent accumulation of DNA damage that is not repaired by the normal mechanisms of genome maintenance, damage tolerance and checkpoint pathways. The hallmark areas of loss or gain in function in developing cancer are shown in Figure 17.1. Whole-genome sequencing experiments are now identifying significant clonal genetic heterogeneity within tumours, including ‘passenger’ (inactive) and ‘driver’ (active) mutations. This heterogeneity is a potential source of treatment-resistant clones and is temporally variable, so that, at relapse, the predominant founder clone that has not been eradicated is seen to have acquired new mutations on its return; alternatively, a sub-clone, selected out by treatment pressure, has gained further mutations and led to a recurrence.
Sustaining proliferative signalling, enabling replicative immortality and resisting cell death

Malignant transformation may result from a gain in function as cellular proto-oncogenes become mutated (e.g. \textit{ras}), amplified (e.g. \textit{HER2}) or translocated (e.g. \textit{BCR-ABL}). However, these mutations are insufficient to cause malignant transformation by themselves. Alternatively, there may be a loss of function of tumour suppressor genes, such as \textit{p53}, that normally suppress growth. Loss or gain of function may also involve alterations in the genes controlling the transcription of the oncogenes or tumour suppressor genes (see p. 119). Over subsequent cell divisions, heterogeneity develops with the accumulation of further genetic abnormalities (\textbf{Fig. 17.2}). The genes most commonly affected can be characterized as those controlling cell cycle checkpoints, DNA repair and DNA damage recognition, apoptosis, differentiation, growth factor receptors, signalling pathways and tumour suppressor genes (\textbf{Box 17.1}). Recognition of critical genetic alterations has enabled extensive development of new targeted drugs, such as imatinib, which inhibits the growth signals of the abnormal tyrosine kinase \textit{BCR/ABL}.
Proliferation may continue at the expense of differentiation, which, together with failure of apoptosis, leads to tumour formation with the accumulation of morphologically abnormal cells varying in size, shape and cytoplasmic or nuclear maturity.

**Evading growth suppression**

Tumour cells are usually not recognized and killed by the immune system. There are two main reasons:

- There is a failure to express molecules such as human leucocyte antigen (HLA) and co-stimulatory B7 molecules that are required for activation of cytotoxic, or ‘killer’, T lymphocytes.
• Tumours may also actively secrete immunosuppressive cytokines and cause a generalized immunosuppression.

Successful strategies for tumour vaccines that overcome these obstacles are developing in renal cancer and prostate cancer. The monoclonal antibody ipilimumab, which works against the inhibitory cytotoxic T lymphocyte-associated antigen 4 (CTLA-4) molecule that is expressed after T-cell activation, is used in melanoma (see p. 601). There is increasing interest in the programmed death pathway (PD/PD-ligand). This checkpoint inhibitor (see p. 130) negatively affects the immune response. Recently, blocking either PD-1 (on T cells) or its ligand, PDL-1, which is present in some tumours, has been associated with an immune response that can produce tumour shrinkages that may be durable. Common tumours, such as squamous lung cancer and transitional cell carcinomas, have responded, in addition to those tumours expected to be susceptible to immunological therapies (melanoma and renal cancer).

**Inducing angiogenesis**

There is a progressive slowing of the rate of growth as many tumours become larger. This occurs for many reasons but outgrowing the blood supply is paramount. New vessel formation (angiogenesis) is stimulated by a variety of peptides produced both by tumour cells and by host inflammatory cells, such as basic fibroblast growth factor (bFGF), angiopoietin 2 and vascular endothelial growth factors (VEGFs), which are stimulated by hypoxia. The anti-VEGF-receptor monoclonal, bevacizumab, has had some success in colorectal and ovarian cancer. Alternatively, small molecules that target post-receptor response (tyrosine kinase inhibitors) may be used; examples include sunitinib and pazopanib.

**Invasion and metastasis**

Solid cancers spread by both local invasion and distant metastasis (*Fig. 17.3*), through the vessels of the blood and lymphatic systems. Infiltration into surrounding tissues is associated with loss of cell–cell cohesion, which is mediated by active homotypic cell adhesion molecules (CAMs). Epithelial cadherin (E-cadherin) is expressed by many carcinomas and mutated in some, such as familial gastric carcinoma (see p. 382).
Invasion is also determined by the balance of activators to inhibitors of proteolysis. The matrix metalloproteinases (MMPs) and their tissue inhibitors (TIMPs) are involved in tumour growth, invasion, metastasis and angiogenesis, and are being targeted by new therapeutic drugs for cancer treatment.

Dissemination of tumour cells occurs through intravasation into the vascular and lymphatic vessels and dissemination to distant sites, partly by chance, but also because of specific interactions between receptors and cytokines found on stromal and tumour cells, such as tumour necrosis factor (TNF), interleukin 6 (IL-6) and chemokines.

Further reading

Aetiology and Epidemiology

For most patients, the cause of their cancer is unknown, probably representing a multifactorial interaction between individual genetic predispositions and environmental factors.
Aetiology

Genetic factors

Rather than occurring by somatic mutation in response to mutagens, germline mutations in the genes that predispose to the development of cancer may be inherited and therefore present in all tissues. Examples of such cancer syndromes are given in Box 17.2. Expression of the mutation, and hence carcinogenesis, will depend on the penetrance (due to the level of expression and the presence of other genetic events) of the gene and whether the mutated allele has a dominant or recessive effect. There is a small group of autosomal dominant inherited mutations, such as RB (in retinoblastoma), and a small group of recessive mutations (Box 17.2). Carriers of the recessive mutations are at risk of developing cancer if the second allele becomes mutated, leading to ‘loss of heterozygosity’ within the tumour, although this is seldom sufficient, as carcinogenesis is a multistep process.

Environmental factors

A wide range of environmental factors has been identified as being associated with the development of malignancy (Box 17.3) and may be amenable to preventative action, such as smoking cessation, dietary modification and antiviral immunization (Box 17.4). Environmental factors interact with genetic predisposition. For example, subsequent generations of people moving from countries with a low incidence to those with a high incidence of breast or colon cancer acquire the cancer incidence of the country to which they have moved, while Northern European people exposed to strong ultraviolet radiation have the highest risk of developing melanoma.

**Box 17.4**

**Key messages for a healthy lifestyle for preventing cancer**

- Stop smoking
- Moderate alcohol consumption
- Maintain a healthy weight
- Take moderate exercise
- Eat healthily (fruit and vegetables, high fibre, low fat/salt/sugar)
- Limit sun exposure
- Minimize occupational risk
- Minimize radiation exposure
- Vaccinate against hepatitis B and human papillomavirus

**Tobacco**

The incidence of lung cancer in both men and women increased dramatically in the last 25 years worldwide, but is now falling in many developed countries. The association of smoking with lung cancer is indisputable and causative mechanisms have been identified; cigarette tobacco is responsible for one-third of all deaths from cancer in the UK. Smoking not only causes lung cancer, but also is associated with cancer of the mouth, larynx, oesophagus and bladder. Smoking is discussed on pages 1074–1075.

**Alcohol**

Alcohol is associated with cancers of the upper respiratory and gastrointestinal tracts, and also interacts with tobacco in the aetiology of these tumours. It may be associated with an increased risk of breast cancer.

**Diet**

One-third of cancer deaths have been attributed to dietary factors, although it is often difficult to differentiate these from other epidemiological factors. For example, the incidence of stomach cancer is particularly high in the Far East, while breast and colon cancers are more common in Western, economically more developed countries. Many associations have been observed without a causative link being identified between the incidence of cancer and the consumption of dietary fibre, red meat, saturated fats, salted fish, vitamin E, vitamin A and many others. Food and its role in the causation of gastrointestinal cancer are discussed on page 183. Higher levels of obesity in the developed world have been associated with increases in cancers associated with oestrogenic stimulation of the breast and endometrium in women.

**Environment/occupation**

**Environmental factors**

**Air pollution**

(see p. 56).

*Ultraviolet (UV) light* is known to increase the risk of skin cancer (basal cell, squamous cell and melanoma). The incidence of melanoma is therefore particularly high in the white Anglo-Celtic population of Australia, New Zealand and South Africa, where exposure to UV light is combined with a genetically predisposed population.

*Arsenical contamination* of water supplies has been linked to a high incidence of lung and
colon cancers in South-east Asia, particularly where boreholes are the main water source.

**Occupational factors**

In 1775, Percival Pott described the association between carcinogenic hydrocarbons in soot and the development of scrotal epitheliomas in chimney sweeps. The principal causes now are *asbestos* (lung and mesothelial cancer) and *polycyclic hydrocarbons* from fossil fuel combustion (skin, lung and bladder cancers). *Organic chemicals*, such as benzene, may cause the development of bone marrow conditions, such as myelodysplastic syndrome or acute myeloid leukaemia.

**Infectious agents**

The geographical distribution of a rare malignancy suggests that it might be caused by, or associated with, an infective agent. Chronic persistent infection provides growth stimulation, while many viruses contain transforming viral oncogenes.

T-cell leukaemia, seen almost exclusively in residents of the southern island of Japan and in the West Indies, is caused by infection with the locally endemic retrovirus human T-cell leukaemia virus (HTLV-1) and integration of the oncogene, *TAX*, into the cellular genome.

Hepatocellular carcinoma occurs in patients with hepatitis B and C virus infections, and Burkitt's lymphoma and nasopharyngeal carcinoma are associated with the Epstein–Barr virus (EBV). EBV is also linked with Hodgkin's lymphoma (see p. 616).

Patients with human immunodeficiency (HIV) infection or immunosuppression from organ transplantation have an increased incidence of EBV-related lymphoma and herpesvirus-8-associated Kaposi's sarcoma.

Human papillomavirus (HPV) infection types 16 and 18, for which an effective vaccine is now available, is an established cause of the rise in cervical cancer among sexually active women; more recently, it has also been associated with an increase in head and neck cancers. Bacterial infection with *Helicobacter pylori* predisposes to the development of gastric cancer and gastric lymphoma, while *Schistosoma japonicum* infection predisposes to the development of squamous cell carcinomas in the bladder.

**Medication**

Oestrogens have been implicated in the development of vaginal, endometrial and breast carcinoma. Certain cytotoxic drugs given, such as those for Hodgkin's lymphoma (see pp. 616–618) are themselves associated with an increased incidence of secondary acute myelogenous leukaemia (AML), and bladder and lung cancer. Androgens have been associated with both benign and malignant liver tumours.

**Radiation**

**Accidental**

The nuclear disasters of Hiroshima, Nagasaki and Chernobyl led to an increased incidence of
leukaemia after 5–10 years in the exposed population, as well as increased incidences of thyroid and breast cancer. Radiation workers are at an increased risk of malignancy due to occupational exposure, unless precautions are taken to minimize the danger by using personal and environmental shielding, and to record and limit the amount of personal exposure.

**Therapeutic**

Long-term survivors following radiotherapy, such as that for Hodgkin's lymphoma, have an increased incidence of cancer, particularly at the radiation field margins.

**Diagnostic**

Imaging procedures involving radiation exposure are associated with an increased risk of cancer. This risk is cumulative, dose-dependent and time-dependent, and so children are at higher risk than adults. The cancer risk of various common investigations is shown in Box 17.5. All doctors should strive to minimize diagnostic exposure to radiation where possible by using alternative modalities such as ultrasound or magnetic resonance imaging (MRI). Good documentation of radiation doses is required. This is particularly so in children and pregnant women.

*UK background radiation is 2.6 mSv per year. 1 mSv carries a lifetime cancer risk of 1 in 17 500 and 5 mSv a risk of 1 in 3500.

**Epidemiology**

The incidence and mortality from cancer vary by tumour type and geographical region across the world.
Geographical distribution

The incidence of cancer across the world is dependent on the local environmental factors, the diet and the genetics of the population (see above) (Figs 17.4 and 17.5). Age is also a factor, as most cancers occur in those over the age of 65, who comprise 3.3% of the population in Africa, compared with 15.2% in Europe. Reproductive patterns also influence breast cancer. Migrating individuals often take on the risks associated with the local environmental factors.

FIGURE 17.4 The most common causes of death from cancer worldwide, 2002 estimates. Non-melanoma skin cancers are excluded. CNS, central nervous system; NHL, non-Hodgkin's lymphoma. (From http://info.cancerresearchuk.org/cancerstats/world/the-global-picture/)
Other factors

Incidence and mortality are closely linked for those cancers for which treatment has yet to make significant improvements, such as lung, stomach and liver. However, in countries with effective screening programmes, there is an increasing incidence, but decreasing mortality, for breast, cervix, bowel and prostate cancers.

Clinical Approach to the Patient with Malignant Disease

Asymptomatic detection through screening

Most common cancers start as focal microscopic clones of transformed cells, and diagnosis only becomes likely once sufficient tumour bulk has accumulated to cause symptoms or signs. In order to try to make an earlier diagnosis and enhance the curative possibilities, an increasing number of screening programmes are being developed that either target the asymptomatic or pre-invasive stages of the cancer, as in cervix, breast and colon, or use serum tumour markers, as in prostate and ovarian cancers. Genetic screening can be used to target screening to those groups at most risk of developing cancer, such as BRCA1-positive
individuals who may develop breast cancer (see Box 17.2). The aim of screening programmes is to improve individual and/or population survival by detecting cancer in its very early stages, when the patient is asymptomatic. This strategy is dependent on finding tests that are sufficiently sensitive and specific, using detection methods that identify cancer before it has spread, and having curative treatments that are practical and consistent with maintenance of a normal lifestyle and quality of life.

Screening is provided to populations – for breast, cervical and colon cancer in the UK, for example – and also to individuals via annual check-ups; alternatively, it may be opportunistic, when patients see their doctor for other reasons.

Unfortunately, earlier diagnosis does not necessarily mean longer survival and randomized trials are necessary to prove benefit. With lead-time bias, the patient is merely treated at an earlier date and hence the survival appears longer; death still occurs at the same time from the point of genesis of the cancer (Fig. 17.6). With length-time bias, a greater number of slowly growing tumours are detected when asymptomatic individuals are screened, leading to a false impression of an improvement in survival.

The characteristics of effective screening programmes are shown in Box 17.6.

**Box 17.6**

**Characteristics of an effective screening programme**

- It must be affordable for the healthcare system
- It must be acceptable to all social groups so that they attend for screening
- It must have a good discriminatory index between benign and malignant lesions
- It must show a reduction in mortality from the cancer

**Cervical cancer**

The smear test is cheap and safe but requires a well-trained cytologist to identify the early changes (dyskaryosis and cervical intraepithelial neoplasia, CIN). However, developments in
liquid cytology and co-testing for HPV DNA may overcome this. Effective treatment for high-risk, pre-invasive, malignant changes reduces the incidence and mortality from cervical cancer, although there are no randomized trials. Screening will continue to be required, despite the introduction of vaccination against HPV infection for women before they become sexually active, because the lag time between infection and the appearance of disease can be in the order of 40–50 years.

Breast cancer
The UK National Health Service Breast Screening Programme (i.e. biplanar mammography every 3 years) for women aged 50–70 years has been shown to reduce mortality from breast cancer in randomized controlled studies. The test is acceptable to most women, with 50–75% of individuals attending for screening when sufficiently educated about the benefits. In North America, there is continuing debate about whether annual mammography from a younger age is more effective.

The cost is estimated to be between £250 000 and £1.3 million per life saved, money which, according to critics, could be used more appropriately in better treatment.

Women from families with BRCA1, BRCA2 and p53 mutations require intensive screening starting at an earlier age, when mammography is inaccurate due to greater breast density and MRI scanning is preferred.

Colorectal cancer
**Faecal occult blood** is a cheap test for the detection of colorectal cancer. Large randomized studies have shown a reduction in cancer-related mortality of 15–33%. However, the false-positive rates are high, meaning many unnecessary colonoscopies (see p. 425). The UK has recently introduced a national screening programme using faecal occult blood in patients aged 60–64 years, in which positive tests have identified that 10% have cancer and 40% have adenomas. A randomized trial in Norway has found an increased number of early-stage cancers in the screened population but a high incidence of interval cancers between biennial screens.

Colonoscopy is the ‘gold-standard’ technique for the examination of the colon and rectum and is the investigation of choice for high-risk patients. Universal screening strategies have been recommended in the USA, but the shortage of skilled endoscopists, the expense, the need for full bowel preparation and the small risk of perforation make colonoscopy impractical as a population screening tool at present; computed tomographic (CT) colonography (‘virtual colonoscopy’) (see Fig. 13.5) may become an alternative, along with genetic testing and stool DNA tests.

Prostate cancer
Serum prostate-specific antigen (PSA) can be used for the detection of this cancer, which is on the increase. Many men over 70 have evidence of prostate cancer at postmortem but had no symptoms of the disease, and it has been suggested that those over 75 should not have screening PSA tests. The test must be interpreted with caution due to the natural increase in
PSA with age, benign prostatic hypertrophy and prostatitis. The early results of screening for prostate cancer have varied greatly, with any reductions in prostate cancer-specific mortality potentially not observed for 10 years or more. Currently, national screening programmes are not recommended but instead an informed choice programme is in existence in the UK. Screening may not be appropriate in those with a life expectancy of less than 10–15 years.

Epithelial ovarian cancer
Serum CA125 can be used for the early detection of this cancer and is the subject of ongoing trials. An improvement in survival of a screened population can be shown but at the cost of many unnecessary laparotomies, so that further enhancements are being investigated by serial testing and in combination with transvaginal ultrasound scans.

The symptomatic patient with cancer
Patients may offer information of predisposing conditions and family history that alerts the clinician to the likelihood of a cancer diagnosis. Many present with a history of tumour site-specific symptoms, such as pain, and physical signs, such as a mass, which readily identify the primary site of the cancer (Box 17.7). Cancer symptoms typically increase with time, and do not respond to measures such as antibiotics. However, some patients only seek medical attention when more systemic and non-specific symptoms occur, such as weight loss, night sweats, fever, fatigue, recurrent infections and anorexia. These usually indicate a more advanced stage of disease, except in some paraneoplastic and ectopic endocrine syndromes (see below). Other patients are only diagnosed on discovery of established metastases, such as the abdominal distension of ovarian cancer, the back pain of metastatic prostatic cancer, or the liver enlargement of metastatic gastrointestinal cancer

Box 17.7
Symptoms and signs of malignant disease
Paraneoplastic syndromes are indirect effects of cancer (Box 17.8 and Fig. 17.7) that are often associated with specific types of cancer and may be reversible with treatment of the cancer. The effects and mechanisms can be very variable. For example, in the Lambert–Eaton syndrome (see p. 890), there is cross-reactivity between tumour antigens and the normal tissue acetylcholine receptors at neuromuscular junctions.

ACTH, adrenocorticotropic hormone; CLL, chronic lymphocytic leukaemia; DIC, disseminated intravascular coagulation; DVT, deep venous thrombosis; NMDAR, N-methyl-D-aspartate receptors; SIADH, syndrome of inappropriate antidiuretic hormone secretion; VGCC, voltage-gated calcium channels.
The coagulopathy of cancer may present with thrombophlebitis, deep venous thrombosis and pulmonary emboli, particularly in association with cancers of pancreas, stomach and breast. Some 18% of patients with recurrent pulmonary embolus will be found to have an underlying cancer and many cancer patients are at increased risk of venous thromboembolism (VTE) following diagnosis. Trousseau syndrome – superficial thrombophlebitis migrans – refers to this process in the superficial venous system. All patients with active cancer admitted to hospital are at high risk of VTE and should be given prophylaxis with, for example, subcutaneous low-molecular-weight heparin in the absence of any contraindications (see p. 578).

Other symptoms are related to peptide or hormone release, such as in carcinoid or Cushing syndrome.

Cachexia of advanced cancer is thought to be due to release of chemokines such as tumour necrosis factor (TNF), as well as the fact that patients lose their appetite. The unexplained loss of >10% of body weight in a patient should always stimulate a search for an explanation.

Cancer-associated immunosuppression can lead to reactivation of latent infections such as herpes zoster (Fig. 17.8) and tuberculosis.
Serum tumour markers

Tumour markers are intracellular proteins or cell surface glycoproteins released into the circulation and detected by immunoassays. Examples are given in Box 17.9. Values in the normal range do not necessarily equate with the absence of disease and a positive result must be corroborated by histology, as these markers can be seen in many benign conditions. They are most useful in the serial monitoring of response to treatment. As discussed in subsequent sections, a proportion of low-grade B-cell lymphomas and a majority of cases of myeloma will produce a monoclonal paraprotein of intact immunoglobulin molecule or light chains. This acts as a valuable tumour marker in the diagnosis and assessment of response.

**Cancer imaging**

Radiological investigation by experts is required at various stages: at initial diagnosis and staging of the disease, during the monitoring of treatment efficacy, at the detection of recurrence, and for the diagnosis and treatment of complications.

The choice of investigations needs to be guided by the patient's symptoms and signs, site and histology of the cancer, the curative or palliative potential of treatment, and the utility of the information in guiding treatment. Specific investigations are described under each tumour type.

Contrast agents are used for increased structural discrimination in cross-sectional imaging and can be further enhanced with functional specificity for metabolically active tissue with 19 fluorodeoxy-glucose uptake positron emission tomography-computed tomography (PET-CT) scan, as used extensively in head and neck cancer, lung cancer and lymphoma. **Radionuclide imaging** of sentinel lymph nodes is used to guide lymphatic surgery in breast cancer and melanoma. Tumour-targeted contrast agents can improve detection rates; examples include the radiolabelled monoclonal antibody (MAb) rituximab for lymphoma, or radiolabelled small molecules such as octreotide for neuroendocrine tumours. Research into the use of reporter agents that become visible only on activation within the tumour environment holds the promise of greater sensitivity and specificity in the future.

**Biopsy and histological examination**

The diagnosis of cancer may be suspected by both patient and doctor but advice about treatment can usually be given only on the basis of a tissue diagnosis. This may be obtained by endoscopic, radiologically guided or surgical biopsy, or by cytology (e.g. lung cancer may be diagnosed by sputum cytology). Malignant lesions can be distinguished morphologically from benign ones by the pleomorphic nature of the cells, increased numbers of mitoses, nuclear
abnormalities of size, chromatin pattern and nucleolar organization, and evidence of invasion into surrounding tissues, lymphatics or vessels. The degree of differentiation (or, conversely, of anaplasia) of the tumour has prognostic significance: generally speaking, more differentiated tumours have a better prognosis than poorly differentiated ones. In some tumours, the surgical procedure will vary depending on the presence of malignancy, and an intraoperative provisional histological opinion can be rapidly obtained with a tissue sample processed using ‘frozen section’ techniques, rather than having the sample paraffin embedded, which takes more than a day.

Immunocytochemistry, using monoclonal antibodies against tumour antigens, is very helpful in differentiating between lymphoid and epithelial tumours, and between some subsets of these (see Box 17.62). However, there is much overlap in the expression of many of these tissue tumour markers and some adenocarcinomas and squamous carcinomas do not bear any distinctive immunohistochemical markers that are diagnostic of their primary site of origin.

Molecular markers of genetic abnormalities have long been available in the haematological cancers and are increasingly available in solid cancers. For example, fluorescence in situ hybridization (FISH; see p. 113) can be used to look for characteristic chromosomal translocations, as in lymphoma and leukaemia, as well as deletions or amplifications, as in breast cancer (see pp. 118–119). The development of the new targeted MAbS and tyrosine kinase inhibitors (TKis) has been guided by increasing use of mutation analysis of common oncogenes, such as RAS and RAF in colon cancer and melanoma. Tissue microarrays can identify patterns of multiple genomic alterations and single nucleotide polymorphisms (SNPs), as in breast cancer and lymphoma (see p. 107), and RNA assays with reverse transcriptase polymerase chain reaction (RT-PCR) can be used to identify tissue of origin with prognostic and predictive relevance.

Genomics and proteomics are being investigated in order to target new (and expensive) therapies, such as imatinib in chronic myeloid leukaemia (CML) and gastrointestinal stromal tumours (GIST); trastuzumab and lapatinib in breast cancer; erlotinib and crizotinib in lung cancer; and cetuximab and bevacizumab in colon cancer.

Cancer Treatment

Aims of treatment
Optimal cancer treatment is delivered by a multidisciplinary team that coordinates the delivery of the appropriate anticancer treatment (surgery, chemotherapy, radiotherapy and biological/endocrine therapy), supportive and symptomatic care, and psychosocial support.

Establishment of agreed patient pathways has enabled more effective and timely delivery of care and post-treatment rehabilitation. Central to this endeavour is the involvement of the patient, through education as to the nature of their disease and the treatment options available.

A curative approach
For most solid tumours, local control is necessary, but not sufficient, for cure because of the presence of systemic (microscopic) disease, while haematological cancers are usually disseminated from the outset. Improvement in the rate of cure of most cancers is thus dependent on earlier detection to increase the success of local treatment and effective systemic treatment. The likelihood of cure of the systemic disease rests on the type of cancer and its expression of appropriate treatment targets, its drug sensitivity and tumour bulk (microscopic or clinically detectable). A few rare cancers are so chemosensitive that even bulky metastases can be cured: for example, leukaemia, lymphoma, gonadal germ cell tumours and choriocarcinoma. For most common solid tumours, such as lung, breast and colorectal cancer, there is no current cure of bulky (clinically detectable) metastases, but micrometastatic disease treated by adjuvant systemic therapy (see below) after surgery can be cured in 10–20% of patients.

Adjuvant therapy for solid tumours
Micrometastatic spread by lymphatic or haematological dissemination often occurs early in the development of the primary tumour and can be demonstrated by molecular biological methods capable of detecting the small numbers (1 in $10^6$) of circulating cells. Studies correlating prognosis with histological features of the primary cancer, such as differentiation, invasion of blood vessels or regional lymph nodes, and molecular markers like Her2 in breast cancer, enable risk stratification and increasing individualization of therapy. Adjuvant therapy is defined as treatment given, in the absence of macroscopic evidence of metastases, to patients at risk of recurrence from micrometastases, following treatment given for the primary lesion. ‘Neoadjuvant’ therapy, alternatively, is given before primary surgery, both to shrink the tumour in order to improve the local excision, and to treat any micrometastases as soon as possible.

The success of adjuvant treatment across many tumour types relies on careful selection of patients according to defined risk criteria, and reduction of treatment toxicity to reach a balanced risk/benefit ratio. However, the majority who receive such treatment do not benefit, either because they were already cured or because the cancer is resistant to the treatment. Better tests, such as gene arrays and circulating tumour cells, are being developed to identify
those with micrometastases, who really benefit from treatment.

**A palliative approach**

When cure is no longer possible, palliation – that is, relief of tumour symptoms, preservation of quality of life and prolongation of life – is possible in many cancers in proportion to their drug and radiation sensitivity. There is, on average, a 2–18-month prolongation in median life expectancy with treatments for solid tumours (see specific tumour types for details) and up to 5–8 years for some leukaemias and lymphomas, those individuals with the most responsive tumours experiencing the greatest benefit. In addition, through early assessment during treatment, it is possible to stop if no evidence of benefit is demonstrable early on, so as to minimize exposure to toxic and unsuccessful treatment.

**Assessment before treatment**

**Staging**

Before a decision about treatment can be made, not only the type of tumour, but also its extent and distribution, need to be established. Various ‘staging investigations’ are therefore performed before a treatment decision is made. To be useful clinically, the staging system must sub-divide the patients into groups with different prognoses, which can guide treatment selection.

The staging systems vary according to the type of tumour and may be site-specific (see *Hodgkin's lymphoma*, p. 617). Alternatively, the TNM (tumour, node, metastases) classification is used (see *Box 17.53*), and can be adapted for application to most common cancers.

**Performance status**

In addition to anatomical staging, the person's age and general state of health need to be taken into account when planning treatment. The latter has been called ‘performance status’ and is of great prognostic significance for all tumour types (*Box 17.10*). Performance status reflects the effects of the cancer on the patient's functional capacity. An alternative performance rating scale is provided by Karnofsky. With a performance status of 2, response to, and survival following, treatment are greatly reduced for most tumour types.

### Assessment of the benefits of treatment

A measurable response to treatment can serve as a useful early surrogate marker when assessing whether to continue a given treatment for an individual patient. Trials to assess response to treatment in advanced disease have identified active agents for use in the more curative setting of adjuvant treatment of early-stage disease.

Response to treatment can be subjective or objective.

**A subjective response** is one perceived by the patient in terms of, for example, relief of pain and dyspnoea, or improvement in appetite, weight gain or energy. Such a subjective response is a major aim of most palliative treatments. Quantitative measurements of these subjective symptoms (patient reported outcome measures, PROMs) form a part of the assessment of response to chemotherapy, especially in those situations where cure is not possible and where the aim of treatment is to provide prolongation of good-quality life. In these circumstances, measures of quality of life enable an estimate of the balance of benefit and side-effects to be made.

**An objective response** to treatment is assessed clinically and radiologically (Fig. 17.9). The term ‘remission’ is often used synonymously with ‘response’, which, if complete, means an absence of detectable disease without necessarily implying a cure of the cancer. The terms used to evaluate the responses of tumours are given in Box 17.11. For a complete response, all previous clinical abnormalities should have resolved and this needs to be confirmed by clinical examination or sampling of the primary disease site, or by detection of serum tumour markers. Radiologically, a partial response, defined since 1999 by the Response Evaluation Criteria in Solid Tumours (RECIST) convention, is a ≥30% reduction in the sum of all measurable lesion diameters.

RECIST, Response Evaluation Criteria in Solid Tumours.

The increasing use of PET-CT has meant that metabolic responses (reduction in tracer avidity with or without a reduction in the size of the mass) may predict long-term outcome more accurately; this is particularly the case in lymphoma, where a classification of metabolic response exists, as well as in gastrointestinal stromal tumour (GIST).
The final assessment of treatment outcome is the impact of the therapy on remission duration and survival: that is, the cure rate. Such survival figures are increasingly incorporating quality-of-life assessments and a health economic assessment to calculate the number of quality-adjusted life years (QALYs) gained for the cost of the treatment and judgements are made about health system affordability.

Further reading

Principles of Chemotherapy
Cytotoxic chemotherapy employs systemically administered drugs that directly damage cellular DNA (and RNA). It kills cells by promoting apoptosis and, sometimes, frank necrosis. Different cytotoxic drugs work at different stages in the cell cycle (Fig. 17.10; see also Fig. 7.16).

There is a narrow therapeutic window between effective treatment of the cancer and normal
tissue toxicity, because cytotoxic drugs are not cancer-specific (unlike some of the targeted biological agents) and the increased proliferation in cancers is not much greater than in normal tissues. The dose and schedule of the chemotherapy are limited by normal tissue tolerance, especially in those more proliferative tissues of the bone marrow and gastrointestinal tract mucosa. All tissues can be affected, however, depending on the pharmacokinetics of the drug and its affinity for particular tissues (e.g. heavy metal compounds for kidneys and nerves).

The therapeutic effect on the cancer is achieved by a variety of mechanisms that seek to exploit differences between normal and transformed cells. While most of the drugs have been derived in the past by empirical testing of many different compounds, such as alkylating agents, the new molecular biology is leading to targeting of particular genetic defects in the cancer (see p. 601).

Toxicity to normal tissue can be limited in some instances by supplying growth factors such as granulocyte colony-stimulating factor (G-CSF) or by infusing stem cell preparations to diminish bone marrow toxicity. The use of more specific targeted biological agents with relatively weak pro-apoptotic effects, in combination with the general cytotoxics, has also improved the therapeutic ratio (e.g. trastuzumab and breast cancer; see p. 634). Certain cytotoxic therapies may also be administered into the pleural space, peritoneum or cerebrospinal fluid (CSF), or into the arterial supply of a tumour.

Most tumours rapidly develop resistance to single agents given on their own through changes in membrane transport and DNA repair pathways. For this reason, the principle of intermittent combination chemotherapy was developed. Several drugs are combined, chosen on the basis of differing mechanisms of action and non-overlapping toxicities. These drugs are given over a period of a few days, followed by a rest of a few weeks, during which time the normal tissues have the opportunity for regrowth. If the normal tissues are more proficient at DNA repair than the cancer cells, it may be possible to deplete the tumour while allowing the restoration of normal tissues between chemotherapy cycles (Fig. 17.11).
In many experimental tumours, it has been shown that there is a log–linear relationship between drug dose and number of cancer cells killed, and that the maximum effective dose is very close to the maximum tolerated dose at which dose-limiting toxicity is reached. With a chemosensitive tumour, relatively small increases in dose may have a large effect on tumour cell kill. It is therefore apparent that, where cure is a realistic option, the dose administered is critical and may need to be maintained despite toxicity. In situations where cure is not a realistic possibility and palliation is the aim, a sufficient dose to exceed the therapeutic threshold, but not cause undue toxicity, is required, as the short-term quality of life becomes a major consideration.

Classification of cytotoxic drugs

See Box 17.12.

Box 17.12

Chemotherapy: some cytotoxic drugs

DNA-damaging agents

- Free radicals:
  - Alkylators, e.g. cyclophosphamide, melphalan, chlorambucil, ifosfamide
  - Nitrosoureas, e.g. carmustine (BCNU), bendamustine, lomustine (CCNU), busulfan
  - Tetrazines, e.g. dacarbazine, temozolomide
- DNA cross-linking – platinum, e.g. cisplatin, carboplatin, oxaliplatin

Antimetabolites

- Pyrimidine synthesis, e.g. 5-fluorouracil, capecitabine, cytarabine, fludarabine
gemcitabine, cladribine, clofarabine, nelarabine, azacitidine

- Purine synthesis, e.g. mercaptopurine, tioguanine
- Antifolates, e.g. methotrexate, pemetrexed

**DNA repair inhibitors**

- Topoisomerase-I inhibitors, e.g. irinotecan
- Topoisomerase-II inhibitors, e.g. etoposide
- Anthracyclines, e.g. daunorubicin, doxorubicin, epirubicin, bleomycin, mitomycin

**Antitubulin agents**

- Tubulin-binding – alkaloids, e.g. vincristine, vinorelbine
- Taxanes, e.g. paclitaxel, docetaxel
- Eribulin, epothilones

**DNA-damaging drugs**

**Alkylating agents**

These act by covalently binding alkyl groups. Their major effect is to cross-link DNA strands, interfering with DNA synthesis and causing strand breaks.

**Platinum compounds**

Cisplatin, carboplatin and oxaliplatin cause interstrand cross-links of DNA and are often regarded as non-classical alkylating agents. They have transformed the treatment of testicular cancer (cisplatin) and have a major role against many other tumours.

**Antimetabolites**

Antimetabolites are usually structural analogues of naturally occurring metabolites that interfere with normal synthesis of nucleic acids by falsely substituting purines and pyrimidines in metabolic pathways.

**Folic acid antagonists**

This class includes methotrexate, which is structurally very similar to folic acid and binds preferentially to dihydrofolate reductase, the enzyme responsible for the conversion of folic acid to folinic acid. It is used widely in the treatment of solid tumours and haematological malignancies. Folinic acid is often given to ‘rescue’ normal tissues from the effects of high doses of methotrexate. A related drug, pemetrexed, targets the enzyme thymidylate synthase, as well as glycinamide ribonucleotide formyltransferase (GARFT).

**Pyrimidine antagonists**

5-Fluorouracil (5-FU) consists of a uracil molecule with a substituted fluorine atom. It acts by
blocking thymidylate synthase, which is essential for pyrimidine synthesis. Oral capecitabine is metabolized to 5-FU, as is tegafur with uracil.

**Arabinosides**

Arabinosides inhibit DNA synthesis by inhibiting DNA polymerase. Cytarabine is used almost exclusively in the treatment of acute myeloid leukaemia, where it remains the backbone of therapy.

**Purine antagonists**

This class includes 6-mercaptopurine and 6-тиогуанин, which are both used almost exclusively in the treatment of acute leukaemia.

**DNA repair inhibitors**

**Epipodophyllotoxins**

These are semisynthetic derivatives of podophyllotoxin, which inhibit the topoisomerase enzymes that allow unwinding and uncoiling of supercoiled DNA, and maintain DNA strand breaks.

**Cytotoxic antibiotics**

The anthracyclines act by intercalating adjoining nucleotide pairs on the same strand of DNA and by inhibiting topoisomerase-II DNA repair. They have a wide spectrum of activity in haematological and solid tumours.

**Antitubulin agents**

**Vinca alkaloids**

Drugs such as vincristine, vinblastine and vinorelbine act by binding to tubulin and inhibiting microtubule formation during mitosis (see p. 92). They are associated with neurotoxicity due to their antimicrotubule effect and must never be given intrathecally, as this is lethal.

**Taxanes**

Paclitaxel and docetaxel bind to tubulin dimers and prevent their assembly into microtubules.

**Side-effects of chemotherapy**

Chemotherapy carries many potentially serious side-effects and should be used only by trained practitioners; however, an appreciation of its common potential side-effects is necessary for any general physician who is called to see a cancer patient on chemotherapy. The five most common side-effects are vomiting, hair loss, tiredness, myelosupression and mucositis (**Box 17.13**). Side-effects are much more directly dose-related than anticancer effects and it has been the practice to give drugs at doses close to their maximum tolerated dose, although this is not
always necessary to achieve their maximum anticancer effect. Common combination chemotherapeutic regimens are shown in *Box 17.14*.

**Box 17.13**

**Side-effects of chemotherapy**

**Common**
- Nausea and vomiting
- Hair loss
- Myelosuppression
- Mucositis
- Fatigue

**Drug-specific**
- Cardiotoxicity, e.g. anthracyclines
- Progressive pulmonary fibrosis, e.g. bleomycin, busulfan
- Neurotoxicity, e.g. cisplatinum, vinca alkaloids, taxanes
- Nephrotoxicity, e.g. cisplatinum, TKis
- Skin, e.g. anti-EGFR TKis
- Skin plantar–palmar dermatitis, e.g. 5-fluorouracil liposomal doxorubicin
- Sterility, e.g. alkylating agents, anthracyclines, docetaxel
- Secondary malignancy, e.g. alkylating agents, epipodophyllotoxins
- CNS, e.g. TKis

  CNS, central nervous system; EGFR, epidermal growth factor receptor; TKi, tyrosine kinase inhibitor.

**Common side-effects**

**Extravasation of intravenous drugs**

Cytotoxic drugs should only be given by trained personnel. They cause severe local tissue necrosis if leakage occurs outside the vein. Stop the infusion immediately and institute local measures: for example, aspirate as much of the drug as possible from the cannula, infiltrate the area with 0.9% saline and apply warm compresses. Antihistamines and corticosteroids may give symptomatic relief.

**Nausea and vomiting**

The severity of these common side-effects varies with the cytotoxic and they can be eliminated in 75% of patients by using modern antiemetics. Nausea and vomiting are particular problems with platinum analogues. A stepped policy with antiemetics, such as metoclopramide and domperidone, followed by 5-HT₃ (serotonin) antagonists (e.g. ondansetron, granisetron) combined with dexamethasone, should be used to match the emetogenic potential of the chemotherapy. Aprepitant, a neurokinin receptor antagonist, is helpful in preventing acute and delayed nausea and vomiting. It is used with dexamethasone and a 5-HT₃ antagonist. Drugs such as cyclizine, olanzapine and levomepromazine, and benzodiazepines can be used to control persistent nausea.

**Effects on hair, skin and nails**

Many, but not all, cytotoxic drugs are capable of causing hair loss. Scalp cooling can sometimes be used to reduce hair loss but, in general, this side-effect can only be avoided by selection of drugs, where this is possible. Hair regrows on completion of chemotherapy. Nails will demonstrate banding, reflecting periods of cessation of growth during each chemotherapy cycle ([Fig. 17.12](#)), and skin toxicity may be particularly pronounced with 5-FU, capecitabine and docetaxel ([Fig. 17.13](#)).
Fatigue
This is often significant and may continue beyond completion of therapy. Other problems, such as anaemia or depression, may exacerbate fatigue. Attention should be paid to nutrition, hydration, sleep hygiene, gentle exercise, task prioritization, pacing, realistic target setting and scheduling rest within the day.
Bone marrow suppression and immunosuppression

Suppression of the production of red blood cells, white blood cells and platelets occurs with most cytotoxic drugs and is a dose-related phenomenon (Fig. 17.14). Severely myelosuppressive chemotherapy may be required if treatment is to be given with curative intent, despite the potential for rare but fatal infection or bleeding. Anaemia and thrombocytopenia are managed by red cell or platelet transfusions. (Neutropenic infection is discussed on pp. 604–605.) The risk of infective problems can be ameliorated by the use of prophylactic antimicrobials, such as ciprofloxacin, or the use of G-CSF as primary prophylaxis in those chemotherapy regimens that carry a significant risk of febrile neutropenia or in those patients on less intensive therapies who are at higher risk due to age or co-morbidity.

**FIGURE 17.14** Cyclical myelosuppression from chemotherapy (arrowed). Hb, haemoglobin; WBC, white blood cells.

Mucositis

This common side-effect of chemotherapy reflects the sensitivity of the mucosa to antimitotic agents. Mucositis causes severe pain in the oropharyngeal region and problems with swallowing and nutrition. It can be generalized throughout the intestinal tract and can cause life-threatening diarrhoea. Treatment is with antiseptic and anti-candidal mouthwash; if
mucositis is severe, fluid and antibiotic support is required, as the mucosa is a portal for entry of enteric organisms. Palifermin, a recombinant keratinocyte-derived growth factor, may ameliorate severe chemotherapy- and radiotherapy-induced mucositis.

Other toxicities

Cardiotoxicity
This is a rare side-effect of chemotherapy, and is usually associated with anthracyclines such as doxorubicin; effects can present as an acute arrhythmia during administration or cardiac failure due to cardiomyopathy after chronic exposure (Fig. 17.15). This effect is dose-related and can largely be prevented by restricting the cumulative total dose of anthracyclines within the safe range (equivalent to 450 mg/m² body surface area cumulative doxorubicin dose). The risk of anthracycline cardiomyopathy is also dependent on other treatments, such as trastuzumab or radiotherapy, as well as other cardiac risk factors, such as hypertension, smoking and hypercholesterolaemia. Cardiotoxicity can also be reduced by using the analogue, epirubicin, or by reducing peak drug concentrations through delayed-release preparations, such as liposomal doxorubicin. 5-Fluorouracil and its prodrug, capecitabine, can cause cardiac ischaemia.

Neurotoxicity
This occurs predominantly with the vinca alkaloids, taxanes and platinum analogues (but not carboplatin). It is dose-related and cumulative. Chemotherapy is usually stopped before the development of a significant polyneuropathy, which, once established, is only partially reversible. Vinca alkaloids, such as vincristine, must never be given intrathecally, as the neurological damage is progressive and fatal.
**Nephrotoxicity**
Cisplatin (but not oxaliplatin or carboplatin), methotrexate and ifosfamide can potentially cause renal damage. This can usually be prevented by maintaining an adequate diuresis during treatment to reduce drug concentration in the renal tubules, and by monitoring of renal function.

**Sterility and premature menopause**
Some anticancer drugs, particularly alkylating agents, but also anthracyclines and docetaxel, may cause gonadal damage, resulting in sterility and, in women, the loss of ovarian oestrogen production, which may be irreversible.

In males, storage of sperm prior to chemotherapy should be offered to the patient when chemotherapy is given with curative intent.

In females, collection of oocytes to be fertilized *in vitro* and cryopreserved as embryos for subsequent implantation is most successful; however, it is also possible to collect and freeze by vitrification of unstimulated oocytes. Cryopreservation of ovarian tissue and retrieval of viable oocytes for subsequent fertilization are still experimental. The recovery of gonadal function is dependent on the status before treatment; in women, this is mostly related to age since menarche, with those under 40 years having significantly more ovarian reserve.

**Secondary malignancies**
Anticancer drugs have mutagenic potential and the development of secondary malignancies, predominantly acute leukaemia, is an uncommon but particularly unwelcome long-term side-effect in patients otherwise cured of their primary malignancies. The alkylating agents, anthracyclines and epipodophyllotoxins are particularly implicated in this complication.

**Principles of Haematopoietic Stem Cell Transplantation**
See pages 561–562.

**Principles of Endocrine Therapy**
Oestrogens are capable of stimulating the growth of breast and endometrial cancers, and androgens can stimulate the growth of prostate cancer. Removal of these growth factors by manipulation of the hormonal environment may result in apoptosis and regression of the cancer. Endocrine therapy can be curative in a proportion of patients treated for micrometastatic disease in the adjuvant setting for breast and prostate cancer, and provides a minimally toxic, non-curative (palliative) treatment in advanced/metastatic disease. The presence of detectable cellular receptors for the hormone is strongly predictive of response. However, this is also modified by the many molecular interactions between the activation pathways of, for example, epidermal growth factor receptor (EGFR), the androgen receptor (AR) and oestrogen receptor (ER) (see pp. 634 and 642).
**Principles of Biological and Targeted Therapy**

**Immunotherapy**

The most dramatic evidence for the effectiveness of immunotherapy is seen in the response of the acute leukaemias to allogeneic haemopoietic stem cell transplantation (HSCT). Certain antigens that are specific to cancer cells, such as sequences of tumour immunoglobulin from B-cell lymphomas, or melanoma antigens, have been used as tumour vaccines, together with manipulation of the immune system to overcome tolerance. Engineered chimeric antigen receptors (CARs) that direct T cells to specific antigenic targets are emerging as a powerful potential tool in the treatment of a wide range of cancers.

**Interferons**

Interferons are naturally occurring cytokines that mediate the cellular immune response. Interferon-alpha (IFN-α) has been used to treat advanced melanoma and renal cell carcinoma.

Treatment with IFN has side-effects (see p. 458): most commonly, influenza-like symptoms, which tend to diminish with time; and fatigue, which generally does not, and can be treatment-limiting. IFN used to be given as a daily subcutaneous injection, but conjugation with polyethylene glycol (PEG interferon) has led to a reduction in frequency of injection and severity of side-effects.

**Interleukins**

Interleukin 2 (IL-2), a recombinant protein, is used to activate T-cell responses, often in conjunction with IFN-stimulated B-cell activation. Anti-tumour activity has been observed in renal cell carcinoma and melanoma, with responses in 10–20% of patients, occasionally for prolonged periods. Toxicity is common; acutely, this includes the capillary leak syndrome with hypotension and pulmonary oedema, while autoimmune thyroiditis and vitiligo occur later.

**Immune checkpoint inhibitors**

These new agents directly interfere with the relationship between T cells and antigen-presenting cells or tumour cells to overcome the common problems of immune tolerance and anergy. Ipilimumab is a monoclonal antibody that blocks the CD152 (CTLA-4) receptor responsible for downregulating T-cell responses, and is active in the treatment of melanoma. The inhibitors of the programmed death (PD-1) receptor or its ligands, PD-L1 and L2, on activated T cells, further reactivate tumour-specific cytotoxic T cells, so that ipilimumab plus nivolumab doubled the response rate from 20% to 40% in metastatic melanoma. Many clinical trials are now examining these agents in the context of a variety of other cancers.

**Immunomodulatory drugs: thalidomide, lenalidomide, pomalidomide**

This family of immunomodulatory drugs (IMIDs) is increasingly being used in a range of malignancies, such as myeloma, chronic lymphocytic leukaemia (CLL) and myelodysplastic
syndrome (MDS), as well some solid tumours. They have anti-angiogenic functions, as well as effects on cytokine production, tumour/stromal interactions and T-cell co-stimulatory functions. They are all considered teratogenic and should be avoided in women of reproductive potential, unless extra precaution is taken against conception. There is increasing evidence that IMIDs work through binding of the E3 ligase protein, cereblon, which acts to degrade two specific B-cell transcription factors, IKZF1 and IKZF3.

**Targeted therapies**

The fast-developing field of targeted therapies includes monoclonal antibodies, receptor kinase inhibitors, and small molecule receptor blockers. Expression of the targeted molecule is not sufficient of itself to indicate that use of the corresponding drug will be therapeutic because it is also necessary for the drug to be able to interrupt a growth-critical pathway in that cancer.

**Monoclonal antibodies**

Monoclonal antibodies (MAbs; *Box 17.15*) directed against tumour cell surface antigens are ‘humanized’ by being genetically engineered to have a range of functions:

- As direct treatment for B-cell lymphoid malignancy (e.g. rituximab anti-CD20 surface antigen). Tumour cell lysis occurs by both complement- and antibody-dependent cellular cytotoxicity
- As a carrier molecule to target toxins or radioisotopes to the tumour cells, e.g. anti-CD20 conjugated to radioactive yttrium for non-Hodgkin’s lymphoma (NHL), and trastuzumab or trastuzumab emtansine for breast cancer.
- As anti-growth factor agents added to chemotherapy by inhibiting dimerization of the extracellular receptor molecules (see *Box 17.14*). Side-effects are those of hypersensitivity to the foreign protein and specific cross-reactivities, e.g. trastuzumab for the myocardium, bevacizumab for the mucosa and renal tubule, and cetuximab for the skin follicles.

### Intracellular signal inhibitors

Many cancer cells are transformed by the activity of the protein products of oncogenes that signal growth by phosphorylation of tyrosine residues on the intracellular portion of growth factor receptors. Small molecule inhibitors (Box 17.16) have many pharmacokinetic advantages over the MAb inhibitors. The first example was the TKi, imatinib, which specifically inhibits the BCR-ABL fusion oncoprotein and c-Kit. This compound is an extremely effective treatment for CML and GIST, which are characterized by the presence of the c-Kit target. Lapatinib, which inhibits Her2, has increased survival in breast cancer. The less specific TKis, sunitinib and pazopanib, which inhibit signalling by EGFR and vascular endothelial growth factor receptor (VEGFR), have proved effective in metastatic renal cancer, while afatinib, erlotinib and gefitinib have shown activity in lung cancer. Vemurafenib is a kinase inhibitor and has a specificity for BRAF-V600, as used in malignant melanoma (pp. 1373–1374). Many other similar molecules are in pre-clinical or early clinical development, but heterogeneity within a single tumour occurs and genomic anomalies may not all be represented in a single biopsy specimen. Vandetanib, a combined VEGF and C-RET inhibitor, is useful in the treatment of medullary thyroid cancer.

### Box 17.16

Intracellular signal inhibitor therapies in cancer
Gene | Genetic alteration | Tumour type | Therapeutic agent
---|---|---|---
**Receptor tyrosine kinase**
EGFR | Mutation, amplification | Lung | Gefitinib, erlotinib, afatinib
ERBB2 | Amplification | Breast | Lapatinib
PDGFRA | Mutation | GIST | Sunitinib, imatinib, nilotinib
PDGFRB | Translocation | Chronic myelomonocytic leukaemia | Sunitinib, sorafenib, imatinib
ALK | Mutation or amplification | Lung, neuroblastoma, anaplastic large-cell lymphoma | Crizotinib
c-Met | Amplification | Gefitinib-resistant NSCLC, gastric | Crizotinib
c-Kit | Mutation | GIST | Sunitinib, imatinib
FLT3 | Internal tandem duplication | AML | Lestaurtinib, midostaurin
RET | Mutation, translocation | Thyroid medullary carcinoma | Vandetanib
JAK2 | Mutation | Myelofibrosis | Ruxolitinib

**Non-receptor tyrosine kinase**
ABL | Translocation (BCR-ABL) | CML | Imatinib, nilotinib, dasatinib, bosutinib, ponatinib
BTK | Mutation in primary B-cell deficiency | CLL, mantle cell lymphoma | Ibrutinib

**Serine–threonine–lipid kinase**
BRAF | Mutation (V600E) | Melanoma | Vemurafenib
mTOR | Increased activation | Renal cell carcinoma, breast | Temsirolimus, everolimus
PEKδ | | CLL, mantle cell lymphoma | Idelalisib

**DNA damage or repair**
BRCA1 and BRCA2 | Mutation (synthetic lethal effect) | Breast, ovarian | Olaparib (PARP inhibitors)

AML, acute myeloid leukaemia; BCR, breakpoint cluster region; CLL, chronic lymphocytic leukaemia; CML, chronic myeloid leukaemia; GIST, gastrointestinal stromal tumour; NSCLC, non-small cell lung cancer; PARP, poly(adenosine diphosphate-ribose) polymerase.

**Proteasome inhibitors**
The proteasome degrades redundant or damaged proteins that have been labelled by a process called ubiquitination. Such proteins include cyclins and cyclin-dependent kinases, as well as factors in the nuclear factor kappa-B (NFκB) pathway. Inhibition of the proteasome leads to apoptosis in cancer cells and is synergistic with other treatments such as steroids and chemotherapy. Bortezomib is the first of such inhibitors to reach clinical practice and is used in myeloma, as well as some types of NHL. There are also recent additions to this class, including carfilzomib and ixazomib.

**Gene therapy**
Antisense oligonucleotides are short sequences of DNA bases that specifically inhibit
complementary sequences of either DNA or RNA. As a result, they can be generated against genetic sequences, which are specific for tumour cells. Their clinical development has been hampered by poor uptake by tumour cells and rapid degradation by natural endonucleases. However, one antisense sequence directed against the Bcl-2 oncogene has been shown to have an anti-tumour effect in patients with NHL. Viral vectors for the transfection of tumour cells in vivo are being tested as a way of delivering specific replacement gene therapy in head and neck cancers.

**Further reading**

**Principles of Radiation Therapy**

**Theoretical background**

Radiation delivers energy to tissues, causing ionization and excitation of atoms and molecules. The biological effect is exerted through the generation of single- and double-strand DNA breaks, inducing apoptosis of cells as they progress through the cell cycle, and through the generation of short-lived free radicals, particularly from oxygen, which damage proteins and membranes. The generation of free radicals depends on the degree of oxygenation/hypoxia in the target tissues. This can affect the biological effect by up to threefold and is the subject of continuing research for hypoxic cell sensitizers to overcome the reduced efficacy of radiation for hypoxic tumours. Hypoxia, however, may also drive a more malignant potential further, so reduced efficacy is only part of the solution to the hypoxia problem.

The radiation effect will also depend on the intensity of the radiation source, measured as the linear energy transfer or frequency of ionizing events per unit of path, which is subject to the inverse square law as the energy diminishes with the distance from the source. The depth of penetration of biological tissues by the photons depends on the energy of the beam. Low-energy photons from an 85-kV source are suitable for superficial treatments, while high-energy 35-MV sources produce a beam with deeper penetration, less dose at the initial skin boundary (skin-sparing), sharper edges and less absorption by bone. Superficial radiation may be also
delivered by electron beams from a linear accelerator that has had the target electrode that
generates the X-rays removed.

The radiation dose is measured in Gray (Gy), where 1 Gray = 1 joule (J) absorbed per
kilogram of absorbing tissue. The biological effect is dependent on the dose rate, duration,
volume irradiated and tissue sensitivity. Sensitivity to photon damage is greatest during the
G2–M phase of the cell cycle and is also dependent on the DNA repair capacity of the cell.

Types of radiation therapy

• **External beam (or teletherapy)** from a linear accelerator source produces X-rays. The
  energy is transmitted as photons and is the most commonly used form of radiotherapy.
  60Cobalt generators can also provide γ-rays and high-energy photons, but are being gradually
  phased out. Most external beam treatments that are given with curative intent are delivered in
  1.5–2-Gy fractions daily for 5 days per week.

• **Fractionation** is the delivery of the radiation dose in increments separated by at least 4–6 h
to try to exploit any advantage in DNA repair between normal and malignant cells.

• **Hyperfractionation** is when more than one fraction per day is given. This approach has been
  shown to improve outcome in head and neck, and lung cancer. The treatment can also be
  accelerated: that is, the total dose is given in a shorter overall time. For example, a standard
  curative treatment taking 6.5 weeks can be accelerated so that the same dose is delivered in
  5.5 weeks. Radiation dose is thus described by three factors:
  
  – total dose in Gy
  – number of fractions
  – time for completion.

• **Brachytherapy** is the use of radiation sources in close contact with the tissue to provide
  intense exposure over a short distance to a restricted volume. Such techniques have been used
to treat localized breast, prostatic and cervical carcinoma.

• **Systemic radionuclides**, e.g. 131iodine- or radioisotope-labelled MAbs (e.g. anti-CD20 for
  lymphoma) and hormones (e.g. somatostatin for carcinoid tumours), can be administered by
  intravenous or intracavitary routes to provide radiation targeted to particular tissue uptake via
  surface antigens or receptors.

Clinical application of radiation therapy

Radiotherapy planning involves both detailed physics of the applied dose and knowledge of
the biology of the cancer; it is also necessary to establish whether the intention is to treat the
tumour site alone, or to include the likely loco-regional patterns of spread. Normal tissue
tolerance will determine the extent of the side-effects and, therefore, the total achievable dose.
A balanced decision is made according to the curative or palliative intent of the treatment and
the likely early or late side-effects.

The cancers for which radiotherapy is usually employed in a primary curative approach,
when the tumour is anatomically localized, are listed in **Box 17.17**, along with those in which
radiotherapy has curative potential when used in addition to surgery (adjuvant radiotherapy). Palliative treatments are frequently used to provide relief of symptoms and to improve quality, if not duration, of survival (Box 17.18). Palliative treatment is usually given in as few fractions as possible over as short a time as possible. Radiotherapy planning, by the use of CT scanning guidance, has been complemented by the introduction of three-dimensional planning and intensity modulated radiotherapy (IMRT), which can deliver curved dose distributions to enable an improved therapeutic ratio. This allows a greater differential in dose between the tumour and critical normal structures, in turn allowing dose escalation or a reduced risk of toxicity. Four-dimensional radiotherapy planning is also becoming widely used, and varies radiation dose over time: for example, the respiratory cycle during lung cancer treatment. Stereotactic focused irradiation (stereotactic body radiotherapy, SBRT), using the γ-knife or Cyberknife, can concentrate gamma radiation from multiple sources on to a small volume to generate an ablative dose for treating tumours of the central nervous system and isolated metastases.

**Curative radiotherapy treatment**

**Primary modality**
- Retina
- Central nervous system
- Skin
- Pharynx and larynx
- Cervix and vagina
- Prostate
- Lymphoma

**Adjuvant to primary surgery**
- Lung
- Breast
- Uterus
- Bladder
- Rectum
- Testis – seminoma
- Sarcoma
Proton beam therapy is an alternative type of external beam radiotherapy using protons, which, due to their larger mass, have little side scatter and so offer a much more focused beam with less dose to surrounding structures. Electron beam therapy uses high-energy electrons that have a short range and so are preferable for superficial tumours, such as melanoma or cutaneous lymphoma.

**Combination chemoradiotherapy**

The local efficacy of radiotherapy can be increased by the simultaneous but not serial addition of chemotherapy with agents such as cisplatin, mitomycin and 5-FU for cancers of the head and neck, lung, oesophagus, stomach, rectum, anus and cervix. Reduced local recurrence rates have translated into survival benefits and further research is investigating the concurrent use of biological agents (e.g. EGFR inhibitors) with radiation.

**Side-effects of radiotherapy**

_Early radiotherapy side-effects_ may occur within days to weeks of treatment; at this point, they are usually self-limiting but associated with general systemic disturbance (Box 17.19). The side-effects will depend on tissue sensitivity, fraction size and treatment volume, and are managed with supportive measures until normal tissue repair occurs. The toxicity may also be enhanced by exposure to other radiation-sensitizing agents, especially some cytotoxics, such as bleomycin, actinomycin, anthracyclines, cisplatin and 5-FU.

**Box 17.19**

**Side-effects of radiotherapy**

**Acute temporary side-effects/dependent on region being treated**

- Anorexia, nausea, malaise
- Mucositis, oesophagitis, diarrhoea
• Alopecia
• Myelosuppression

**Late side-effects**

• Skin: ischaemia, ulceration
• Bone: necrosis, fracture, sarcoma
• Mouth: xerostomia, ulceration
• Bowel: stenosis, fistula, diarrhoea
• Bladder: fibrosis, frequency, incontinence
• Vagina: dyspareunia, stenosis
• Lung: fibrosis, breathlessness
• Heart: pericardial fibrosis, cardiomyopathy, vasculopathy
• Central nervous system: myelopathy
• Gonads: infertility, menopause
• Secondary malignancies: e.g. leukaemia, cancer (e.g. thyroid)
• Other: carotid artery stenosis

Later side-effects occur months to years later, and are unrelated to the severity of the acute effects because of their different mechanism. Late effects reflect both the loss of slowly proliferating cells and a local endarteritis that produces ischaemia and proliferative fibrosis. The risks of late side-effects are related to the fraction size and total dose delivered to the tissue. Growth may be arrested if bony epiphyses are not yet fused and are irradiated, leading to distorted skeletal growth in later life.

**Secondary malignancies** following radiotherapy may appear 10–20 years after cure of the primary cancer. Haematological malignancies tend to occur sooner than solid tumours from the irradiated tissues. The latter are very dependent on the status of the tissue at the time of treatment; for example, the pubertal breast is up to 300 times more sensitive to malignant transformation than the breast tissues of a woman in her thirties. Patients who smoke are more liable to develop lung cancer. Treatment of these secondary cancers can be successful, providing there is normal bone marrow to reconstitute the haemopoietic system, or the whole tissue at risk can be resected (e.g. thyroid after mantle radiotherapy for lymphoma).

**Acute Oncology**

The acute care of all patients admitted to hospital with a cancer diagnosis has become known as acute oncology, in order to ensure a coordinated patient care, with access to all facets of the multidisciplinary team and thus the most efficient use of high-cost inpatient facilities. In addition, there are a number of common oncological emergencies for which urgent treatment is critical for success (*Box 17.20*).

## Neutropenic sepsis

This is the most common cause of attendance in the accident and emergency department for any cancer patient and must be always considered in any patient who is unwell within a month of chemotherapy. Neutropenic patients are at high risk of bacterial and fungal infections, most often from enteric bowel flora; hence, many units will advocate a specific neutropenic diet that is low in bacterial and fungal contamination (Box 17.21). Patients must be warned of the possibility of neutropenic fever occurring. Non-specific symptoms are also common, such as nausea, diarrhoea, drowsiness and breathlessness. A fever may not always be present. The critical test is the full blood count. Patients with neutrophils \(<1.0 \times 10^9/L\) are managed by the immediate introduction of broad-spectrum antibiotics and fluid resuscitation. Signs of systemic illness, such as tachycardia, hypotension or oliguria, mandate urgent admission and resuscitation with intravenous treatment (Box 17.22). Initial empirical therapy should be reviewed following microbiological results.
**Neutropenic diet**

**Foods and drinks that should be avoided**

- All uncooked vegetables and most fruits – peel off thick skin from foods like oranges and bananas
- Raw or rare meat
- Fish
- Uncooked or undercooked eggs
- Foods from salad bars and delicatessen counters
- Soft blue/mould cheeses, e.g. brie, camembert, stilton
- ‘Well’ water – or boil it for 1 min before drinking

**Foods and drinks that are safe**

- Cooked vegetables
- Canned fruits and juices
- Well-done meat
- Hard-boiled eggs (no runny yolks)
- Vacuum-packed lunch meats (not freshly sliced meats)
- Pasteurized milk, cheese, yogurt and other dairy products only
- Tap water if the source is known – or boil it; bottled water

---

**Box 17.22**

**Management of febrile neutropenia**

- Febrile neutropenia is classed as a one-off reading ≥38.5°C or a reading ≥38°C sustained for 1 h
- Patients on antipyretics/steroids and elderly patients may not mount a febrile response
- Hypothermia or clinical deterioration may be the first sign

  *Immediate intervention is essential*

- Resuscitate with i.v. fluids to restore circulatory function; monitor urine output, Glasgow Coma Scale score and central venous pressure
- Take cultures of blood, urine, sputum and stool
- Give empirical antibiotics as per local policy and sensitivities
- Review intensive care and consider inotropic support at an early stage:
  - Commonly used antibiotics should include activity against enteric Gram-negative bacteria and *Pseudomonas*, e.g. co-amoxiclav, ceftazidime or piperacillin–tazobactam with gentamicin; meropenem monotherapy
– Antibiotics against staphylococci may be needed, e.g. vancomycin, especially with indwelling venous access lines
– Neutropenic diet should be started, low in bacteria and fungi
• Change antibiotics according to culture results, or empirically increase Gram-negative cover and consider adding Gram-positive cover, if the patient deteriorates clinically and/or temperature is still elevated after 48 h; discuss with the microbiology department
• Consider imaging, e.g. chest CT, if fever is not responding to broad-spectrum antibiotics, to detect an occult source of fever; consider adding treatment for opportunistic infections:
  – Liposomal amphotericin B or voriconazole – Candida and Aspergillus
  – High-dose co-trimoxazole – Pneumocystis
  – Clarithromycin – Mycoplasma and Legionella
  – Anti-tuberculous therapy – Mycobacterium tuberculosis

All such patients need to be discussed with the appropriate specialist oncology team and hospitals should have clear protocols for the rapid institution of antibiotics in such patients within an hour of arrival in the accident and emergency department. In units practised in the assessment of febrile neutropenia, it is possible to follow a more risk-stratified antibiotic policy and to avoid or curtail admission with oral co-amoxiclav plus ciprofloxacin when low-risk features are present: that is, absence of tachycardia, hypotension, hypoxia and mucositis and an expected short duration of myelosuppression.

**Pulmonary embolus**
This is a common complication of the coagulopathy of cancer and is a side-effect of chemotherapy (Fig. 17.16). It often presents with unexplained breathlessness and episodic exacerbations from multiple small emboli, rather than chest pain. A high level of suspicion should be maintained in any cancer patient with breathlessness, hypoxia or chest pain. CT pulmonary angiography is the investigation of choice. Prophylactic anticoagulation is given to all immobilized patients (see p. 580). Warfarin is ineffective in reversing the coagulopathy of cancer, and low-molecular-weight heparin is preferred.
Superior vena caval obstruction

Superior vena caval obstruction *(Fig. 17.17)* can arise from any upper mediastinal mass but is most commonly associated with lung cancer and lymphoma. The patient presents with difficulty breathing and/or swallowing; stridor; a swollen, oedematous facies and arms; venous congestion in the neck; and dilated veins in the upper chest and arms. Treatment is with immediate steroids, chemotherapy, where the tumour is expected to respond, and possibly mediastinal radiotherapy. Vascular stents and anticoagulation are also sometimes required. Some tumours, such as lymphomas, small cell lung cancers and germ cell tumours, are so sensitive to chemotherapy that this is preferred to radiotherapy, as the masses are likely to be both large and associated with more disseminated disease elsewhere. An early decision is necessary based on the patient's likely prognosis, as ventilatory support may be required until treatment has had time to relieve the obstruction.
Spinal cord compression

Spinal cord compression (see pp. 872–873) needs to be rapidly diagnosed and urgent treatment arranged within 24 hours of onset of paresis to salvage as much functional capacity as possible. Early neurological clinical features may be incomplete, more subjective than objective, and gradual in onset. MRI scanning is the investigation of choice. Treatment should begin with high-dose steroids and a joint neurosurgical and oncological consultation, with the neurosurgeons advising on spinal stability, the need for spinal precautions for movement, and the role of decompressive surgery and external bracing for limited-extent disease. In the absence of surgery, radiotherapy alone may be used.

Tumour lysis syndrome

This occurs if treatment triggers a massive breakdown of tumour cells, leading to increased serum levels of urate, potassium and phosphate, and a secondary hypocalcaemia. These biochemical changes can lead to cardiac arrhythmias and seizures. Urate deposition in the renal tubules can cause renal failure (hyperuricaemic nephropathy). Vigorous hydration, often with diuretics, is crucial to maintain high urine outputs in such patients; however, a proportion will require dialysis for uraemia, oliguria or severe electrolyte disturbances. The xanthine oxidase inhibitor, allopurinol, should be given before treatment is started in low-risk patients. Intravenous rasburicase, a recombinant urate oxidase, is used for prophylaxis in high-risk patients and in the treatment of tumour lysis syndrome.

Acute hypercalcaemia

This presents with vomiting, confusion, constipation and oliguria. Treatment is by resuscitation with intravenous fluids first, to establish a saline diuresis, and an intravenous bisphosphonate,
such as pamidronate or the more potent zoledronic acid (see Box 26.48). Treating the cause is crucial. Denosumab and calcitonin can be used in intractable cases.

### Raised intracranial pressure

Raised intracranial pressure due to intracerebral metastases presents classically with headache, nausea and vomiting. There are often no localizing neurological signs and almost never papilloedema until very late in the disease. However, for many, there is a slower onset with non-specific symptoms such as drowsiness or mental deterioration. Treatment is by high-dose steroids and investigation by MRI. Surgery is appropriate if the condition is unifocal and/or threatening the fourth ventricle; otherwise, whole-brain or local stereotactic Cyberknife radiotherapy is required.

### Hyperviscosity

This can affect patients with a very high haematocrit (haemoglobin >180 g/L), white cell count (>100 × 10⁹/L) or platelet cell count (>1000 × 10⁹/L) from untreated leukaemia or from a myeloproliferative disorder. Viscosity can also be increased by high levels of monoclonal immunoglobulin molecules, as seen in myeloma or Waldenström’s macroglobulinaemia. IgA and IgM are more commonly implicated due to their respective dimeric and pentameric structures. Clinical features include hypoxia, pulmonary infiltrates, confusion, headache, visual disturbances, papilloedema and retinal venous dilatation; rarely, cardiac failure or priapism may be present. Treatment is by leucopheresis or plasmapheresis, followed by urgent treatment for the underlying malignancy.

### Malignant bile duct obstruction

This will present with cholestatic jaundice. Lymphomatous obstruction will respond very well to prompt initiation of therapy. A small proportion of pancreatic and bile duct tumours are surgically resectable, more commonly those in the distal bile duct as compared to those in the hilar region. However, in the greater proportion of patients, treatment is palliative. In recent years, endoscopic techniques have allowed the insertion of stents into the biliary tree to re-establish bile flow. Self-expanding metal stents have long periods of patency but are at risk of ascending infection. In the small proportion of patients in whom bile duct drainage is not possible endoscopically, the percutaneous route offers an alternative. Endoscopic photodynamic laser therapy with a photoporphyrin sensitizer can also prolong patency.

### Further reading

Haematological Malignancies

The leukaemias, the lymphomas and multiple myeloma are an interrelated spectrum of malignancies of the myeloid and lymphoid systems. They are uncommon but not rare, the lymphomas alone being the fifth most common cancer in the UK. The aetiology of these diseases is unknown, for the most part, although viruses, irradiation, cytotoxic poisons and immune suppression have been implicated in a small proportion of cases (see pp. 589–590). The pathogenesis involves at least one molecular abnormality, or usually more, and non-random chromosomal abnormalities have been detected in several leukaemias and lymphomas. Classification has become increasingly complex, with the universally applied World Health Organization (WHO) scheme demanding morphological, cytogenetic and sometimes molecular criteria to be fulfilled. Transformation from low-grade to high-grade pathological sub-type may occur. Treatment options are multiple. Patients need to be supported through treatment involving prolonged myelosuppression and immunosuppression. These therapies are potentially life-threatening but can also be curative. These complexities have given rise to the need for highly skilled staff and specialist facilities; patients should be referred to these centres for treatment.

Haematological malignancies can be divided on the basis of speed of evolution of the disease and cell of origin, and according to whether there is primarily a marrow-based leukaemic presentation (with obvious circulating disease in the peripheral blood), or a nodal or extranodal lymphomatous presentation in which soft tissue masses predominate and there is little peripheral blood involvement. ‘Acute’ disorders are rapidly progressive and fatal within days to weeks if not treated, whereas ‘chronic’ disorders are typically indolent and slowly progressive, and patients can live with their disease for long periods. Myeloid disorders arise from the lineages within the marrow that produce granulocytes, red cells or platelets. Lymphoid disorders can arise from either B- or T-cell lineages. This classification is summarized in Box 17.23. This is an arbitrary division and there is movement across the divisions; for example, chronic myeloid leukaemia can transform to either acute myeloid leukaemia or acute lymphocytic leukaemia; myeloproliferative neoplasms and myelodysplastic syndrome (MDS; pp. 551–552) can transform to acute myeloid leukaemia; and chronic lymphocytic leukaemia and low-grade non-Hodgkin's lymphoma can transform to high-grade forms in ‘Richter’s transformation’. MDS and myeloma may both present with a range of clinical phenotypes, from indolent disease to very aggressive and rapidly progressive presentations that include MDS-refractory anaemia with excess of blasts or the plasma cell leukaemia variant of myeloma.

Box 17.23

Classification of leukaemia and lymphoma
In the management of these diseases, it is critical for patients to be appraised of the natural history, its potential modification by treatment, and the risks of both severe morbidity and mortality. It must be made clear from the outset whether a curative or palliative strategy is most appropriate and the reasons for this decision should be explained. If cure is to be pursued, the patient must be informed of the approximate probability of success and its potential price. The possibility of failure needs to be addressed at the outset.

### The Leukaemias

There are four main subtypes, as discussed above:

1. acute myeloid leukaemia (AML)
2. acute lymphoblastic leukaemia (ALL)
3. chronic myeloid leukaemia (CML)
4. chronic lymphocytic leukaemia (CLL).

These are relatively uncommon diseases with an incidence of about 10/100 000 per year. They can occur at any age and the type of leukaemia varies with age; ALL is mainly seen in childhood and CLL is a disease of the elderly.

Leukaemia can be diagnosed by examination of a stained slide of peripheral blood and bone marrow, but immunophenotyping, cytogenetics and molecular genetics are essential for complete sub-classification and prognostication. The lineage and degree of maturity of the leukaemic clone can be assessed by the expression of cytosolic enzymes and surface antigens.

### Aetiology

In the majority of patients, this is unknown but several factors have been associated:

- **Radiation.** This can induce genetic damage to haemopoietic precursors and ALL, AML and CML have been seen in increased incidences in survivors of Hiroshima and Nagasaki, and in patients treated with ionizing radiation.

- **Chemical and drugs.** Exposure to benzene, used in industry, may lead to marrow damage. AML occurs after treatment with alkylating agents (e.g. melphalan) and topoisomerase-II inhibitors (e.g. etoposide).

- **Genetic factors.** Leukaemia risk is highly elevated in a number of germline conditions that result in genetic instability or bone marrow failure. These include Fanconi anaemia, ataxia
telangiectasia and Li–Fraumeni syndrome. The risk is elevated some 30 times in people with trisomy 21. There is a high degree of concordance among monozygotic twins. Several genes have also been associated with familial AML, such as CEBPA and RUNX1.

- **Viruses.** A type of leukaemia is associated with human T-cell lymphotropic retrovirus type 1 (HTLV-1), which is found particularly in Japan and the Caribbean.

### Genetics

Leukaemic cells often have a somatically acquired cytogenetic abnormality, which may be of prognostic, as well as diagnostic, significance. These genetic alterations change the normal cell-regulating process by interfering with the control of normal proliferation, blocking differentiation, maintaining an unlimited capacity for self-renewal and, lastly, promoting resistance to death signals: that is, decreased apoptosis.

The first non-random chromosomal abnormality to be described was the Philadelphia (Ph) chromosome, which is associated with CML in 97% of cases (see Fig. 17.21A, p. 612). The Ph chromosome is also found in ALL, the incidence in the latter illness increasing with age. The translocation is shown schematically in **Figure 17.21A**. The Ph chromosome is an abnormal chromosome 22, resulting from a reciprocal translocation between part of the long arm of chromosome 22 and chromosome 9. The resulting karyotype is described as t(9; 22) (q34; q11). The molecular consequences of the translocation are that part of the Abelson proto-oncogene (c-ABL), normally present on chromosome 9, is translocated to chromosome 22, where it comes into juxtaposition with a region of chromosome 22 named the ‘breakpoint cluster region’ (BCR). The new ‘fusion’ gene, BCR-ABL, is capable of being expressed as a chimeric messenger RNA, which has been identified in cells from patients with CML. When translated, this produces a fusion protein that has tyrosine kinase activity and enhanced phosphorylating activity compared with the normal protein, resulting in altered cell growth, stromal attachment and apoptosis. The breakpoint differs in CML and Ph-positive ALL, leading to the production of two different tyrosine kinase proteins with molecular weights of 210 kDa and 190 kDa, respectively. It is unclear whether the presence of BCR-ABL is sufficient for development of the disease. It has been shown that normal subjects can carry low levels of the BCR-ABL fusion gene in their blood without developing leukaemia. Other genetic and cytogenetic abnormalities are often seen in leukaemic cells.

As well as cytogenetic and molecular aberrations, epigenetic modification via abnormal methylation patterns and chromatin modification due to histone acetylation is increasingly understood to be involved in oncogenesis and may represent potential therapeutic targets.

### Acute leukaemias

The acute leukaemias increase in incidence with advancing age. Acute myeloid (myeloblastic, myelogenous) leukaemia has a median age at presentation of 65 years and may arise *de novo* or against a background of myelodysplasia or prior cytotoxic chemotherapy (‘secondary’). Acute lymphoid (lymphoblastic) leukaemia has a substantially lower median age at presentation and,
in addition, is the most common malignancy in childhood. The simplified WHO classification is shown in Box 17.24.

**Box 17.24**

**World Health Organization classification of acute leukaemia**

**Acute myeloid leukaemia**

- AML with recurrent genetic abnormalities
- AML with MDS-related changes
- Therapy-related myeloid neoplasm
- AML, not otherwise categorized

**Acute lymphoid leukaemia**

- B-cell lymphoblastic leukaemia/lymphoma

*These entities correspond with the French–American–British classification. MDS, myelodysplastic syndrome.

(Modified from Jaffe ES, Harris NL, Stein H et al. (eds). *World Health Organization Classification of Tumours. Pathology and Genetics of Tumours of Haematopoietic and Lymphoid Tissues*. Lyon: IARC Press; 2008, with permission from the World Health Organization.)

**Clinical features**

The majority of patients with acute leukaemia, regardless of subtype, present with symptoms (Box 17.25) reflecting inadequate haemopoiesis secondary to infiltration of the bone marrow by leukaemic cells, symptoms due to tissue infiltration by leukaemic cells (Box 17.26), the consequences of a high white blood cell count, or substance release from the tumour cells.

### Box 17.26

**Characteristics of blast cells**

- A blast cell is an immature precursor of myeloid cells (myeloblasts) or lymphoid cells (lymphoblast)
- They are bigger than their normal counterparts
- There is an immature nucleus (nucleolus, open chromatin)
- Cytoplasmic appearances are often atypical
• They are rarely seen in normal individuals
• If present, they are highly suggestive of an acute leukaemia or a chronic disorder that is beginning to transform into an acute disease, e.g. transformed myeloproliferative neoplasms, MDS-RAEB, CML blast crisis.

CML, chronic myeloid leukaemia; MDS-RAEB, myelodysplastic syndrome-refractory anaemia with excess blasts.

Investigations

For confirming diagnosis

• Blood count. Haemoglobin is low, the white blood cell count is usually raised (sometimes low) and platelets are low.

• Blood film. Blast cells are almost invariably seen *(Fig. 17.18A)*; lineage may be identified morphologically, e.g. the presence of Auer rods is consistent with a diagnosis of AML.
• **Bone marrow aspirate.** Increased cellularity *(Fig. 17.18B)*, reduced erythropoiesis and reduced megakaryocytes may be seen. Replacement by blast cells is >20% (often approaching 100%). Lineage is confirmed by immunophenotyping, e.g. AML – CD33 or CD13; B lineage ALL – CD10 and CD19; and T lineage – CD3. Cytogenetic and FISH analysis, as well as real-time PCR and molecular genetics, may be used for prognostication.

• **Chest X-ray.** Mediastinal widening is often present in T-lymphoblastic leukaemia.

• **Cerebrospinal fluid examination.** This is performed in all patients with ALL, as the risk of central nervous system involvement is high. It is less critical in AML.

• **Coagulation profile.** This is performed to exclude the presence of disseminated intravascular coagulation (DIC): raised prothrombin time and activated partial thromboplastin time, reduced fibrinogen, and increased fibrinogen degradation products, e.g. D-dimers.

### For planning therapy

• Biochemistry, serum urate, renal and liver biochemistry.

• Cardiac function: electrocardiography and direct tests of left ventricular function, e.g. echocardiogram (see pp. 944–948).

• HLA type.

• Check HBV status (p. 456).

### Management

Untreated acute leukaemia is invariably fatal, most often within a few months, though with judicious palliative care it may be extended, perhaps to a year. Treatment with curative intent may be successful, or may fail, either because the leukaemia does not respond (i.e. refractory to treatment), because the disease returns after an initial favourable response (relapse), or because the patient succumbs to complications of the therapy (treatment-related mortality). At initial presentation, acute leukaemias range from being probably curable (e.g. childhood ‘good-risk’ ALL) through to probably incurable (e.g. AML with adverse cytogenetic features in the elderly). Since curative treatment carries considerable morbidity and potential mortality, it is essential for the ‘risk/benefit’ ratio to be clearly understood by physician and patient alike.

### Palliative therapy

Every attempt should be made to ensure that the patients are at home as much as possible, while making available the full range of supportive care. Palliation may well include low-dose chemotherapy in addition to blood product support and antimicrobials.

### Curative therapy

The decision to treat with curative intent, particularly if successful, implies severe disruption of normality for the patient and family for at least 6 months and often up to a year. In the short
term, it may demand transfer to another hospital, as acute leukaemia should only be treated in units seeing a sufficient number of patients. It is highly likely to involve admission to hospital for up to a month in the first instance, with further, partly predictable, subsequent admissions of several days' to weeks' duration, requiring discussions and decisions about work or education. The decision to treat with curative intent implies that the chance of cure justifies the risks of the therapy. It does not imply that cure is guaranteed or even expected.

**Active therapy**

**Supportive care**

This forms the basis of treatment, whether for cure or palliation:

- **Avoidance of symptoms of anaemia** (haemoglobin >80–100 g/L). Repeated transfusion of packed red cells is needed (sometimes, irradiation of cells is required)

- **Prevention or control of bleeding** (platelet count <10 × 10⁹/L in the stable patient and <20 × 10⁹/L in the septic patient, or <50 × 10⁹/L if a procedure is planned, e.g. lumbar puncture). The role of prophylactic platelet transfusion has been evaluated and remains superior to any alternative, certainly for patients with AML.

- **Correction of coagulation abnormalities**. This is achieved with fresh frozen plasma (FFP) to keep the activated partial thromboplastin time ratio and INR <1.5 times normal, and with cryoprecipitate to keep the fibrinogen level >1.5 g/dL. Norethisterone is given to women of menstrual age to avoid menorrhagia during their thrombocytopenic phase.

- **Leucopheresis**. This may be required to reduce the white cell count rapidly before the chemotherapy has started to be effective.

- **Treatment of infection** (see **Box 17.22**):

  - **Prophylactic**. Education of patients, relatives and staff about diet, hand washing and isolation facilities is necessary. Selected antibiotics, antifungals, antivirals and *Pneumocystis jirovecii* prophylaxis may be required.

  - **Therapeutic**. Fever is managed using local protocol/algorithm for antibiotic and antifungal combinations.

- **Control of hyperuricaemia**. This should be achieved with hydration, prophylactic allopurinol and occasionally rasburicase (see p. 606).

  Indwelling venous devices, such as a Hickman line, are required to allow easy access to the blood for tests and administration of therapy. Sperm banking is offered to postpubertal men and oocyte collection to women, if there is time before treatment.

**Specific treatment**

The initial requirement of therapy is to return the peripheral blood and bone marrow to normal (complete remission, CR). This ‘induction chemotherapy’ is tailored to the particular leukaemia and the individual patient's risk factors. Since this treatment is not leukaemia-specific but also impairs normal bone marrow function, it leads to a major risk of life-
threatening infection, which increases the risk of early death in the short term.

Successful remission induction is always followed by further treatment (consolidation). Details are determined by the type of leukaemia and by the patient’s risk factors and tolerance of treatment. Recurrence is almost invariable if ‘consolidation’ therapy is not given. This reflects the lack of sensitivity of the definition of ‘complete remission’, which has been solely morphological. Cytogenetics and molecular genetic techniques can, however, identify residual leukaemic cells not detected morphologically (‘minimal residual disease’, MRD) and they are highly predictive of recurrence. Failure to achieve morphological CR with two cycles of therapy (‘refractory’) carries almost as bad a prognosis as the untreated leukaemia. If CR can be achieved – by new experimental approaches, for instance – cure may still be possible with stem cell transplantation (see pp. 561–562). A small proportion of patients with refractory disease may also be cured by a myeloablative allograft.

**Acute myeloid leukaemia**

In AML, the prognosis is dependent on a range of key variables, the two main ones being age and cytogenetics *(Fig. 17.19 and Box 17.27).*

![Graph showing prognosis related to cytogenetics and molecular data in acute myeloid leukaemia (AML). Outcome of younger adults with AML treated in the Medical Research Council AML10 and AML12 trials, stratified according to cytogenetic and molecular abnormalities. (Reproduced with permission from Smith ML, Hills RK, Grimwade D. Independent prognostic variables in acute myeloid leukaemia. Blood Reviews 2011; 25(1):39–51.)*
Box 17.27

Risk factors in acute myeloid leukaemia

Good risk

• *De novo* disease
• Favourable cytogenetics: t(15; 17) t(8; 21) or inv(16) or its variant t(16; 16)
• CEBPA bi-allelic mutation
• NPM1 mutation with FLT3 wild type

Poor risk

• Age >60
• Male gender
• Secondary disease, e.g. prior MDS or MPN
• High WBC
• Adverse cytogenetics: −5, del(5q), −7, abnormal 3q26 or a complex karyotype
• FLT3 internal tandem duplication mutation
• MRD positivity

CEBPA, transcription factor CCAAT/enhancer binding protein; FLT3, FMS-like tyrosine kinase 3; MDS, myelodysplastic syndrome; MPN, myeloproliferative neoplasm; MRD, minimal residual disease; NPM1, nucleophosmin; WBC, white blood cell count.

Management

**Young patients: intensive therapy unless unfit**

Treatment with curative intent is undertaken in the majority of adults below the age of 60 years, provided there is no significant co-morbidity. Treatment success reflects the cytogenetic pattern. Those with ‘favourable risk’ disease (e.g. inv(16) or t(8; 21) karyotypes, or solely NPM1-mutated AML, or AML with the bi-allelic transcription factor CCAAT/enhancer binding protein (CEBPA) mutation) are treated with moderately intensive combination chemotherapy. This always includes an anthracycline such as daunorubicin and cytarabine (cytosine arabinoside) and consolidation with a minimum of four cycles of treatment given at 3–4-week intervals. Patients with favourable-risk disease do not benefit from allogeneic stem cell transplantation during their first complete remission because the risks outweigh the benefits. Those with ‘intermediate-risk’ cytogenetics (e.g. normal karyotype, +8, +21) are a heterogeneous and increasingly complex group. Where possible, they should be given consolidation chemotherapy after an initial remission has been achieved, followed by allogeneic transplantation in those deemed at increased risk of relapse because of risk factors,
such as FLT3 internal tandem duplication. Patients with adverse cytogenetics (e.g. −7, −5, complex karyotype) should proceed to a stem cell transplant in first complete remission (CR1) because they respond poorly to conventional chemotherapy and have a high risk of relapse.

CR will be achieved in about 80% of patients under the age of 60. Failure is due to either resistant leukaemia (10%), or death due to infection or bleeding (10%). Approximately 50% of those entering complete remission will be cured (i.e. approximately 40% overall), although this varies from 60–70% in the favourable cytogenetic group to 10–20% in the adverse cytogenetic group.

Older patients: intensive versus non-intensive strategies

The initial treatment of the older patient (>60 years) is much more contentious. A decision needs to be taken initially as to whether the patient is ‘fit’ enough to tolerate intensive chemotherapy. This will require a full assessment of their co-morbidities and organ function. Older patients tolerate cytotoxic therapy less well than younger patients due to additional co-morbidities, and their disease is often more aggressive in its biology; for example, adverse cytogenetics are more common with increasing age. As a result, treatment-related morbidity and mortality are both higher and outcome is less successful. Reduced-intensity allogeneic transplantation is increasingly being used for this group but is limited by its toxicity. For those who are not fit for intensive chemotherapy, treatment will have a palliative aim to improve marrow function and to maximize quality of life. Choice of therapy will include low-dose cytarabine, azacitidine, oral cytotoxics (such as hydroxycarbamide) or enrolment into any one of a range of clinical trials of novel agents.

Relapsed AML

The management of recurrence is undertaken on an individual basis, since the overall prognosis is very poor, despite the fact that second remissions may be achieved. Long survival following recurrence is rarely achieved without allogeneic transplantation. New therapy should be considered. The use of minimal residual disease monitoring may allow the detection of a subgroup of patients during initial therapy who require treatment intensification, such as allograft, as well as patients in CR who are in the early stages of relapse and need pre-emptive therapy before frank marrow relapse occurs.

Newer agents that target the FLT3 mutation, present in a significant proportion of cases of AML, are in clinical trials in conjunction with conventional chemotherapy. Other novel therapies that are being considered in AML include chemotherapy-labelled monoclonal antibodies (gemtuzumab ozogamicin) and hypomethylating agents (e.g. azacitidine).

Acute promyelocytic leukaemia

Acute promyelocytic leukaemia (APML) is a variant of AML, occurring in 10–15% of cases; it is characterized by the translocation t(15; 17) and has particular morphological features. There is an almost invariable coagulopathy, which remains a major cause of early death. The
empirical discovery that all-trans-retinoic acid (ATRA) causes differentiation of promyelocytes and rapid reversal of the bleeding tendency was a major breakthrough. APML is treated with ATRA combined with several courses of chemotherapy. Complete remission and molecular remission occur in at least 90% of younger adults with APML, and at least 70% will expect to be cured. Transplantation may be necessary either if the leukaemia is not eliminated at the molecular level, or following recurrence and re-induction therapy. Arsenic trioxide, which induces apoptosis via activation of the caspase cascade (see p. 105), is used in resistant or relapsed disease and is under investigation as first-line therapy.

### Acute lymphoblastic leukaemia

This condition may present in leukaemic phase with significant marrow involvement (acute lymphoblastic leukaemia, ALL) or may present as localized disease, typically a mediastinal mass (lymphoblastic lymphoma). The tumour cells in each condition are indistinguishable and similar therapies are therefore used. The overall strategy for the treatment of ALL differs in detail from that for AML. Remission induction is undertaken with combination chemotherapy that includes vincristine, a glucocorticoid, an anthracycline and asparaginase. Once remission is achieved, the details of consolidation will be determined by the anticipated risk of relapse. Intensive consolidation of remission with variable numbers of chemotherapy cycles comprising cytotoxics with different mechanisms of action has been standard practice, including the administration of high-dose methotrexate. In those patients with high-risk features (see below) or an HLA-matched sibling donor, allogeneic transplantation is recommended on achieving CR1.

A major difference between therapy for ALL and AML is the need for central nervous system-directed therapy. Prophylaxis should be given with intrathecal chemotherapy under platelet cover if necessary, as soon as blasts are cleared from the blood. Depending on risk, this may be continued for up to 2 years and complemented by high doses of systemic cytarabine or methotrexate. Cranial irradiation was previously given to all patients to reduce the risk of relapse within the central nervous system; some risk-adapted strategies reserve this only for those patients at very high risk.

Additionally, after intensive induction and consolidation, maintenance therapy for 2 years is required to reduce the risk of disease recurrence. This typically comprises 2 years of treatment with methotrexate and mercaptopurine, although more intensive regimens are used by many groups.

### Prognosis

A number of clinical and laboratory features are determinants of treatment response and survival in ALL (Box 17.28). Increasingly, therapeutic strategies based on prognostic risk are being used in management of the disease. Minimal residual disease (MRD) stratification is increasingly employed to select out patients who are at high risk (for treatment intensification) or low risk (for treatment de-escalation).

CR, complete remission; CSF, cerebrospinal fluid; MRD, minimal residual disease; WBC, white blood cell count.

The prognosis (Fig. 17.20) of ALL in childhood is now excellent: complete remission is achieved in almost all, with up to 80% being alive without recurrence at 5 years. Failure occurs most frequently in those with high presentation blast counts or an 11q23 $MLL$ translocation. Current treatment strategies lessen therapy for ‘good-risk’ children in order to avoid some of the long-term consequences of therapy, such as avascular necrosis of bone, infertility, neurotoxicity and cardiotoxicity.

The situation is far less satisfactory for adults, the prognosis getting worse with advancing years. Co-morbidity and t(9; 22) translocation increase in frequency with age. Overall, the CR rate is 70–80%. Disease that is refractory to first-line therapy carries a very poor prognosis.
Between 30% and 40% of patients continue in durable first remissions, resulting in approximately 25–30% overall patient cure. Increasing numbers of patients are receiving transplants for this condition, including those with sibling donors and those high-risk individuals who have an available unrelated or alternative donor. Imatinib used in conjunction with chemotherapy increases the response rate and quality of response in patients with the t(9; 22) translocation and ALL. As with AML, most recurrences occur within the first 3 years and the outcome is extremely poor. Second remissions, though usually achieved, are rarely durable, except following allogeneic transplantation. Isolated extramedullary recurrences, however, may be cured. Novel cytotoxics drugs, including clofarabine and nelarabine, are increasingly used for relapsed/refractory cases. A range of monoclonals are currently under evaluation for use in B-ALL, including rituximab (anti-CD20), inotuzumab (calicheamicin-labelled anti-CD22) and blinatumomab (CD19/CD3 bi-specific T-cell engager antibody).

**Chronic leukaemias**

**Chronic myeloid leukaemia**

Chronic myeloid leukaemia (CML), which accounts for about 14% of all leukaemias, is a member of the family of myeloproliferative neoplasms (MPNs); it is almost exclusively a disease of adults, the peak of presentation being between 40 and 60 years. It is defined by the presence of the Philadelphia chromosome (*Fig. 17.21*), which is demonstrated either cytogenetically (95%) or molecularly (5%). Unlike the acute leukaemias, which are either rapidly reversed or rapidly fatal, CML has a more slowly progressive course; if not initially cured, it will be followed eventually by ‘blast crisis’ transformation to acute leukaemia (75% myeloid, 25% lymphoid) or myelofibrosis with death in a median of 3–4 years.
The Philadelphia chromosome (Ph). A. The long arm (q) of chromosome 22 has been shortened by the reciprocal translocation with chromosome 9. B. The Philadelphia chromosome is formed by a reciprocal translocation of part of the long arm (q) of chromosome 22 to chromosome 9. It is seen in 90–95% of patients with chronic myeloid leukaemia. The karyotype is expressed as 46XX, (9;22)(q34;q11).

Clinical features
CML usually presents in the chronic phase and some patients have no symptoms.
**Symptoms**

When present, symptoms include:

- symptomatic anaemia (e.g. shortness of breath)
- abdominal discomfort due to splenomegaly
- weight loss
- fever and sweats in the absence of infection
- headache (occasionally) or priapism due to hyperleucocytosis
- bruising and bleeding (uncommon).

**Signs**

These include:

- pallor
- splenomegaly, often massive
- lymphadenopathy (uncommon; suggests blast crisis)
- extramedullary soft tissue leukaemic deposit – ‘chloroma’ (indicates blast crisis)
- retinal haemorrhage due to leucostasis.

**Investigations**

- **Blood count.** Haemoglobin is low (normochromic and normocytic) or normal; the white blood cell count is raised (usually >100 × 10⁹/L); and platelets are low, normal or raised.
- **Blood film.** There is neutrophilia with the whole spectrum of mature myeloid precursors. Basophils and eosinophils are elevated. Increased numbers of blasts are suggestive of an accelerated phase or blast crisis *(Fig. 17.22).*

![FIGURE 17.22](image-url)

*Blood film showing blast cells (arrow) in chronic myeloid leukaemia.*

- **Bone marrow aspirate.** Increased cellularity is seen, with increased myeloid precursors. Cytogenetics reveals a t(9; 22) translocation (the Philadelphia chromosome; see *Fig. 17.21B*).
- **FISH (Fig. 17.23)** or **RT-PCR** is used to demonstrate the cytogenetic/molecular abnormality.
These tests are also used to monitor response to therapy quantitatively.

**FIGURE 17.23** Fluorescence *in situ* hybridization photomicrograph of a patient with chronic myeloid leukaemia. A. 17p (green probe) and 11q (red probe) shows two green signals (TP53 deletion) with normal diploid complement of 11q. B. 12 centromere (green probe) and 13q14 (red probe) shows three green signals (trisomy 12) with normal diploid complement of 13q. (Courtesy of Debra Lillington, Barts and the London NHS Trust.)

### Management

Treatment has been transformed by the advent of imatinib, a tyrosine kinase inhibitor that specifically blocks the enzymatic action of the BCR-ABL fusion protein, and is now first-line treatment for the chronic phase. Imatinib produces a complete haematological response in over 95% of patients, and 70–80% of these have no cytogenetically detectable Ph+ cells in the marrow (complete cytogenetic remission). A significant proportion will lose molecularly detectable BCR/ABL transcripts from the blood, achieving a molecular remission (MR) of varying depths: MR3 (a 3 log reduction; <0.1%), MR4 (<0.01%) or MR5 (<0.001%). Event-free and overall survival appears to be better than for other treatments. Side-effects of imatinib include nausea, headache, rashes and cytopenia. Imatinib can be continued indefinitely, although it should be stopped before attempts to conceive. Resistance to imatinib as a single agent may develop as a result of secondary BCR/ABL kinase mutations beyond t(9; 22). The use of second-generation TKis, dasatinib and nilotinib, may restore haematological or molecular remissions in those patients in the chronic phase that have primary or acquired resistance to imatinib, or are intolerant of imatinib. Both dasatinib and nilotinib have demonstrated promise in the first-line setting, although it remains to be seen whether their advantage over imatinib in speed and depth of response is sustained over time. Bosutinib and ponatinib are also available for intolerant or resistant patients.

In the acute phase (blast transformation), most patients have only a short-lived response to imatinib and other chemotherapy, as for acute leukaemia, and stem cell transplantation is used in the hope of achieving a durable remission.

### Stem cell transplantation.

Allogeneic haemopoietic stem cell transplantation (HSCT; pp. 561–562) can cure approximately 70% of chronic-phase CML patients. It is now used in those with an inadequate
response to imatinib or disease progression on therapy.

### Chronic lymphocytic leukaemia

Chronic lymphocytic leukaemia (CLL) is the most common leukaemia, occurring predominantly in later life and increasing in frequency with advancing years (median age of presentation is between 65 and 67 years). It results from the clonal expansion of small B lymphocytes. The majority of patients are asymptomatic, and are identified as a chance finding on a blood count performed for another indication. Others, however, present with the features of marrow failure or immunosuppression. The median survival is about 10 years and prognosis correlates with clinical stage at presentation (Box 17.29). A number of cytogenetic and molecular abnormalities are now recognized as being of prognostic significance (see below). This condition may present in leukaemic phase with significant marrow/blood involvement (CLL), or may present as localized disease (small lymphocytic lymphoma, SLL). The tumour cells in each condition are indistinguishable and a similar therapeutic approach is therefore used. A pre-malignant condition, monoclonal B cell lymphocytosis (MBL), exists where there are less than the $5 \times 10^9$/L B cells required for a diagnosis of CLL. Some of these have a CLL phenotype and may progress to CLL.

\(^a\) Lymphocytosis is present in all stages of the disease. \(^b\) Progression is defined by weight loss, fatigue, fever, massive organomegaly and a rapidly increasing lymphocyte count. \(^c\) Lymphoid areas include the cervical, axillary and inguinal lymph nodes, the spleen and the liver. \(^d\) Stage A includes all patients with Rai stage 0 disease, two-thirds of patients with Rai stage I disease, and one-third of those with Rai stage II.

(From Dighiero G, Binet JL. When and how to treat chronic lymphocytic leukaemia. N Engl J Med 2000; 343:1800, with permission.)

**Clinical features**

The majority of patients are asymptomatic at presentation. Common symptoms are:

- recurrent infection because of (functional) leucopenia and immune failure (reduced immunoglobulins)
- anaemia due to haemolysis or marrow infiltration
- painless lymphadenopathy
- left upper quadrant discomfort (from splenomegaly).

The most common findings on examination are:

- anaemia
- fever (due to infection)
- lymphadenopathy (may involve a single area or be generalized)
- hepatosplenomegaly, sometimes massive.

However, none of these may be present.

**Investigations**

- **Blood count** reveals a normal or low haemoglobin; a raised white blood cell count, which
may be very high; lymphocytosis (criteria for diagnosis >5 × 10⁹/L); and normal or low platelets.

- **Blood film** demonstrates small or medium-sized mature and normal-appearing lymphocytes. Smudge cells may be seen *in vitro*. No immature blasts are evident.
- **Bone marrow** reflects peripheral blood, often very heavily infiltrated with lymphocytes.
- **Immunophenotyping** shows mainly CD19+, CD5+ or CD23+ B cells with weak expression of CD20, CD79b and surface immunoglobulin (kappa and lambda light chains).
- **Cytogenetics/FISH analyses** are not essential for diagnosis but help in the assessment of prognosis (see *Fig. 17.23*).
- **Direct Coombs' test** may be positive if there is haemolysis.
- **Immunoglobulins** are low or normal.

### Prognosis

The clinical course of CLL is variable. Several biomarkers are used to supplement clinical stage and have been shown to predict progression and survival. Cytogenetic abnormalities are detected in >90% of cases. Patients with an isolated deletion of 13q have an excellent prognosis, in contrast to those with either 11q deletion or 17p deletion (sites of the tumour suppressor genes *ATM* and *TP53*, respectively), who tend to have a rapidly evolving clinical course. In those tumours that demonstrate a high level of mutation within the variable region of the rearranged immunoglobulin heavy chain (IgVH) (‘mutated’), the clinical course is more indolent than in those where the IgVH sequence more closely resembles that of the germline (‘unmutated’). Expression of ZAP70, a 70-kDa tyrosine kinase protein, correlates well with mutational status. Patients with <20% expression of ZAP70 have median 10-year survival of >50%; in >20% expression, the median survival is <5 years. High expression of CD38 on leukaemic cells may also indicate adverse prognosis.

### Management

In CLL, the major consideration is when to treat; indeed, 30% of patients will never require intervention. Treatment depends on the ‘stage’ (*Box 17.29*) of the disease. Early-stage disease is usually managed expectantly, advanced-stage disease is always treated immediately; and the approach to the intermediate stage is variable. Absolute indications for treatments are:

- marrow failure, manifest by worsening anaemia and/or thrombocytopenia
- recurrent infection
- massive or progressive splenomegaly or lymphadenopathy
- progressive disease manifest by doubling of the lymphocyte count in 6 months
- systemic symptoms (fever, night sweats or weight loss)
- presence of haemolysis or other immune-mediated cytopenias.
**General/supportive treatment**

Anaemia due to haemolysis is treated with steroids. Anaemia and thrombocytopenia caused by marrow infiltration is treated with chemotherapy and, when necessary, transfusion. Erythropoietin (see p. 519) may avoid the need for transfusions, particularly in patients receiving chemotherapy. Infection is treated as indicated, with prophylactic antibiotic, antiviral, anti- *Pneumocystis* and antifungal therapy potentially being given during periods of chemotherapy. Immunoglobulin replacement may be helpful, as well as pneumococcal and influenza vaccination. Allopurinol is given to prevent hyperuricaemia.

**Specific treatment**

Choice of therapy will depend on patient-related factors, such as age and co-morbidity, adverse prognostic features, and anticipated response and toxicities to therapy. Intervention, when indicated, usually causes improvement in symptoms and blood count. The effect on survival is unclear. There is a range of therapies available and these must be tailored to the patient's age, fitness, prior therapy exposure and concurrent co-morbidities. Those individuals with adverse cytogenetics are a particularly difficult group to treat.

- **Purine analogues**, fludarabine alone or in combination with cyclophosphamide or mitoxantrone (with or without steroids), can induce complete remissions (and MRD-negative remissions), although they are not helpful in patients with 17p deletion or TP53 mutation.
- **Rituximab** used as combination therapy shows a dramatic improvement in response rate, and **FCR** (fludarabine, cyclophosphamide, rituximab) has become the standard of care as first-line therapy.
- **Chlorambucil** usually reduces the white cell count in older patients and decreases lymphadenopathy and splenomegaly to palliate the disease successfully. Bendamustine is an alternative alkylator that may be appropriate for first-line therapy in older and less fit patients who cannot tolerate FCR.
- **Alemtuzumab**, a humanized monoclonal antibody targeting CD52, which is highly expressed in B-CLL, is used in those patients that progress after fludarabine or who have 17p deletion or TP53 mutation.
- **Ofatumumab** is a new-generation anti-CD20 monoclonal antibody that binds to a different epitope to that of rituximab and is used for treatment of fludarabine- or alemtuzumab-refractory CLL. **Obinutuzumab** (GA101) is another novel anti-CD20 monoclonal antibody with type 2 binding, associated with increased direct cell death effects. In combination with chlorambucil, it has been shown to be superior to either chlorambucil alone or chlorambucil with rituximab.
- **Allogeneic stem cell transplantation** with non-myeloablative conditioning regimens is increasingly performed.

Novel drugs at varying stages of evaluation include lenalidomide and ABT-199 (a BCL-2 inhibitor), as well as three fascinating small molecules that work downstream of the B-cell
receptor: ibrutinib (an inhibitor of the enzyme Bruton's tyrosine kinase, BTK), acalabrutinib (a selective inhibitor of BTK), and idelalisib (an inhibitor of phosphoinositide 3-kinase delta, PI3Kδ). These inhibit malignant B-cell survival signalling and disrupt B-cell localization in protective niches within lymph nodes. The consequence is a lymphocytosis, as tumour cells are displaced into the peripheral blood. Current trials are looking at combining these agents with conventional cytotoxics and monoclonals, and evaluating their place in current treatment algorithms.

**Lymphomatous transformation**

CLL may undergo lymphomatous (Richter's) transformation in 5–10% of cases, most typically to diffuse large B-cell lymphoma, although Hodgkin's-like transformation is recognized. In the main, response to cytotoxic chemotherapy is unsatisfactory and survival short.

**Hairy cell leukaemia**

Hairy cell leukaemia (HCL) is a clonal proliferation of abnormal B (or, very rarely, T) cells, which, as in CLL, accumulate in the bone marrow and spleen. It is a rare disease; median age at presentation is 52 years and the male to female ratio is 4 : 1. The bizarre name relates to the appearance of the cells on a blood film and in the bone marrow: they have an irregular outline owing to the presence of filament-like cytoplasmic projections. V600E BRAF mutations (see pp. 1373–1374) are seen in the majority of cases.

**Clinical features**

Clinical features include anaemia, fever and weight loss. Splenomegaly occurs in 80%; lymphadenopathy is uncommon. Anaemia, neutropenia, thrombocytopenia and low monocyte counts are found.

**Management**

The purine analogues 2-chloroadenosine acetate (2-CDA; cladribine) and pentostatin have specific activity in this condition; complete remission is achieved in 90% with just one cycle of treatment. The remissions can last for many years and patients can be successfully retreated. Rituximab is used in cases that do not respond to the above drugs.

**Further reading**

The Lymphomas

The lymphomas are malignancies of the lymphoid system and hence may arise at any site where lymphoid tissue is present. Certain subtypes have increased in frequency over the past 50 years for reasons that are not clear, the overall incidence being 15–20 per 100 000 population, which makes them the fifth most common malignancy in the Western world. Most commonly, patients have peripheral lymphadenopathy or symptoms due to occult lymph nodes, although approximately 20% arise at primary extranodal sites. A relatively small proportion present with lymphoma-associated ‘B’ symptoms of weight loss, fever and sweats. The natural history and clinical course are determined by the pathological subtype, classified by histological, immunological and molecular criteria, the distribution of the disease (‘stage’), non-specific prognostic features and general co-morbidity.

A significant proportion of patients are cured and many others are helped, in terms of both quality and length of life.

The increasingly complex WHO classification of tumours of haemopoietic and lymphoid tissues primarily distinguishes Hodgkin's lymphoma from non-Hodgkin's lymphoma, an umbrella term covering a multiply subclassified spectrum of B- and T-cell malignancies, reflecting the stage of lymphoid development at which they arise. Thus, lymphoblastic lymphoma and lymphoblastic leukaemia are considered as a single entity, as are small lymphocytic lymphoma and chronic lymphatic leukaemia, both discussed in the section above.

Overall management strategy common to all lymphomas

A suspected diagnosis of lymphoma should always be confirmed by an excision biopsy of the relevant tissue large enough to allow histological, immunological and molecular analysis. Cutting needle biopsy is an acceptable substitute for biopsy of impalpable, ‘occult’ disease but fine needle aspiration is inadequate. The opinion of an expert haemato-pathologist is essential.

Investigations

The diagnosis having been established, treatment strategy and details will depend on the outcome of investigations that are common to all the lymphomas. These investigations are conducted to provide a basis for prognostication and treatment decisions, against which the
outcome of treatment may be assessed (*Box 17.30*), ‘stage’ being assigned notionally to the modification of the Ann Arbor classification for all nodal lymphomas, despite the fact that this was planned only for Hodgkin’s disease.

**Box 17.30**

*Investigation of the patient with lymphoma*
For diagnosis

- Clinical history and examination
- Chest X-ray for mediastinal widening (see Fig. 17.25)
- CT scan of chest, abdomen, pelvis ± neck
- PET scan (see Fig. 17.26)
- ± Bone marrow biopsy (for stage III or IV, or HIV-positive patients, or patients with B symptoms)
- Blood count, differential, film

For planning specific therapy

- Electrolytes and renal function, liver function tests and biochemistry
- Serum uric acid
- Virology: HIV, hepatitis B and C
- Cardiac function
- Respiratory function
- Fertility

Depending on circumstances. CT, computed tomography; PET, positron emission tomography.

The tests listed in Box 17.30 are essential for planning specific therapy. Serum uric acid measurement is helpful, particularly in those lymphomas that carry a risk of tumour lysis syndrome (see p. 606); tests of cardiac function are valuable when potentially cardiotoxic chemotherapy is to be recommended, as is assessment of HIV and hepatitis B and C status.

Once a decision to ‘treat’ has been made, a course of treatment will begin, during which benefit will be assessed at appropriate intervals, and subsequent to which complete re-evaluation (‘re-staging’) will be performed. Depending on the outcome, future plans will be made. In the event of a decision to stop treatment, surveillance will, in the first instance, be close, the interval between attendances being extended with the passage of time. Beyond 5 years, the focus of attention is on the possible long-term consequences of therapy, rather than the disease itself. When initial therapy has been less successful than wished, management will be dictated by individual circumstances. As conventional treatment becomes exhausted, experimental therapy may be broached.

Hodgkin's lymphoma

Hodgkin's lymphoma (HL) has an incidence of approximately 3 per 100 000 in the Western world; there is a male predominance of approximately 1.3 : 1. The majority of cases occur between the ages of 16 and 65, with a peak in the third decade. The incidence is stable.
Aetiology

There is epidemiological evidence linking previous infectious mononucleosis with HL; up to 40% of patients with HL have increased Epstein–Barr virus (EBV) antibody titres at the time of diagnosis, and EBV DNA has been demonstrated in tissue from patients with HL. These data suggest a role for EBV in pathogenesis. Other viruses have not been detected. Other environmental and occupational exposures to pathogens have been postulated.

Diagnosis

Hodgkin's lymphoma is subclassified, according to the WHO classification (Box 17.31), into:

- **Classical Hodgkin's lymphoma (cHL)**, the hallmark of which is the Reed–Sternberg cell (*Fig. 17.24*). cHL accounts for 90–95% of cases and is further subdivided into four distinct categories.

- **Nodular lymphocyte predominant HL (NLPHL)**, characterized by the Reed–Sternberg cell variant, the ‘popcorn cell’.

Clinical features

The most common presentation of HL is painless cervical lymphadenopathy, commonly described in examination as ‘rubbery’. Other causes of cervical lymphadenopathy are shown on page 606. A smaller proportion of patients (often young women) present with disease localized to the mediastinum, with cough due to mediastinal lymphadenopathy (Fig. 17.25); others present with ‘generalized disease’, including hepatosplenomegaly and constitutional ‘B’ symptoms. Other less common symptoms, undoubtedly associated with HL but not recognized in the staging classification, are pruritus and alcohol-related pain at the site of lymphadenopathy.

FIGURE 17.24 Histological appearance of Hodgkin’s lymphoma. Scattered mononuclear Hodgkin’s cells and a classical malignant binucleate Reed–Sternberg cell (arrowed) are seen to the right of centre on a background of benign small lymphocytes and histiocytes. (Courtesy of Dr AJ Norton.)

FIGURE 17.25 Chest X-ray of a mediastinal mass (arrowed) that is due to Hodgkin’s lymphoma.
These are summarized in **Box 17.30**. Bone marrow biopsy is indicated only in patients with clinically advanced disease (stage III or IV), those with ‘B’ symptoms and those who are HIV-positive. The clinical utility of the PET scan is becoming established in the management of HL (**Fig. 17.26**) to stage a patient accurately and to establish sites of extranodal disease.

Malignant lymphoma: mediastinal mass on CT scan (left), shown to be metabolically inactive on PET (centre) and PET/CT (right). (Courtesy of Dr N Avril.)

‘Stage’ is currently assigned according to the Cotswolds modification of the Ann Arbor classification, although this is under review (**Box 17.32**). The Hasenclever score is used for prognostication (**Box 17.33**); however, its relevance to treatment planning is limited because of the very small number of patients at high risk of standard treatment failure. On the basis of ‘stage’ and other prognostic factors, patients with HL are divided into three groups (**Box 17.34**).

Management

Principles of management

Management is aimed towards a curative intent with expectation of success. However, in patients with NLPHL, who usually present with stage I disease with longstanding lymphadenopathy, an expectant policy with close surveillance is followed. Older patients, with or without co-morbidity, require considerable modification of therapy and there is an expectation of success. Patients with HIV infection should be managed, in conjunction with their HIV clinicians, in the same way as those who are seronegative.

Treatment of early-stage, ‘low-risk’ disease

‘Moderate’ chemotherapy, comprising 2–4 cycles of doxorubicin, bleomycin, vinblastine and dacarbazine (ABVD), non-sterilizing and of a low second cancer risk, followed by involved field irradiation (20–30 Gy), has replaced large field irradiation (see p. 604), with 90% being cured. Current trials are evaluating the role of PET scanning to see if patients who become ‘PET’-negative' after chemotherapy can be spared irradiation altogether. NLPHL is strongly CD20-positive and, as such, is often treated with retuximab-ABVD chemoimmunotherapy.

Treatment of advanced disease (including locally advanced, unfavourable, early-stage)

This is also curable for a significant proportion of patients, having a median survival easily exceeding 5 years for 50–60%. Cyclical chemotherapy with 6–8 cycles of ABVD, with involved field irradiation to sites which were initially bulky, or at which there is ‘persistent disease’ after chemotherapy, is standard. Increasingly, the data from studies incorporating PET scanning, both part way through and after planned chemotherapy, have shown that PET-positive masses are likely to represent fibrous tissue; in this situation, irradiation may be omitted.

The major short-term toxicity relates to myelosuppression and mucositis, the mortality being no more than 1% and the long-term risks being to the heart and lungs. Infertility and second malignancy are uncommon.

The above approach fails for about 25% of patients. More intensive treatment programmes,
e.g. BEACOPP with the addition of etoposide (E), procarbazine (P) and prednisolone (P) to the drugs in ABVD, have been tested, with an overall increase in efficacy but greater toxicity profiles (and expense). It remains a challenge to identify those who will be ‘ABVD failures’ at initial presentation. An alternative is to develop ‘risk-adapted’ therapy, based on response to the first two cycles of therapy, again with PET scanning, and then to escalate to more intensive therapy when the response is deemed inadequate, or de-escalate when response is superior.

**Management of failure of initial therapy**

Treatment failure has become a declining problem because of improvements in the outcome of first-line therapy. The median survival from first recurrence is more than 10 years, possibly influenced by the duration of the first remission; it may not be so good if failure occurs after very intensive therapy. Second and third remissions may be achieved with ‘appropriate’ re-induction therapy, consolidated, if possible, with an autograft. Registry data suggest this may be curative for up to 50%, but follow-up only extends to 15 years.

**Experimental approaches**

With such excellent results with first- and second-line conventional therapy, experimental treatment is seldom required. The antigen-targeted immunoconjugate, anti-CD-30–auristatin (SGN-35, brentuximab), has shown great efficacy in phase II trials; it is increasingly being used for relapsed patients and is in clinical trials for first line patients as ABrVD, in comparison to standard ABVD with bleomycin. Allogeneic HSCT following myeloablative conditioning has high treatment-related mortality and morbidity. Reduced-intensity conditioning HSCT, followed, if necessary, by donor lymphocyte infusion, is being investigated.

**Long-term follow-up**

The risks of late effects of therapy, particularly second malignancy and cardiac and endocrine problems, require appropriate and indefinite surveillance of patients at ‘high risk’.

**Non-Hodgkin's lymphomas**

As defined by the WHO classification ([Box 17.35](#)), approximately 80% of non-Hodgkin's lymphoma (NHL) is of B-cell origin and 20% of T-cell origin, there being considerable geographical variation. The incidence has increased, not necessarily for all subtypes, from 5 to 15 per 100 000 per year in the last half century.

---

**Box 17.35**

**Modified WHO classification of lymphoid neoplasms other than ALL (2008)**

**B-cell lymphomas**
**Mature B-cell lymphoma**
- Chronic lymphocytic leukaemia/small lymphocytic lymphoma
- B-cell prolymphocytic leukaemia
- Splenic marginal zone lymphoma
- Hairy cell leukaemia
- Lymphoplasmacytic lymphoma
- Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT-lymphoma)
- Nodal marginal zone B-cell lymphoma
- Follicular lymphoma (aggressive)
- Mantle cell lymphoma
- Diffuse large B-cell lymphoma (aggressive)
- Mediastinal (thymic) large B-cell lymphoma
- Intravascular large B-cell lymphoma
- Primary effusion lymphoma
- Burkitt's lymphoma/leukaemia (highly aggressive)

**T/NK cell lymphomas**

**Mature T/NK cell lymphoma**
- T-cell prolymphocytic leukaemia
- T-cell large granular lymphocytic leukaemia
- Chronic/lymphoproliferative disorder of NK cells
- Aggressive NK cell leukaemia
- Adult T-cell leukaemia/lymphoma (very aggressive)
- Extranodal NK/T-cell lymphoma, nasal type
- Enteropathy-type T-cell lymphoma
- Hepatosplenic T-cell lymphoma
- Subcutaneous panniculitis-like T-cell lymphoma
- Mycosis fungoides
- Sézary syndrome
- Primary cutaneous CD30+ peripheral T-cell lymphoproliferative disorders
- Peripheral T-cell lymphoma, unspecified (aggressive)
- Angioimmunoblastic T-cell lymphoma
- Anaplastic large cell lymphoma (aggressive) ALK-positive
- Anaplastic large cell lymphoma (aggressive) ALK-negative

*ALK, anaplastic lymphoma kinase (gene); ALL, acute lymphoblastic leukaemia; NK,
natural killer.

(Modified from Jaffe ES, Harris NL, Stein H et al. (eds). World Health Organization Classification of Tumours. Pathology and Genetics of Tumours of Haematopoietic and Lymphoid Tissues. Lyon: IARC Press; 2008, with permission from the World Health Organization.)

Aetiology

A family history is associated with a minor increase in risk of lymphoma, and common genetic polymorphisms with only a small risk for an individual may be significant in population terms. Certain inherited syndromes, such as ataxia–telangiectasia and Wiskott–Aldrich syndrome, are associated with an increased risk of lymphoma. The human T-cell leukaemia virus type 1 (HTLV-1) is causally related to adult T-cell lymphoma/leukaemia. Helicobacter pylori is known to ‘cause’ extranodal marginal zone lymphoma in the stomach, and Chlamydia psittaci may be implicated in ocular MALT lymphoma. There is a very strong epidemiological relationship between EBV and endemic Burkitt's lymphoma, and a lesser one with sporadic Burkitt's lymphoma and Hodgkin's lymphoma.

Immune suppression, immunosuppressant drugs, particularly as used for solid organ transplantation, and HIV infection are all associated with an increased incidence of lymphoma. Agricultural work is associated with lymphoma, but no other data show any convincing evidence of a link with occupation or lifestyle. In the majority of individual cases, the cause is unknown.

Pathogenesis

Malignant clonal expansion of lymphocytes occurs at different stages of lymphocyte development, leading to the different subtypes of lymphoma (Fig. 17.27). In general, neoplasms of non-dividing mature lymphocytes are ‘indolent’, whereas those of proliferating cells (e.g. lymphoblastic) are much more ‘aggressive’. Malignant transformation is usually due to errors in gene rearrangements, which occur during the class switch, or gene recombinations for immunoglobulin and T-cell receptors. Thus, many of the errors occur within immunoglobulin loci or T-cell receptor loci. For example, an abnormal gene translocation may lead to the activation of a proto-oncogene, by moving it next to a promoter sequence for the immunoglobulin heavy chains (Ig-H).
The NHLs are subclassified according to the cell of origin (T or B lineage) and the stage of lymphocytic maturation at which they develop (precursor or mature).

**Cytogenetic features**

Burkitt's lymphoma was the first tumour in which a cytogenetic change was shown to involve the translocation of a specific gene (*Box 17.36*). The most frequent change is a translocation between chromosomes 8 and 14, in which the MYC oncogene is translocated from chromosome 8 to a position near the constant region of the immunoglobulin heavy chain gene on chromosome 14, resulting in upregulation of myc. Similar rearrangements involving the light
chain loci are seen in the alternative Burkitt's lymphoma translocations between chromosome 8 and either chromosome 2 or 22. Other somatic cytogenetic abnormalities associated with human lymphoma are the t(14; 18) in follicular lymphoma, involving upregulation of BCL2, or the t(11; 14) in mantle cell lymphoma, involving upregulation of the cell cycle regulator cyclin D1. Gene expression profiling and other molecular techniques are identifying new molecular subclasses of lymphoma with prognostic significance.

MALT, mucosa-associated lymphoid tissue.

Clinical features

The most common presentation overall is with painless lymphadenopathy or with symptoms caused by a lymph node mass. Primary extranodal lymphomas present with soft tissue masses and related symptoms at the relevant site.

The more common subtypes of NHL are described below.

B-cell lymphomas

See Figure 17.28.
**Follicular lymphoma**

This is the second most common NHL (comprising approximately 20% of lymphomas worldwide).

**Clinical features and course**

Follicular lymphoma occurs in middle to late life, being rare in childhood. The majority of patients will present with painless lymphadenopathy at more than one site, although a small proportion will be ill, some with ‘B’ symptoms. In the latter, there should be suspicion that the diagnostic biopsy was not representative. This may be the case when the presenting symptom relates to an abdominal mass but a peripheral node is biopsied. Percutaneous needle biopsy of the abdominal mass may reveal transformation to diffuse large B-cell lymphoma, with potentially different management. Bone marrow infiltration is common in certain subtypes.

There have been dramatic improvements in the outcome of therapy since the introduction of antibody therapy (rituximab), targeting the CD20 antigen expressed on almost all B-cell lymphomas, leading to the development of chemoimmunotherapy; to date, however, the proportion of patients cured has been small. The illness has been shown to regress spontaneously in some cases, which has led to an expectant policy of treatment for many patients. The clinical course following initiation of treatment to date has been that of a remitting–recurring disease, often with several biopsy-proven episodes of lymphadenopathy that are responsive to therapy, albeit usually transiently. Transformation to diffuse large B-cell lymphoma occurs in up to 25% of patients over 15 years and usually heralds a grave prognosis, although this may be improving. Death occurs because of resistant disease, transformed or not, the complications of therapy, or unrelated causes. The median survival now exceeds 10 years. Prognostic factor comprising the FLIPI (follicular lymphoma international prognostic index) are shown in Box 17.37.
Prognostic factors for survival in non-follicular lymphoma (FLIPI)

- Haemoglobin <120 g/L
- >4 nodal sites involved
- Age >60 years
- Stage III or IV disease
- Elevated serum LDH

FLIPI, Follicular Lymphoma International Prognostic Index; LDH, lactate dehydrogenase.

Management

General management

Lymph node biopsy, accompanied by appropriate further investigation, should precede any treatment decision. The ‘well’ patient – variously defined, but certainly having no symptoms, organ impairment, ‘bulky disease’ or evidence of rapid progression or transformation – should be managed expectantly, after a careful explanation of the rationale. This approach is followed by progression mandating therapy in about 2.5 years for half of the patients, with 20% having had some spontaneous regression and 15% having had no treatment more than 10 years from diagnosis. A large trial comparing expectant management against immunotherapy with rituximab, however, showed a very considerable delay before having the first treatment in the rituximab group. The implications of this are unclear. Indications for treatment of low-grade NHL are shown in Box 17.38.

Indications for treatment of low-grade NHL at presentation or progression

- Stage I disease; possibly limited stage II disease
- Advanced disease, i.e. stages II–IV with ‘B’ symptoms
- Organ impairment (i.e. bone marrow failure)
- Bulky disease (i.e. lymph node mass >10 cm)
- Histological transformation
- Progression of lymphadenopathy after expectant management
- Philosophy of physician and patient
**Initial treatment: early disease**

Stage I (possibly stage II) disease is treated with involved field megavoltage irradiation, which almost always induces complete remission, 50% of patients being disease-free after 10–15 years. In terms of overall survival, there are no randomized trials to show this is better than expectant management (i.e. observing and treating if progression occurs). Functional imaging – that is, PET scanning – may identify patients who are in ‘surgical CR’ post biopsy; no therapy is indicated for this group.

**Initial treatment: advanced disease (stages II–IV)**

Chemoimmunotherapy incorporating rituximab is the treatment of choice, having been shown in randomized trials to be superior to chemotherapy alone, in terms of disease-free, progression-free and overall survival. ‘CHOP-R’ (cyclophosphamide, doxorubicin, vincristine and prednisolone plus rituximab) and the less intensive ‘R-CVP’ (rituximab plus cyclophosphamide, vincristine and prednisolone) are both widely used and R-bendamustine is gaining popularity. Over the next few years, it will become clear which chemotherapy is the best for which group of patients. It has been shown that continuing rituximab ‘maintenance’ for 2 years has a dramatic effect on progression-free survival, although any benefits for overall survival remain unclear.

**Second therapy and beyond**

Patients are managed expectantly in the first instance, provided full re-evaluation, including repeat biopsy, reveals no evidence of transformation. A number of options are available, including re-induction of remission with combined chemoimmunotherapy, followed by rituximab maintenance in those not ‘rituximab-resistant’. Myeloablative autologous consolidation chemotherapy is used in younger patients, particularly those in whom the first remission was short. Reduced-intensity conditioning allogeneic HSCT has yielded very impressive results in selected patients and may be curative despite the toxicity of the treatment, due to the presence of a ‘graft-versus-lymphoma effect’ that can be enhanced by escalating doses of donor lymphocyte infusions.

The biggest challenges lie in patients with ‘resistant disease’ and in the treatment of ‘transformation’. A number of experimental agents with new antibodies, immunomodulatory agents and drugs targeted to specific pathways are showing promise.

---

**Prognosis**

There has been a dramatic improvement in the overall survival pattern of follicular lymphoma as the result of introducing anti-CD20 (rituximab) in the treatment of advanced disease. The median survival has been extended, well beyond 10 years in several series, although these may possibly have involved selected patients. Improvements in disease-free survival, after both initial and second-line therapy, are encouraging. It is reasonable to anticipate that further improvement will be seen with the selective use of allogeneic stem cell transplantation and the
new targeted therapies under investigation.

**Diffuse large B-cell lymphoma**

This is the most common adult lymphoma worldwide (increasing in incidence with age) and the second most common lymphoma in childhood, accounting for approximately 30% of all cases. There is a slight male preponderance. There is overlap between classical diffuse large B-cell lymphoma (DLBCL) and Burkitt's lymphoma, certain cases having a germinal centre phenotype and a high proliferative fraction but non-Burkitt morphology and variable occurrence of MYC and BCL2 translocations detected by FISH. Gene expression profiling may, in the future, help place these tumours in the correct category to guide appropriate therapy.

**Clinical features**

The majority of patients present with painless lymphadenopathy, clinically at one or several sites. Intra-abdominal disease presents with bowel symptoms due to compression or infiltration of the gastrointestinal tract. In a small proportion, there is a primary mediastinal presentation, most often in men, with symptoms and signs akin to those of HL. There may be ‘B’ symptoms, which should not be confused with symptoms related to the site of involvement. Investigation will lead to the demonstration of either locally or systemically advanced disease in the majority of cases. The illness is itself rapidly progressive without intervention, death occurring within months rather than years. Approximately 30% of cases present at an extranodal site, as opposed to having nodal disease with extranodal spread.

**Management**

**Initial treatment**

Treatment should be initiated immediately after the diagnosis is confirmed. In younger patients without co-morbidity, there is a high expectation of cure. Treatment is assigned on the basis of the revised International Prognostic Index (R-IPI; Box 17.39 and Fig. 17.29). Further refinement using gene expression profiling has identified at least two distinct subtypes of DLBCL (Fig. 17.30): germinal centre cell (GC) and activated B-cell (AB).

---

**Box 17.39**

**Adverse prognostic factors in diffuse large B-cell lymphoma (R-IPI)**

- Age >60 years
- Stage III or IV, i.e. advanced disease
- High serum lactate dehydrogenase level
• More than one extranodal site involved
• ECOG performance status 2 or more (see Box 17.10)

ECOG, Eastern Cooperative Oncology Group; R-IPI, revised International Prognostic Index.

**FIGURE 17.30** Kaplan–Meier plot of overall survival of DLBCL patients. Patients are grouped on the basis of gene expression profiling. GC, germinal centre cell. (Reproduced with permission from Alizadeh AA. Distinct types of diffuse large B-cell lymphoma identified by gene expression profiling. *Nature* 2000; 403(6769):503–511.)

**Low-risk (IPI score 0–1) with anatomically localized disease**

At present, ‘CHOP-R’ followed by involved field irradiation, or ‘more CHOP-R’ is used. Interim PET scanning may be used to inform individualization of therapy.

Two studies conducted in France suggest that the prognosis is better with chemotherapy alone, provided ‘enough’ is given, with more than 80% of younger patients being alive 10 years after therapy. A trial comparing chemotherapy with and without rituximab in all patients with low-risk disease showed a marked advantage for those receiving chemoimmunotherapy. Further studies are awaited (*Fig. 17.31*).
Intermediate and poor-risk (IPI score 2+)

The age of the patient and co-morbidity are critical for both the selection of treatment and the prognosis. Recognition of this fact has led to the use of an age-adjusted prognostic index for patients over the age of 60. Chemoimmunotherapy was established to be superior to chemotherapy alone for older patients in this category. ‘CHOP-R’, to a total of 6 or 8 cycles, has become standard care for the large majority of patients of all ages with DLBCL.

Many trials of increasing intensity of therapy for selected patients have yet to yield convincing results. However, there is an increasing consensus that the small group of patients having DLBCL with ‘Burkitt-like features’ should be treated as for Burkitt's lymphoma. The ability to distinguish between the molecularly distinct, ‘germinal-centre’ DLBCL and ‘activated B-cell’ DLBCL with immunohistochemistry has made it possible to explore different therapeutic approaches in the two groups, with appropriate targeted agents.

Involvement of the central nervous system, most often meningeal, is an uncommon but devastating complication, confirming a very poor prognosis overall. Patients with a high IPI score, and particularly those with specific extranodal sites of involvement (breast, testis, paranasal sinuses, bone marrow) and those who are HIV-positive, should receive intrathecal methotrexate with each cycle of therapy. The management of overt leptomeningeal or parenchymal involvement, often in the context of generalized lymphoma, is difficult and usually unsuccessful in the long term. Most strategies involve high doses of systemic methotrexate and cytarabine (cytosine arabinoside), both of which cross the blood–brain barrier. Cranial or craniospinal irradiation may also be used.

Second (and subsequent) therapy
Although there may be responsiveness initially to alternative chemotherapy, after failure of initial therapy or subsequent progression, the prognosis is very poor. Patients entering a partial remission do better than those in whom disease recurs after they enter an initial complete remission.

The major issues to be addressed are whether treatment is to be undertaken with palliative or curative intent, and if the latter, what are the expectations of success. The *palliative approach* involves both chemotherapy and irradiation. The *curative approach* involves complete re-evaluation, followed by second-line chemotherapy; this has a proven response rate of approximately 50%. If at least a further partial remission is achieved, in the younger, fitter patient, peripheral blood stem cell harvest is undertaken, followed, if successful, by an autograft. Overwhelmingly, the best results are achieved in those entering an unequivocal second CR. Even so, the proportion of patients in a prolonged second remission does not exceed 25%.

### Prognosis

The outlook for patients with DLBCL has improved by at least 15% in terms of cure, with the incorporation of rituximab into the initial therapy, the expectation of cure now being between 40% and 80% depending on the presenting features. The challenge of progressive disease following initial treatment is great, with less than 20% of patients overall staying alive in the long term. Options include palliation, clinical trial entry, lenalidomide, bortezomib combinations or the single agent pixantrone.

### Burkitt's lymphoma

This is the most rapidly proliferating lymphoma, with a doubling time approaching 100% and a very rapid evolution. The most common childhood malignancy worldwide, it has a male to female preponderance of approximately 3:1 and occurs at all ages. There are three types:

- **Endemic:**
  - Always Epstein–Barr virus (EBV)-associated
  - Occurs in equatorial Africa
  - Corresponds to the distribution of malaria.

- **Sporadic:**
  - 30% EBV-related

- **AIDS-related.**

  A similar picture to AIDS-related lymphoma may appear post transplant.

  The most common presenting feature in the endemic type is a rapidly growing jaw tumour in a young child *(Fig. 17.32)*. The next most common is an abdominal mass that is often associated with bone marrow involvement. Other common sites are the central nervous system, the kidney and the testis.
Investigation is along conventional lines for lymphoma, at least in the Western world, but must be conducted as a matter of urgency. A different staging classification is applied to children.

Management
Burkitt's lymphoma should be treated with curative intent whenever feasible, regardless of HIV status. Investigation having been completed, it is essential that the patient is haemodynamically and metabolically stable prior to the initiation of specific therapy. Particular attention must be paid to the risk of the tumour lysis syndrome so rasburicase prophylaxis should be given if available (see p. 606). If it is not, other standard measures based on fluids and allopurinol should be pursued to minimize the risk of tumour lysis syndrome. Very frequent monitoring of electrolyte balance is essential for at least 72 hours after treatment is commenced, with particular attention to potassium and phosphate levels.

Standard treatment comprises, if possible, intensive, cyclical combination chemotherapy, including cyclophosphamide, methotrexate and cytarabine in high doses. Rituximab is now included, although the evidence base for this is minimal. The details and number of cycles administered will be determined by the perceived level of ‘risk’. Prophylactic central nervous system therapy is essential, intrathecal methotrexate or cytarabine often being given in addition to high-dose systemic administration.

Prognosis
In the Western world, the prognosis of Burkitt's lymphoma has improved markedly over the past 10 years. The chances of cure are very high for ‘low-risk’ patients and exceed 50% for ‘poor-risk’ patients, as well as the HIV-positive cases, provided all treatment can be administered.

Failure to achieve CR is a very poor prognostic factor, as is recurrence, which supervenes.
within the first year after completion of initial therapy if it does so at all. Although there may be further chemoresponsiveness, it is rare for second-line therapy to be more than transiently beneficial, regardless of whether it is followed by consolidation, with either myeloablative chemotherapy or allogeneic haemopoietic stem cell transplantation.

**Mantle cell lymphoma**

This is one of the less common B-cell lymphomas, usually presenting in later life, with a male to female preponderance of 3:1. The most frequent presentation is with painless lymphadenopathy, often generalized. There may be non-specific symptoms of tiredness, or ones related to the gastrointestinal tract. ‘B’ symptoms occur in <50%. Examination and standard investigation usually confirm generalized lymphadenopathy with or without hepatosplenomegaly (*Fig. 17.33*). Patients with bowel symptoms frequently have multiple lesions found on endoscopy. The bone marrow is usually involved and there may well be lymphoma cells in the peripheral blood. The t(11; 14) translocation with dysregulation of cyclin D1 is a classical feature of this lymphoma.

![FIGURE 17.33](image.png) CT of the abdomen of a patient with mantle cell lymphoma (arrowed). Significant splenomegaly is also shown.

**Management**

In the majority of patients, therapy is started after investigation has been completed. It is usual for there to be regression of disease with chemotherapy, although it is not often that CR is achieved. A prognostic index is used to help determine whether more or less ‘aggressive’ treatment is best employed. In reality, the major determining factors are the age of the patient and the presence or absence of co-morbidities. The outcome is likely to be best when ‘more’
treatment is given. Hence, younger, fitter patients are now treated with relatively intensive chemoimmunotherapy, incorporating cycles of high-dose cytarabine as well as rituximab, followed by, in first remission, myeloablative chemotherapy with autologous stem cell rescue. Older, less fit patients are treated with less intensive therapy, such as CHOP-R or bendamustine. In general, the strategy is to stop treatment after the planned initial course of treatment, provided the patient is well and at least a partial remission has been achieved. Almost inevitable progression occurs in both older and younger patients, palliation being the expectation for most. Experimental approaches include reduced-intensity allogeneic HSCT and novel drugs targeting both the NFκB and mammalian target of rapamycin (mTOR) pathways, such as bortezomib and temsirolimus, respectively. In a recent study, replacement of vincristine with bortezomib in combination therapy has shown benefit.

Recently, two other drugs that inhibit malignant B-cell survival signalling and disrupt B-cell localization in their protective niches within lymph nodes have been successfully trialled in mantle cell lymphoma. These are ibrutinib (BTK inhibitor) and idelalisib (PI3Kδ inhibitor). Current trials are under way looking at combining these agents with current standards of care such as CHOP-R or R-bendamustine.

### Prognosis

Untreated mantle cell lymphoma has a natural history that lies between that of DLBCL and follicular lymphoma. The prognosis has improved in recent years with the introduction of treatment strategies that have prolonged the period of remission without curing the patient, and with the discovery of new agents, bringing the overall median survival nearer 5 years.

### Lymphoplasmacytic lymphoma

This is an uncommon B-cell malignancy, which is known as **Waldenström's macroglobulinaemia** when associated with an IgM paraprotein and bone marrow infiltration. It usually occurs in later life, the incidence being approximately the same in men and women. It may be preceded by a pre-lymphomatous phase, in which a small, monoclonal IgM band is present for many years; it is often an incidental finding. The presentation is with lymphadenopathy or, alternatively, symptoms of anaemia or hyperviscosity caused by the paraprotein (e.g. headaches, visual disturbance). Examination and investigation usually reveal little beyond minimal adenopathy and, commonly, splenomegaly.

### Management

Following completion of investigation, the critical decision is whether to initiate specific therapy or not. In an emergency, with severe symptoms of hyperviscosity, it is most appropriate to lower the paraprotein by plasmapheresis. In some circumstances, particularly in the otherwise less fit, it may be best to use maintenance pheresis and blood transfusion as the primary therapy. Responses are seen in about 50% of cases, with a fall in the paraprotein to
50% of the baseline level with single-agent therapy and higher with combination chemotherapy and rituximab. Ibrutinib has shown promise in a recent study, particularly with **MYD88** and **CXCR4** mutations. Treatment, either repeating the initial therapy or changing it, is reinstated only when progression is clearly documented, most often by a fall in the haemoglobin or a significant rise in the M band. In the very small proportion of younger patients for whom CR is achieved, consolidation with a bone marrow transplant is used. Similarly, in the same group of patients who have recurrent disease, which is again responsive, allogeneic HSCT is also used.

### Prognosis

Lymphoplasmacytic lymphoma is a relatively rare chemotherapy- and immunotherapy-sensitive disease, which may follow an indolent course for some years without therapy. Although the median survival is only 5 years, 10–20% of patients die of unrelated causes as it presents in later life.

### Primary extranodal lymphoma

Lymphoma may arise anywhere in the body where there is lymphoid tissue and therefore the clinical presentation is that of a lesion or mass at the relevant site. In practice, the majority occur in the central nervous system, stomach or skin.

### Primary central nervous system lymphoma

This diffuse, large B-cell lymphoma occurs in both the immunocompetent (predominantly the elderly) and the immunosuppressed, in the context of HIV infection or following solid organ transplant. It presents with symptoms relating to single or multiple parenchymal mass lesions. The diagnosis needs to be made on the basis of a biopsy, particularly in the immunocompromised, in whom an infectious aetiology of the symptoms is possible, such as toxoplasmosis. An MRI scan is the first choice of investigation; cerebrospinal fluid is usually normal. Further investigation is necessary to exclude the cerebral lesion being a manifestation of generalized disease.

### Management

In some patients in the post-transplant setting, reduction of immunosuppression may be beneficial. Chemotherapy alone, with high-dose methotrexate and cytarabine, is used. The best ‘disease-free’ results have possibly been obtained by the use of chemotherapy and irradiation but toxicity is greater, with a risk of irreversible loss of cerebral function. The overall results are disappointing, only a small proportion of patients remaining alive in the long term without disability. The situation in the HIV-positive patient with cerebral lymphoma (fortunately, a declining problem) is much worse and palliative irradiation is the best option.
**Primary gastric lymphoma**

This B-cell lymphoma, either extranodal marginal-zone lymphoma of mucosa-associated lymphoid tissue (MALT) or DLBCL arising on a background of MALT lymphoma, is closely related to *Helicobacter* infection. It presents with symptoms of gastric ulceration or a mass, indigestion or bleeding; the diagnosis is made by endoscopic biopsy to include both the confirmation of lymphoma and *H. pylori* status. This is followed by investigation as for nodal lymphoma, which reveals local nodal involvement in a proportion of patients and distant spread in a small number only.

**Management**

Management is entirely dependent on whether or not there is any evidence of DLBCL. If only ‘low-grade’ gastric ‘MALT’ lymphoma is present, *Helicobacter* eradication therapy is the treatment of choice (see p. 380). This almost invariably alleviates the symptoms. Re-evaluation is carried out after 3 months with endoscopy, repeat biopsy and, in some circumstances, endoscopic ultrasound. In general, a conservative approach is followed, as responses may take many months to achieve and rapid progression is very unlikely. Regular endoscopy every 6 months should be continued for at least 2 years. Failure is not common. If it does occur, it is rarely rapid and the biopsy should be repeated. If the histology is unchanged after further *Helicobacter* eradication therapy (if necessary), either irradiation to the gastric bed or chemoimmunotherapy is likely to be effective or possibly curative. Overall, the prognosis is very good, the very large proportion of patients being alive 10 years after diagnosis.

Any evidence of DLBCL is an indication for chemoimmunotherapy. *Helicobacter* eradication therapy should also be given, but should not be considered definitive treatment. The potential risk of gastric perforation or haemorrhage because of therapy is not a contraindication to treatment. Surgery is rarely needed, but irradiation is used for persistent disease. The prognosis is approximately the same as for nodal DLBCL of equivalent extent.

**Primary cutaneous (T- or B-cell) lymphoma**

Lymphomas of both B- and T-cell types may arise singly and multiply in the skin and pursue a very long natural history, even though they may give rise to considerable discomfort.

**Mycosis fungoides (Sézary syndrome)**

This is the most common cutaneous lymphoma, predominantly arising in and confined to the skin, although spreading to other organs later in the disease. It has a long natural history, being sometimes preceded by a scaly ‘pre-mycotic phase’. This T-cell lymphoma presents with multiple erythematous lesions, plaques and tumours, which, when associated with spread to the blood, become the Sézary syndrome. Generalized erythema may occur (erythroderma). The
likelihood over time of disease extending beyond the skin is highest in patients with tumours.

Management

Treatment is palliative and there is little indication that the disease is ever eradicated. Many treatments result in regression of disease. Phototherapy (PUVA), topical steroids and topical chemotherapy all produce a response. Radiation is effective, and total skin electron beam therapy particularly so, although attention must be paid to potential side-effects, including erythroderma. Systemic chemotherapy, either at conventional or high doses, has been disappointing. Newer approaches include anti-T-cell antibodies and histone deacetylase inhibitors.

The median survival is approximately 10 years, there being a close correlation with the extent of disease at presentation. Interaction between oncologist and dermatologist is essential.

Cutaneous B-cell lymphoma

The two major subtypes have their origins in the extranodal marginal zone or follicle centre. Both usually present with either single or clustered cutaneous lesions, biopsy of which confirms the diagnosis. All conventional staging investigations are negative. Treatment is either expectant, surgical excision or irradiation, which may be used repeatedly over time. Antibiotics are used for marginal-zone lymphoma if there is evidence of Borrelia burgdorferi infection. Only if there are lesions at multiple sites should systemic chemotherapy be used. The long-term prognosis is excellent.

T-cell and natural killer cell lymphomas

These are much less common than their B-cell counterparts, although they are relatively more frequent in the East than the West. The most common presentations are nodal or cutaneous (see p. 1374) and specific subtypes involve the liver and subcutaneous tissue (Fig. 17.34). Peripheral T-cell lymphomas with nodal presentation have a poor prognosis. They are treated as for DLBCL without rituximab.

The two most common subtypes of nodal T-cell lymphoma are ‘peripheral T-cell lymphoma,
not otherwise specified (NOS)’ and ‘angioimmunoblastic T-cell lymphoma’, which together account for about 50% of T-cell lymphomas. Both occur in the middle-aged to elderly population, the primary presentation being lymphadenopathy. In contrast to the B-cell lymphomas, ‘B symptoms’ are common. Patients with angioimmunoblastic T-cell lymphoma also present with features akin to inflammatory disease, with fevers, rashes and electrolyte abnormalities; in the first instance, these may be rapidly responsive to corticosteroids or low doses of alkylating agents.

Management

Following standard investigation, which usually reveals widespread disease, patients are treated with cyclical combination chemotherapy as used for DLBCL. CD20 is not expressed on T cells so rituximab is not used and, as yet, there is no equivalent drug for T-cell lymphoma. Resolution of symptoms almost invariably occurs, although they may recur between cycles. Overall, the outcome of treatment is worse than for DLBCL, in terms of quality of response, duration of response and overall survival. Second-line therapy is rarely satisfactory, although a small proportion of patients may benefit from myeloablative therapy to consolidate a second response.

Further reading

Myeloma

Myeloma is a malignant disease of bone marrow plasma cells, accounting for 1% of all malignant disease. There is a clonal expansion of abnormal, proliferating plasma cells producing a monoclonal paraprotein, mainly IgG (55%) or IgA (20%), and rarely IgM and IgD. The paraproteinaemia may be associated with excretion of light chains in the urine (Bence Jones protein), which are either kappa or lambda. In approximately 20%, there is no paraproteinaemia, only light chains in the urine. Rarely, patients produce no paraprotein or light chains – this is termed ‘non-secretory myeloma’ (<5%).

Clinicopathological features

Myeloma is a disease of the elderly, the median age at presentation being over 60 years. It is rare under 40 years of age. The annual incidence is 4 per 100 000 and it is more common in males and in black Africans, but less common in Asians. The clinical features include:

- **Bone destruction**, often causing fractures of long bones or vertebral collapse (which can cause spinal cord compression) and hypercalcaemia. Soft tissue plasmacytomas also occur and they are the usual cause of spinal cord compression in myeloma.

- **Bone marrow infiltration with plasma cells**, resulting in anaemia, neutropenia and thrombocytopenia, together with production of the paraprotein, which may (rarely) result in symptoms of hyperviscosity.

- **Kidney injury** (see p. 751) owing to a combination of factors: deposition of light chains in the renal tubules (**Fig. 17.35**), hypercalcaemia, hyperuricaemia, use of NSAIDs and, rarely, the deposition of AL amyloid (see p. 1288).
In addition, there is a reduction in the normal immunoglobulin levels (immune paresis), contributing to the tendency for patients with myeloma to have recurrent infections, particularly of the respiratory tract. The WHO classification (2008) of plasma cell neoplasms is shown in Box 17.40.

### Box 17.40

**WHO (2008) classification of plasma cell neoplasms**

- Monoclonal gammopathy of undetermined significance
- Plasma cell myeloma
- Solitary plasmacytoma of bone
- Extraosseous plasmacytoma
- Monoclonal immunoglobulin deposition diseases
- Heavy chain diseases:
  - Gamma (γ) heavy chain disease
  - Mu (µ) heavy chain disease
  - Alpha (α) heavy chain disease

### Cytogenetics

With FISH and microarray techniques, abnormalities are found in most cases of myeloma. Abnormalities of chromosome 13 and hypodiploidy (<45 chromosomes) have been shown to be associated with poor survival, as have t(4; 14), t(14; 16) and p53 (17p) deletions. Conversely, t(11; 14) and hyperdiploidy (>50 chromosomes) are associated with a better

**FIGURE 17.35** Kidney biopsy of a patient with myeloma and acute kidney injury due to light chain cast nephropathy. (Courtesy of Professor Michael Sheaff, Barts and The London NHS Trust.)
prognosis.

**Bone disease**

There is dysregulation of bone remodelling, which leads to the typical lytic lesions, usually seen in the spine, skull, long bones and ribs. In myeloma, there is increased osteoclastic activity with no increased osteoblast formation of bone. Bisphosphonates that inhibit osteoclast activity are useful in myeloma but, surprisingly, there is no increase in bone deposition.

Adhesion of stromal cells to myeloma cells stimulates the production of receptor activator of nuclear factor kappa-B ligand (RANKL), IL-6 and also VEGF, which plays a role in angiogenesis. RANKL also stimulates osteoclast formation and the lytic lesions. Myeloma cells also produce dickkopf-1 (DKK1), which inhibits osteoblast activity and therefore production of new bone. This occurs because DKK1 binds to the Wnt co-receptor, lipoprotein receptor-related protein 5 (LRP5), inhibiting Wnt signalling (see p. 98) and osteoblast differentiation.

**Symptoms**

- Bone pain: most commonly backache, owing to vertebral involvement (60%).
- Symptoms of anaemia.
- Recurrent infections.
- Symptoms of renal failure (20–30%).
- Symptoms of hypercalcaemia.
- Rarely, symptoms of hyperviscosity and bleeding due to thrombocytopenia.

Patients can be asymptomatic, the diagnosis being suspected by abnormal ‘routine’ blood tests. Life-threatening complications are shown in **Box 17.41**.

---

**Box 17.41**

**Life-threatening complications of myeloma**

- **Renal impairment** – often a consequence of hypercalcaemia – requires urgent attention and patients may need to be referred for long-term peritoneal dialysis or haemodialysis.
- **Hypercalcaemia** should be treated by rehydration and use of bisphosphonates, such as pamidronate.
- **Spinal cord compression** due to myeloma is treated with dexamethasone, followed by radiotherapy to the lesion delineated by a magnetic resonance imaging scan.
- **Hyperviscosity** due to high circulating levels of paraprotein may be corrected by plasmapheresis.

---

**Investigations**
General

• **Full blood count.** Haemoglobin, white blood cell count and platelet count are normal or low.

• **Erythrocyte sedimentation rate.** This is often high.

• **Blood film.** There may be rouleaux formation as a consequence of the paraprotein and circulating plasma cells in the aggressive plasma cell leukaemia variant of myeloma.

• **Urea and electrolytes.** There may be evidence of kidney injury (see above).

• **Serum calcium.** This is normal or raised. Serum alkaline phosphatase is usually normal.

Immunological

• **Total protein** is normal or raised.

• **Serum protein electrophoresis and immunofixation** characteristically shows a monoclonal band and immune paresis (*Fig. 17.36*). The serum free light chain assay, more sensitive than urine electrophoresis, may show an abnormal ratio and an increased total amount of free kappa or lambda chains, and is often abnormal earlier than routine electrophoresis.

![FIGURE 17.36  Serum protein electrophoresis and immunofixation. A. Immunofixation of immunoglobulin G (IgG) kappa monoclonal paraprotein. B. Quantitation and serum electrophoresis of IgG paraprotein. Serum electrophoresis and immunofixation of a patient with an IgG K paraprotein (left). The column on the far left is the total serum electrophoresis stained with anti-protein reagents. Albumin is at the top and the increased immunoglobulins at the bottom. These are shown to stain with anti-IgG and anti-kappa light chain reagents (arrows). The paraprotein is quantified (right) by calculating the area under the paraprotein spike and comparing it with the albumin concentration. A, immunoglobulin A; ELP, electrophoresis; G, immunoglobulin G; K, kappa; L, lambda; M, immunoglobulin M.]

• **Twenty-four-hour urine electrophoresis and immunofixation** is used for assessment of light-chain excretion.

Radiological

• **Skeletal survey** may show characteristic lytic lesions, most easily seen in the skull (*Fig. 17.37*). CT, MRI and PET are used in plasmacytomas (bone or soft tissue deposits).
Myeloma affecting the skull. Note the rounded lytic translucencies produced by infiltration of the skull with myeloma cells (arrowed).

- **MRI spine** is useful if there is back pain; it may show imminent compression/collapse.

**Other**

Bone marrow aspirate or trephine shows characteristic infiltration by plasma cells (Fig. 17.38). Amyloid may be found (see pp. 1288–1289).
Prognosis

Reduced serum albumin, increased serum $\beta_2$-microglobulin and increased serum lactate dehydrogenase (LDH) indicate a poor prognosis at diagnosis (*Box 17.42*) on an international prognostic index.

**Box 17.42**

Diagnosis

**Symptomatic myeloma (SMM)** can be diagnosed if either of the following is present:

- significant paraproteinaemia (see *Fig. 17.36*)
- increased bone marrow plasma cells (>10%); (see *Fig 17.38*).

  with evidence of end-organ failure: that is, hypercalcaemia, renal impairment, anaemia and lytic bone lesions (CRAB).

**Asymptomatic myeloma (AMM; 10% of cases)** has a significant paraprotein (IgG or IgA >30 g/dL or urinary light chain excretion >1 g/day) and/or a marrow plasmacytosis >10% but no end-organ damage. The median time to progression for these patients is 2–3 years. The risk is highest for those with IgA isotype and light chains in the urine.

**Monoclonal gammopathy of unknown significance (MGUS)** describes an isolated finding of a monoclonal paraprotein in the serum, usually in the elderly, that does not fulfil the diagnostic criteria for SMM or AMM. Between 20% and 30% go on to develop multiple myeloma over a 25-year period. Low-risk MGUS is characterized by an IgG subtype, a paraprotein <15 g/dL and a normal serum free light chain ratio.

**Plasmacytoma** is an isolated tumour of neoplastic plasma cells. Patients may present with a plasmacytoma and no evidence of multiple myeloma. This may be a ‘solitary plasmacytoma of bone’ within the skeleton or an ‘extramedullary plasmacytoma’ outside the marrow cavity, typically in the upper aerodigestive tract.

For paraprotein-associated neuropathy and POEMS syndrome, see page 884.
Management

With good supportive care and chemotherapy, median survival is now 5 years, some patients surviving to 10 years. Young patients receiving more intensive therapy may live longer.

Supportive therapy

• Anaemia should be corrected; blood transfusion may be required. Erythropoietin often helps. Transfusion should be undertaken slowly in patients with hyperviscosity.
• Hypercalcaemia, kidney injury and hyperviscosity should be treated as indicated (see pp. 606 and 772–773).
• Infection should be treated promptly with antibiotics. Give pneumococcal and yearly influenza vaccinations.
• Bone pain can be alleviated most rapidly by radiotherapy and systemic chemotherapy or high-dose dexamethasone. NSAIDs are usually avoided because of the risk of acute kidney injury. Bisphosphonates, such as zoledronate, which inhibit osteoclast activity, help ensure rapid normocalcaemia and, given long-term, reduce skeletal events such as pathological fracture, cord compression and bone pain.
• Pathological fractures may also be prevented by prompt orthopaedic surgery with pinning of lytic bone lesions at critical sites seen on the skeletal survey, such as the femoral shaft. Kyphoplasty and vertebroplasty may be useful in treating vertebral fractures (see p. 659).

Specific therapy

Myeloma remains incurable. Therapy is aimed at treatment or prevention of specific complications and prolongation of overall survival. There are a plethora of agents that can be used at first line or subsequent relapse in myeloma.

Initial treatment typically consists of an alkylator (cyclophosphamide or melphalan), steroid (prednisolone or dexamethasone) and novel agent (bortezomib or thalidomide). Melphalan is avoided in those who may require stem cell mobilization subsequently. Bortezomib is preferable in those with renal impairment. Thalidomide has activity as a single agent and is widely used in first-line and relapsed settings. It is teratogenic and associated with neuropathy, somnolence, constipation and an increased risk of venous thrombosis. Lenalidomide is a thalidomide analogue, which is also used for relapsed myeloma. It has greater potency than thalidomide with less toxicity.

In younger patients (<65–70 years), an orally active cyclophosphamide, thalidomide and dexamethasone-based induction (CTD), followed by a high-dose melphalan autograft, has a significantly higher response rate, with 40% of patients achieving a CR and median survival increasing to 6 years. A bortezomib-containing initial treatment schedule, such as bortezomib, thalidomide and dexamethasone, is also appropriate. The role of allogeneic transplantation is currently unclear but it should be considered in young patients, with a suitable donor and high-risk disease.
In older or less fit patients, melphalan and prednisolone was used, with a median survival of 29–37 months; complete remissions were rare. Recent phase III studies have suggested that these agents, combined with thalidomide as MPT, result in improved response rates and overall survival, albeit with increased toxicity. Additionally, a phase III study has shown that bortezomib plus melphalan and prednisolone (VMP) is superior to the latter two alone. Finally, the FIRST study showed superiority of lenalidomide/dexamethasone to MPT for older patients and this may come to be standard of care.

For relapsed patients, a second autograft may be considered if there was a favourable response duration to the first (>12–18 months). Choice of reinduction therapy will be tailored to the patient according to prior exposure and toxicities. New agents available or currently under evaluation include the proteasome inhibitors ixazomib and carfilzomib; pomalidomide, bendamustine, elotuzumab (monoclonal antibody to CS1), daratumumab (monoclonal antibody to CD38), panobinostat (histone deacetylase inhibitor) and plitidepsin are in clinical trials.

**Common Solid Tumour Treatment**

Common solid cancer mortality is listed in *Box 17.43*; the improvements in survival in recent years have come from advances in prevention, diagnosis and treatment. The presentation, diagnosis, natural history and systemic treatment of the common cancers are described in the relevant chapters. The decision to treat and the aim of that treatment, whether palliation or cure, require knowledge of the natural history of the disease, prognostic and predictive factors, the patient's performance status and the potential efficacy of treatment. Management should be carried out by multidisciplinary teams, usually led by an oncologist.

## Lung Cancer

The presentation and diagnosis of lung cancer (**Fig. 17.39**) are covered more fully on pages 1126–1127. Current treatment reflects the fact that the majority of patients are diagnosed at an advanced stage with a poor prognosis; there are therefore many trials assessing different screening strategies to try to achieve earlier diagnosis and more curative treatment.
Prognosis

Lung cancer histology is divided into two main types: small-cell (neuroendocrine) lung cancers (SCLC), which tend to disseminate early in their development, and non-small-cell lung cancers (NSCLC), which are more likely to be diagnosed in a localized form. As treatments have changed, it has become clear that what was simply called non-small-cell lung cancer needs to be separated into individual pathological entities, as the management varies and some therapies are effective only in particular subtypes. Tumour stage and patient performance status are used in selecting treatment and predicting response and prognosis. While overall 5-year survival has remained approximately 10%, treatment is beginning to have an impact in selected groups and the multidisciplinary team can greatly aid in the appropriate application of treatment and the avoidance of nihilism.

Non-small-cell lung cancer

Staging of NSCLC has been improved by CT and PET scanning and is classified according to the TNM system (see Box 24.58 and Fig. 24.44); this system divides the disease into local, locally advanced and advanced stages, with 5-year survival varying from 55–67% to 23–40% and 1–3%, respectively.

Management

Surgery can be curative in NSCLC (T1, N0, M0) but only 5–10% of all cases are suitable for resection; about 70% of these survive for 5 years. Surgery is rarely appropriate in patients over 65 years, as the operative mortality rate exceeds the 5-year survival rate. Trial data suggest that neoadjuvant chemotherapy may downstage tumours to render them operable and may also improve 5-year survival in patients whose tumours are operable at presentation.

Preoperative assessment
Lung function tests, including walking oximetry, are used to predict postoperative potential. An active life after pneumonectomy is unlikely if the gas transfer is reduced below 50%.

In operable disease stages T1N0–T3N2 (stage I–IIIa), adjuvant radiotherapy and chemotherapy following surgery can improve prognosis in patients of good performance status, as shown by the international adjuvant lung cancer trial and a meta-analysis of 12 randomized controlled trials. Cisplatin-based combination chemotherapy induced a response in 60% and produced a relative risk reduction of 11% with an absolute improvement in 5-year survival for stage II and IIIa disease of 4%, from 40.4% to 44.5%. There appears to be no difference in survival if chemotherapy is given before (neo-adjuvant) or after surgery.

A practical molecular assay to predict survival in resected non-squamous lung cancer is still in development.

**Radiation therapy for cure**

In patients who are fit and who have a stage 1 NSCLC, high-dose radiotherapy (65 Gy or 6500 rads) can result in a 27-month median survival and a 22% 5-year survival. It is the treatment of choice if surgery is not appropriate; however, poor lung function can also be a relative contraindication to radiotherapy. Radiation pneumonitis (defined as an acute infiltrate precisely confined to the radiation area and occurring within 3 months of radiotherapy) develops in 10–15% of cases. Radiation fibrosis, a fibrotic change occurring within a year or so of radiotherapy and not precisely confined to the radiation area, occurs to some degree in all cases but is usually asymptomatic.

For unresectable disease, the combination of concurrent cisplatin with radiotherapy (chemoradiation), when compared with radiotherapy alone, has increased the resection rate and 3-year survival from 11% to 23%, at the expense of greater oesophageal toxicity.

**Adenocarcinoma**

Therapy depends on the presence or absence of activating mutations in the epidermal growth factor receptor (EGFR); these are much more likely to be present in non-smokers or light smokers and in those with an Asian background. In the most common mutation (del 19), the drug afatinib (EGFR tyrosine kinase inhibitor) has been associated with a survival advantage over first-line chemotherapy. In other activating mutations, while progression-free survival and quality of life with afatinib are improved over the use of chemotherapy, survival rates remain the same as when a tyrosine kinase inhibitor (TKi, e.g. erlotinib) is deferred until chemotherapy has failed. If mutations are found, the response to a TKi in the first-line setting is >60%, or 40% following chemotherapy. Other oncogenetic mutations include the anaplastic lymphoma kinase (ALK) which is seen in 57% of NSCLC adenocarcinoma, and these respond to crizotinib. Where chemotherapy is chosen, cisplatin plus either pemetrexed or vinorelbine is the most effective combination. Normally, four 3-weekly cycles are given. In patients who are fit at the end of chemotherapy (performance status 0–1), maintenance chemotherapy with pemetrexed until progression has been shown to prolong median survival by 3–5 months to around 14 months.
**Squamous cell lung cancer**

Unlike adenocarcinoma, this is usually smoking-associated and activating mutations are uncommon. Cisplatin (or carboplatin) plus gemcitabine remains the standard treatment (and is superior in this group to regimes based on cisplatin and pemetrexed). An alternative, particularly in older patients, is carboplatin and paclitaxel.

**Second-line therapy in NSCLC**

In all non-small-cell tumours where current targeted agents are not predicted to be beneficial, the single agent docetaxel may be offered as second-line therapy if patients are fit. A recent study has shown that nivolumab has a significantly better survival and response rate than docetaxel in advanced disease.

**Small-cell lung cancer**

**Prognosis**

SCLC is an aggressive neuroendocrine tumour. It is staged in the same way as NSCLC and stage 1 tumours may benefit from surgery. For non-operable cases, disease is split into limited- or extensive-stage disease.

**Management**

*Limited-stage disease* is confined to one anatomical area and is present in approximately 30% of patients. It is best treated with concurrent chemotherapy and radiotherapy using a combination of cisplatin and etoposide or irinotecan, which increases the survival at 5 years from 15% to 25%, compared with radiotherapy alone. A similar degree of improvement can also be achieved with hyperfractionated radiotherapy. Prophylactic whole-brain radiation to prevent cerebral metastases can reduce symptomatic central nervous system disease and improve overall survival by 5%.

*Extensive disease* can be palliated with the combination of carboplatin and etoposide or irinotecan; compared with best supportive care, this can increase median survival from 6 months to 9–13 months, and the 2-year survival to 20%. Second-line chemotherapy can provide further palliation for patients with good performance status.

**Symptomatic care for lung cancer patients**

The prognosis for the majority of patients remains poor because the disease is diagnosed at an advanced stage and the co-morbidity from other smoking-related diseases compromises treatment. Therefore, much of the treatment, whether symptomatic or anticancer, is delivered with palliative intent. (General palliative care is discussed in Chapter 3.) Specific issues for lung cancer are the relief of bronchial obstruction and breathlessness, and the alleviation of local pain, for which radiotherapy is often employed alongside appropriate opiate analgesia.
Laser therapy, endobronchial irradiation and tracheobronchial stents are used (see p. 1132).

**Metastases in the lung**

Metastases are very common and usually present as round shadows (1.5–3.0 cm diameter). They are usually detected on chest X-ray in patients already diagnosed as having carcinoma, but may be the first presentation. Typical sites for the primary tumour include the kidney, prostate, breast, bone, gastrointestinal tract, cervix or ovary.

Metastases usually develop in the parenchyma or pleura and are often relatively asymptomatic, even when the chest X-ray shows extensive disease. Rarely, metastases may develop within the bronchi and present with haemoptysis.

Carcinoma, particularly of the stomach, pancreas and breast, can involve the mediastinal glands and spread along the lymphatics of both lungs (lymphangitis carcinomatosa), leading to progressive and severe breathlessness. Chest X-ray signs of hilar lymphadenopathy and basal shadowing are unreliable compared with the characteristic signs on CT scan of irregular thickening of the interlobular septa in a polygonal pattern around a thick-walled central vessel.

Occasionally, a pulmonary metastasis may be detected as a solitary round shadow on chest X-ray in an asymptomatic patient. The most common primary tumour to do this is a renal cell carcinoma.

The differential diagnosis includes:

- primary bronchial carcinoma
- tuberculoma
- benign tumour of the lung
- hydatid cyst.

Single pulmonary metastases can be removed surgically but, as CT scans usually show the presence of small metastases that remain undetected on chest X-ray, detailed imaging, including PET scanning and assessment, is essential before undertaking surgery.

Breast Cancer

Breast cancer is the most common cancer in women who do not smoke. The screening programme in the UK, with biplanar digital mammography every 3 years in women aged 50–70, and improvements in multimodality treatment have increased overall survival and rates of cure, while breast-conserving surgery has greatly ameliorated the psychosexual impact of the disease.

Aetiology and pathology

The majority of breast cancers arise from the epithelial cells of the milk ducts and reproduce their histological features in a variety of patterns (Box 17.44), of which the most common is an infiltrating ductal carcinoma. Further biological typing (Box 17.45) has revealed that some triple negative cancers also resemble the BRCA1 mutated cancers with an associated DNA repair deficiency that has been targeted with new drugs such as poly-ADP-ribose polymerase (PARP) inhibitors. For many cancers, it is thought that there is an identifiable precursor in situ stage, which is confined within the basement membrane and is still truly localized and detectable by its trademark microcalcification on a screening mammogram. For others, this stage may be non-existent or so brief as to be undetectable, and invasive disease is present from very early in development with a consequently worse prognosis. Approximately 10% of women have familial breast cancer (Box 17.46) and 3% have detectable mutations in the BRCA1 and BRCA2 genes and TP53. The hormonal environment exerts a major effect on expression of the breast cancer potential and is related to reproductive behaviour, diet, exercise, weight and exogenous hormones from oral contraception and postmenopausal hormone replacement therapy.

**Familial patterns of breast and ovarian cancer with increased risk of inherited BRCA mutations**

- A mother or sister diagnosed with breast cancer before the age of 40
- Two close relatives from the same side of the family diagnosed with breast cancer; at least one must be a mother, sister or daughter
- Three close relatives diagnosed with breast cancer at any age
- A father or brother diagnosed with breast cancer at any age
- A mother or sister with breast cancer in both breasts, the first cancer diagnosed before the age of 50
- One close relative with ovarian cancer and one with breast cancer, diagnosed at any age;
at least one must be a mother, sister or daughter

- A close relative of Ashkenazi Jewish origin with breast or ovarian cancer
- A close relative with pancreatic cancer and breast or ovarian cancer

**Clinical features**

Most women with symptomatic rather than screen-detected breast cancer present with a painless, increasing mass that may also be associated with nipple discharge, skin tethering, ulceration and, in inflammatory cancers, oedema and erythema. In developing countries, 80% are likely to present with advanced disease *(Fig. 17.40)* and metastases.

![Locally advanced breast cancer invading skin and axillary lymph nodes.](image)

**Investigations**

The triple assessment of any symptomatic breast mass by palpation, radiology (mammography, ultrasound and MRI scan) and fine needle aspiration cytology is the most reliable way to differentiate breast cancer from the 15 times more common benign breast masses. Large-bore core needle biopsy should follow to provide histological confirmation and predictive factors, such as grade, Ki-67 (immunohistochemical test) proliferation index and oestrogen, progesterone and Her2 receptor status, to inform the subsequent decision-making process. Molecular profiling to assess risk of recurrence and benefit of chemotherapy with the Oncotype Dx assay (see below) of the expression of 21 genes is able to better identify good-prognosis patients who do not need chemotherapy. Assessment should be carried out in a dedicated one-stop clinic that is able to provide the appropriate support and referral. Staging is both surgical, with respect to tumour size and axillary lymph node status, and, in advanced disease, investigative, examining common sites of metastasis by chest X-ray and CT scan of lungs and liver, and by bone scan. At present, only 20% of patients are diagnosed with no
evidence of microscopic nodal metastases.

**Prognosis**

The following are all significant independent predictors of a high risk of recurrence: large size of the primary tumour; metaplastic histological subtype that is high-grade/poorly differentiated; oestrogen and progesterone receptor (ER, PR)-negative; and young age and pre-menopausal status. Expression of Her2 is an adverse factor for small, otherwise good-prognosis tumours and, like ER and PR, is a predictor of treatment response.

Several gene expression profiles, such as the Oncotype Dx test score, have identified sets of between 20 and 70 genes, whose expression pattern can identify low- and high-risk subsets independently of clinical risk factors and predict treatment benefit. Clinical trials are in progress to test whether this leads to better decision-making and outcome than the traditional clinical factors. BRCA gene mutation testing, when there is a strong familial breast or ovarian cancer history, can inform the choice of local and contralateral breast treatment. *Box 17.47* shows the risk of cancer with BRCA genes in different cancers.

Local treatment

Surgery may vary from wide local excision or segmental mastectomy and breast conservation for masses <3 cm in diameter, to simple mastectomy with or without reconstruction. The choice is dictated by the location and extent of the breast mass in relation to the breast size and patient preferences. In the absence of clinical or radiological (usually ultrasound) evidence of lymphadenopathy, surgery of the axilla can be minimized by sentinel lymph node-guided sampling (after dye or radioactive tracer injection); otherwise, dissection to level 3 is required if there are clinically involved nodes, in order to gain local control and provide prognostic information to guide adjuvant treatment. The greater the amount of axillary surgery, the greater is the risk of postoperative lymphoedema.

Radiotherapy is given to the conserved breast after wide local excision to reduce local recurrence, and to the chest wall after mastectomy if there are risk factors for local recurrence to complete the local control measures (Box 17.49).

Box 17.49

Indications for adjuvant radiotherapy in breast cancer

- Breast-conserving surgery
- Large, high-grade primary tumour
- Proximity to surgical margins
- Lymph node metastases

Radiotherapy to the axilla is an equally effective alternative to axillary dissection following a positive sample but should not be added after full dissection of the axilla because the combination raises the risk of severe lymphoedema to 30%. Adjuvant radiotherapy reduces the
risk of local recurrence by 25% and improves 10-year survival by 3%.

Data suggest that women over 70 years with oestrogen receptor (ER)-positive cancers of up to 2 cm diameter may be offered surgery and tamoxifen alone without radiotherapy, without compromising outcome.

**Endocrine treatment**

**Anti-oestrogen drugs**

In *pre-menopausal women*, a reduction in oestrogens can be achieved via oophorectomy or via pituitary downregulation using a gonadotrophin-releasing hormone (GnRH) analogue, such as goserelin or leuprorelin.

Tamoxifen is a mixed agonist and antagonist of oestrogen action on the oestrogen receptor, while the more recent drug fulvestrant is a more selective oestrogen receptor modulator (SERM).

Synthetic progestogens, such as medroxyprogesterone acetate and megestrol acetate, have a direct effect on breast tumour cells through progesterone receptors, as well as effects on the pituitary/ovarian (pre-menopausal) and adrenal/pituitary axis (post-menopausal). They can be as effective as tamoxifen in metastatic breast cancer.

In *post-menopausal women*, androgens are synthesized by the adrenal glands and converted in subcutaneous fat to oestrone by the enzyme aromatase. The aromatase inhibitors, anastrozole, letrozole and exemestane, reduce circulating oestrogen levels and oestrogen synthesis in tumour cells; they have shown greater efficacy than tamoxifen in the treatment of metastatic breast cancer and reduced distant recurrence rates in the adjuvant setting.

**Side-effects** (*Box 17.50*) are those of oestrogen deprivation, and women need support in managing them if they are to be able to complete the standard 5-year course.

---

**Box 17.50**

**Side-effects of endocrine agents for breast cancer in order of frequency**

**Tamoxifen**

- Hot flushes
- Weight gain
- Mood changes
- Vaginal discharge
- Thromboembolism
- Endometrial hyperplasia and neoplasia

**Aromatase inhibitors**
• Hot flushes
• Vaginal dryness
• Arthralgia
• Skin rash
• Osteoporosis
• Adverse lipid profile

**Adjuvant systemic treatment**

**Endocrine therapy**

In about one-third of patients, the breast cancer will express receptors for oestrogen and progesterone. For pre-menopausal women, tamoxifen adjuvant therapy for 5 years immediately following surgery for receptor-positive disease reduces the 10-year relative risk of women dying from breast cancer by about 25%, and the absolute 10-year death rate by an average of 12% for all stages. Recent trials have shown increased benefit from either continuing tamoxifen for a total of 10 years or, in those becoming post-menopausal on treatment, switching to an aromatase inhibitor (AI) for a further 5 years.

For post-menopausal women with ER- and/or PR-positive disease, adjuvant tamoxifen or an AI such as anastrozole, letrozole or exemestane, all given for 5 years, reduces the risk of death from breast cancer by a similar 25%. Extended AI treatment schedules are still under investigation.

AIs, however, are the treatment of choice for post-menopausal women because they avoid the adverse effects of tamoxifen on the uterus and venous thromboembolism, and achieve a greater reduction in contralateral breast cancers and in distant metastases, contributing to an overall improvement in relapse-free survival, though not an overall survival advantage. It is recommended that the choice should be discussed for each patient, taking the individual co-morbidities into account. The effects of endocrine therapy are additive to those of chemotherapy and are most effective when given after, not concurrently with, the chemotherapy.

**Chemotherapy and targeted therapy**

A meta-analysis of all randomized trials of adjuvant therapy in breast cancer has shown that, for women with high-risk features (Box 17.51), adjuvant chemotherapy with first-generation regimens, such as CMF (cyclophosphamide, 5-fluorouracil (5-FU) plus methotrexate) for 6 months, reduces the absolute 10-year death rate by about 10% and the relative risk of death (RR) by 20%. Ovarian ablation using a GnRH analogue for 2 years is equally effective as CMF chemotherapy in pre-menopausal women. More effective second-generation regimens that include an anthracycline, such as Epi-CMF (epirubicin) or FEC100 (5-FU, epirubicin 100 mg/m², cyclophosphamide), increase the RR to 25%. A third-generation regimen with a taxane, such as FEC-D (fluorouracil, epirubicin, cyclophosphamide followed by docetaxel) (see Box
17.14), gives a 33% RR reduction but with increased toxicity.

### Box 17.51

**Poor prognostic factors for breast cancer**

- Young age
- Pre-menopausal status
- Large tumour size
- High tumour grade
- Oestrogen/progesterone/Her2 receptor-negative
- Positive nodes

Chemotherapy is less effective in hormone receptor-positive disease, and although menopausal status does not affect the relative efficacy of chemotherapy, the risk of recurrence is lower after the menopause and thus the absolute improvement in survival is less. Toxicity may also be higher with increasing age, so that treatment decisions may need to be more individualized in discussion between the patient and her doctors. The combined effect of radiotherapy, chemotherapy and tamoxifen or AI approximately halves the risk of dying of breast cancer for appropriately selected patients.

**Her2-/cERBB2-targeted therapy**

The addition of adjuvant intravenous trastuzumab for a further year to chemotherapy for the treatment of the 15–20% of patients in whom the breast cancer overexpresses Her2 further reduces the risk of mortality by 25% when trastuzumab is used alone, and by 33% when it is administered concurrently with a taxane. Intravenous or, more recently, subcutaneous trastuzumab is the standard of care for these patients but has a direct toxic effect on the myocardium that is additive to pre-existing myocardial damage, especially that caused by anthracyclines, and should not be given concurrently. An alternative regimen with docetaxel, carboplatin and trastuzumab is equally as effective and can avoid much of the myocardial toxicity. Left ventricular ejection fraction must be monitored before and during treatment to avoid potentially severe congestive heart failure.

Her2 blockade is also clinically effective with the monoclonal antibody pertuzumab or the receptor tyrosine kinase inhibitor (TKi) lapatinib. The combination of pertuzumab and trastuzumab has doubled response rates in metastatic treatment and results of adjuvant trials are awaited.

**Neoadjuvant and primary systemic treatment**

There is no survival advantage for preoperative endocrine or chemotherapy treatment when compared with postoperative treatment; that is, the advantage over surgery alone is the same.
However, there is a significant benefit from either rendering inoperable tumours operable (called primary systemic therapy) or making large tumours smaller and suitable for breast-conserving surgery in about two-thirds of such patients (called neoadjuvant therapy), in addition to the reduction in risk of death from distant metastases.

### Management of advanced breast cancer

Patients with established metastatic disease may require endocrine therapy, chemotherapy and radiotherapy. The treatment is not curative but is of great palliative benefit and often consistent with many years of good-quality life. Little additional benefit has been gained by adding endocrine therapy and chemotherapy together, although the inclusion of anti-HER2 (antibodies) in chemotherapy has produced a survival advantage. Prolonging treatment can delay relapse but at the expense of treatment toxicity; therefore, the serial use of intermittent courses of the different endocrine and chemotherapies, starting with the least toxic and most effective treatment, is usually most consistent with maintaining a good quality of life for as long as possible. Median survival from diagnosis is 2 years with a wide 95% confidence interval of 6–54 months. Surgical resection of unifocal metastases in the liver, lung or chest wall may be appropriate for cancers with a long disease-free interval.

### Endocrine treatment

Women who have high levels of ERs and PRs in their tumour have a greater chance of responding to endocrine treatments (i.e. 60% versus 10% for ER-negative disease; **Box 17.52**).

### Box 17.52

**Oestrogen-sensitive metastatic breast cancer characteristics**

- Expression of oestrogen receptors and/or progesterone receptors
- Disease-free interval >1 year
- Skin, lymph node or bone disease
- Absence of life-threatening visceral disease

Endocrine therapy is usually tried first in those patients who have characteristics suggesting they are likely to respond and who do not have immediately life-threatening organ failure. Remission lasts 2 years on average and is consistent with an excellent quality of life. When relapse occurs, further treatment with different agents may produce another remission.

### Chemotherapy

Chemotherapy is used for patients who lack the above features of hormone-responsive disease, those who fail to respond to endocrine therapy, or those who require a rapid response if at risk
of, for example, liver or respiratory failure. Chemotherapy can provide good-quality palliation and prolongation of life. The drugs listed below are all able to induce objective responses in metastatic disease, and when the disease responds, patients are likely to experience further serial responses to subsequent treatment at relapse. Single-agent treatment is often as effective as combination therapy; there is no benefit with combining more than two drugs at a time, which has the advantage of preserving more options for future use. There is very little difference in efficacy between the different regimens for Her2-negative metastatic disease, with response rates varying from 40% to 60% for a median duration of 8–10 months. The most common regimens with either single agents or doublet combinations include:

- **MM**: mitoxantrone and methotrexate
- **AC/EC**: doxorubicin or epirubicin and cyclophosphamide
- **DC**: docetaxel and capecitabine
- **PG**: paclitaxel and gemcitabine
- **vinorelbine**, carboplatin, mitomycin and eribulin.

The multiple regimens provide the possibility of avoiding drug resistance over several episodes of treatment interspersed with treatment-free periods so that the disease can be palliated, often for several years.

The addition of trastuzumab and pertuzumab or, to lesser degree, lapatinib to the cytotoxic drugs (except the anthracyclines; see above) has significantly improved survival for those women whose tumour overexpresses the c-ERBB2/Her2 oncogene. Inhibition of VEGFR by bevacizumab may be effective in a small proportion of patients but as yet it lacks a predictive biomarker. Markers of DNA repair deficiency, such as BRCA1 mutations, render the breast cancer potentially sensitive to the PARP inhibitors in development.

**Anti-osteolytic therapy**

Bone metastases are a common problem in the management of breast cancer. The bisphosphonates and the more potent anti-RANKL monoclonal antibody, denosumab, have a major role in reducing the incidence of new osteolytic deposits, bone pain and fracture when used preventatively, and in treating pain and hypercalcaemia from established metastases. While the second-generation bisphosphonate, pamidronate, may be sufficient, the more potent third-generation drugs, such as zoledronate or denosumab (the most effective), can be associated with hypocalcaemia and, in rare cases, impaired bone healing and osteonecrosis of the jaw (see p. 714).

Gastrointestinal Cancer

Upper gastrointestinal cancers

Oesophageal cancer

Presentation and diagnosis are described on page 374. Early diagnosis, as pioneered in Japan, where there is a particularly high incidence, has shown that it is possible to improve the prognosis of a disease that otherwise is typically diagnosed only when local metastases have already occurred.

Management and prognosis

Pre-treatment histology, stage, age and performance status are critical prognostic factors for treatment decisions, which should be made by a multidisciplinary team in designated units with the surgical expertise to avoid treatment mortality. The prognosis for the majority of symptomatic patients is poor, 50% have distant metastases at the time of diagnosis, and the majority of the remainder having loco-regional spread into adjacent mediastinal structures. Staging with endoscopic ultrasound, CT scan and PET-CT scan has improved the selection of patients of good performance status with truly localized disease, for whom curative treatment may be attempted.

Surgery provides the best chance of a cure and should be used as the primary modality only when imaging (see above) has shown that the tumour has not infiltrated outside the oesophageal
wall (stage 1). The overall 5-year survival figures are poor (see p. 376), and only 4% for stage 4 cancers, because 70% of patients present late with stage ≥3 disease.

Response to neoadjuvant therapy is a further strong prognostic factor. Treatment of potentially resectable squamous carcinomas with cisplatin, 5-FU and concurrent radiotherapy, or postoperative chemotherapy with epirubicin, cisplatin and 5-FU for adenocarcinomas at the oesophagogastric junction in those of good performance status, achieves complete remission in 20–40%; there is a median survival of 19 months, and 25–35% of patients are alive 5 years after surgery.

Locally advanced or metastatic disease can be palliated with 5-FU or capecitabine chemotherapy in approximately 30%, increasing to 45–55% with the addition of oxaliplatin or irinotecan for a median duration of 6–8 months.

Distressing symptomatic problems with dysphagia can be partially relieved by endoscopic insertion of expanding metal stents or percutaneous endoscopic gastrostomy tubes to support liquid enteral feeding and endoscopic ablation to help control bleeding. The patient and family need considerable support and explanation to enable them to understand that feeding, including parenteral methods, does not improve survival beyond that dictated by the underlying cancer, and may introduce its own complications with adverse effects on quality of life.

Gastric cancer

The presentation and diagnosis of gastric cancer are described on pages 381–384.

Prognosis

The majority of patients are still diagnosed at an advanced stage, except in Japan, which has an active surveillance policy. Thus, in the West, the overall prognosis has not improved above 10% survival at 5 years. Selected groups may do much better and the histological grade and staging, with respect to the presence of serosal involvement (T3), nodal involvement (N1–2) and performance status, are the main factors in determining prognosis and selecting treatment.

Management

Early non-ulcerated, mucosal lesions can be removed endoscopically.

Surgery remains the most effective form of treatment if the patient is operable. Selection on operability has reduced the numbers undergoing surgery and has improved the overall surgical 5-year survival rates from 20% to 30%. Five-year survival rates in ‘curative’ operations are as high as 50%.

Adjuvant treatment trials of perioperative chemotherapy with regimens such as epirubicin, cisplatin and infusional 5-FU (ECF), or epirubicin, oxaliplatin and capecitabine (EOX), improved 5-year survival in operable gastric and lower oesophageal adenocarcinomas from 23% to 36–51%, depending on the preoperative stage. Adjuvant postoperative treatment with cisplatin, 5-FU and radiotherapy, compared with surgery alone, significantly increased median
survival from 28 to 35 months, and 5-year survival from 41% to 47%.

Advanced disease may be palliated with chemotherapy, such as epirubicin or docetaxel combined with cisplatin and infusional 5-FU, or oxaliplatin and capecitabine, with a response in 40–50% of patients for a median of 8–12 months in those with good performance status (see p. 383). The addition of trastuzumab for tumours overexpressing Her2 has improved median survival from 11 to 16 months, but the addition of treatments targeting VEGFR (bevacizumab) or EGFR (cetuximab or panitumumab) have not proved successful.

Supportive care for patients with upper gastrointestinal cancers, more than cancers in any other site, must include attention to nutrition with the use of endoscopic stents to relieve obstruction, nasojejunal and percutaneous gastrostomy feeding tubes, and occasionally parenteral nutrition. When the disease progresses beyond active anticancer treatment, management of the distressing obstructive symptoms can include octreotide to reduce secretions and, if necessary, a venting gastrostomy.

### Gastrointestinal stromal tumours

Gastrointestinal stromal tumours (GIST) are rare, slow-growing neoplasms that may arise in the stomach or small or large intestine. Prognosis depends on size, site, Ki-67 proliferation index (see p. 384), and association with neurofibromatosis type 1. Immunohistochemistry for CD117 and DOG-1 is usually positive. If it is negative, diagnosis can be reached by analysis of the known mutational sites in cKIT or PDGFRA oncogenes. These mutations are also predictive of dose requirements and treatment response to the receptor TKi, imatinib, or sensitivity to alternative TKis (see pp. 601–602). Surgery is potentially curative for localized disease, and imatinib adjuvant therapy for 3 years prolongs survival. In metastatic disease, imatinib treatment should continue until relapse and can induce remissions in 50–80% on PET-CT criteria for a median of 2 years; further responses are possible to alternative TKis, such as sunitinib and nilotinib.

### Lower gastrointestinal cancers

#### Small intestine cancer

Predisposing factors for small intestinal cancer, and its presentation and treatment, are described on pages 402–403. The principles of treatment are determined by extrapolation from management of the more common colorectal cancers.

#### Colorectal cancer

Presentation and diagnosis of colorectal cancer are described on page 424.

#### Prevention
• **A low-fat, high-fibre diet** for the prevention of sporadic colorectal cancer, along with endoscopic screening, is recommended for at-risk patients with a strong family history and for inherited syndromes (e.g. familial adenomatous polyposis, Lynch syndrome).

• **NSAIDs or aspirin** may play a role in prevention. After 5 years’ treatment with daily aspirin, there is a 35% reduction in all gastrointestinal cancers (used for those who are not at risk of gastric erosions).

### Screening
See page 425.

### Management
Management should be undertaken by multidisciplinary teams working in specialist units. About 80% of patients with colorectal cancer undergo surgery, though fewer than half of these survive more than 5 years. The operative procedure depends on the cancer site. Long-term survival is determined by the stage of the primary tumour, the achievement of clear surgical margins and the presence of metastatic disease (**Box 17.53**). There has been a gradual move from using Dukes' classification to the TNM system.

### Prognostic factors
The site of the disease, above or below the pelvic peritoneal reflection, CT scan staging, surgical margins, TNM stage and performance status are the main clinical prognostic factors (**Box 17.54**). Gene expression profiling, using Oncotype Dx and Coloprint, for example, can identify prognostic subgroups but is not predictive of treatment benefit. High microsatellite instability (MSI) predicts for a better prognosis and can be used to identify low-risk patients for whom adjuvant therapy is unlikely to be of benefit. Mutations in **BRAF** occur in 6–8% and indicate a poor prognosis, as do mutations with predictive effect in **KRAS** in 40% and **NRAS** in...
10–15% of cancers.

### Box 17.54

  - RAS wild type

## Surgery

### Rectal cancer

Total mesorectal excision (TME) is used for careful removal of the entire package of mesorectal tissue surrounding the cancer. A low rectal anastomosis is then performed. Abdomino-perineal excision, which requires a permanent colostomy, is reserved for very low tumours within 5 cm of the anal margin. TME combined with preoperative chemo-radiotherapy reduces local recurrence rates in rectal cancer to around 8% and improves survival. Local transanal surgery is used very occasionally for early superficial rectal cancers.

### Colon cancer

A segmental resection and restorative anastomosis, with removal of the draining lymph nodes as far as the root of the mesentery, is employed for cancer elsewhere in the colon. Surgery in patients with obstruction carries greater morbidity and mortality. Where technically possible, preoperative decompression by endoscopic stenting with a mesh-metal stent relieves obstruction; surgery can therefore be elective rather than emergency, and is probably associated with a decrease in morbidity and mortality.

### Neoadjuvant chemotherapy and radiotherapy

Neoadjuvant chemo-radiation treatment of rectal cancers, using cisplatin and 5-FU with radiotherapy, has increased the proportion of locally advanced tumours that can be resected with clear surgical margins (long-course radiotherapy) and reduced local relapse rate (both short- and long-course radiotherapy), but has not improved distant metastatic relapse and overall survival. Preoperative rather than postoperative treatment has reduced toxicity to the other pelvic structures due to preservation of the normal anatomical relations.

Adjuvant chemotherapy with 6 months of infusional 5-FU and folinic acid (leucovorin) or oral capecitabine for rectal and colonic adenocarcinoma reduces the risk of death by 30% and
significantly increases 5-year survival for node-positive stage III disease (Dukes' C) by 10–15%, from 40% to 55%. A further 4% improvement in one trial was achieved by the addition of oxaliplatin but with additional toxicity. Less benefit is seen for stage II node-negative patients. The adjuvant use of anti-VEGF or EGFR-targeted treatments is still being investigated with respect to RAS gene status.

**Follow-up**

All patients who have surgery should have a total colonoscopy performed before surgery to look for additional lesions. If total colonoscopy cannot be achieved before surgery, a second ‘clearance’ colonoscopy within 6 months of surgery is essential. Patients with stage II or III disease should be followed up with regular colonoscopy and carcinoembryonic antigen (CEA) measurements; rising levels of CEA suggest recurrence. CT scanning to detect operable liver metastases should be performed for up to 5 years post surgery.

**Metastatic colorectal cancer**

Advanced colorectal cancer is successfully palliated with little toxicity by 5-FU and folinic acid regimens or oral capecitabine in approximately 30% of patients for a median of 12–14 months. The addition of irinotecan or oxaliplatin increases the proportion who benefit to 55%, and extends median survival to 18 months but with increased toxicity. Anti-EGFR and VEGFR agents (Box 17.55) increase the response rate with chemotherapy, such as 5-FU/folinic acid with oxaliplatin or irinotecan (FolFOX or FolFIRI), to 68% and the median survival from 19 to 24 months. Toxicity of the anti-VEGFR agents commonly leads to hypertension, proteinuria, arterial thrombus, mucosal bleeding and perforation, and delayed wound healing. The anti-EGFR agents cause acneiform rash, hypomagnesaemia, and hypersensitivity reactions.

**Box 17.55**

EGFR, endothelial growth factor receptor; FolFIRI, folinic acid (leucovorin), fluorouracil, irinotecan; FolFOX, folinic acid (leucovorin), fluorouracil, oxaliplatin; VEGFR, vascular endothelial growth factor receptor.
Treatment can be intermittent or may comprise an intensive induction phase followed by maintenance with 5-FU and a relevant targeted agent which prolongs the progression-free survival but not the overall survival.

Liver and lung metastases are a common problem with colorectal cancers. With appropriate selection of patients who have a good performance status and in whom MRI and PET-CT scans do not demonstrate disease elsewhere, local treatment can prolong good-quality survival. This includes a variety of methods from surgical resection to gamma-knife irradiation, radiofrequency, cryo-ablation or hepatic artery embolization. Small lesions can be ablated, but larger lesions are best managed by partial hepatectomy or a combination approach, so that embolization is followed by hepatic regeneration before final resection. Patient selection is critical; long-term survival without recurrence is reported in up to 20% of patients at 5 years with a single <4-cm lesion amenable to resection presenting more than a year from initial diagnosis. More patients can be rendered suitable with perioperative chemotherapy, such as FolFOX or FolFIRI with cetuximab if RAS is wild-type.

**Anal cancer**

Management, where possible, is with surgery. If disease is locally advanced, downstaging is achieved by using chemoradiotherapy with mitomycin-C (MMC) and 5-FU, followed by surgery.

**Further reading**

Hepatobiliary and Pancreatic Cancers

Liver

Hepatocellular carcinoma

Hepatocellular carcinoma (HCC; see p. 485) arises in a cirrhotic liver in 95% of cases and can be screened and detected by cross-sectional imaging and a rise in serum α-fetoprotein.

Management and prognosis

Surgical resection of isolated lesions <5 cm in diameter or up to three lesions <3 cm in diameter is associated with a median survival of 5 years, although the remaining liver remains at risk of further recurrence. Liver transplantation offers the only opportunity for cure for patients with a small primary but is often limited by the underlying cause of the hepatitis and cirrhosis. Conventional chemotherapy and radiotherapy are unsuccessful; transarterial embolization or radiofrequency ablation in patients with small primaries as above and adequate liver function prolongs survival, though less successfully than surgery. Antiangiogenic compounds are being evaluated: sorafenib prolongs survival to 10 months in patients with non-resectable tumours.

Biliary tract

Cancer of the biliary tract may be intra- or extrahepatic. These malignancies represent approximately 1% of all cancers. A number of associations have been identified, such as choledochal cyst and chronic infection of the biliary tract with, for example, Clonorchis sinensis. There are also associations with autoimmune disease processes, such as primary sclerosing cholangitis, and inflammatory bowel disease.

Carcinoma of the gall bladder

(See pp. 497–498).

Cholangiocarcinoma

(See also p. 498.) This usually presents with jaundice and is detected by imaging: initially ultrasound and thereafter CT and, in particular, magnetic resonance cholangiopancreatography (MRCP). Spread is usually by local lymphatics or local extension. Cholangiocarcinoma of the common bile duct may be resectable at presentation but local extension precludes such management in the majority of more proximal lesions. Localized disease justifies an aggressive surgical approach, including partial hepatic resection. Hepatic transplantation for selected stage 1 and 2 disease has achieved 80% 5-year survival.

Palliative chemotherapy for patients with good performance status and advanced disease,
using gemcitabine and cisplatin, achieves a response in 50% with a median survival of 12 months. Chemo-radiation has been used to treat localized small hilar cholangiocarcinoma, and radiotherapy can provide good analgesia.

**Pancreas**

**Pancreatic adenocarcinoma**

**Prognosis**

The 5-year survival rate for carcinoma of the pancreas is approximately 2–5%, with surgical intervention representing the only chance of long-term survival. Approximately 20% of all cases have a localized tumour suitable for resection and a median survival of 2 years, but in an elderly population, many of these individuals have co-morbid factors that preclude such major surgery.

**Management**

There is no proven adjuvant therapy for pancreatic cancer following surgery. To optimize the percentage of patients undergoing possible surgical resection, it is necessary to review each case in a multidisciplinary meeting. This approach also allows formulation of treatment strategies for those considered unsuitable for surgery.

In the majority of cases, management is palliative. Obstruction of the biliary tree and jaundice is a debilitating complication, often associated with severe pruritus but also the cause of non-specific malaise, lethargy and anorexia. Endoscopic placement of endoprostheses (stents) offers excellent palliation.

Palliative surgery has a role in duodenal obstruction (a complication seen in 10% of cases), but in advanced disease, self-expanding metal stents can be placed across the duodenal obstruction with excellent short-term results.

Chemo-radiotherapy with gemcitabine for small, locally advanced disease can achieve a response in 30% and a median survival of 17 months. Palliative chemotherapy for advanced disease with gemcitabine and cisplatin can achieve a response in approximately 20% of patients with advanced disease and an improvement in median survival from 6 to 12 months.

With disease progression, abdominal pain is a frequent complicating factor; it may prove extremely difficult to treat but can be sometimes helped by radiotherapy.

**Neuroendocrine tumours of the pancreas**

Treatment options for pancreatic neuroendocrine tumours (see also pp. 512–513) require a multidisciplinary approach and depend on the presence or absence of metastatic (usually hepatic) disease. Surgical resection of the pancreatic lesion is the only potential curative
approach. Aggressive surgical intervention, including resection of the primary lesion, as well as liver resection for metastasis, has been used in selected cases. Somatostatin analogues, such as octreotide and lanreotide, have been used specifically for the control of symptoms secondary to the hormonal secretion. Radionuclide-labelled octreotide can also be used to induce responses in 23% for a median of 17 months.

The chemotherapeutic agents streptozotocin, 5-FU and cisplatin produce partial remission in 33% for a median of 9 months, while median survival is 31 months, reflecting the indolent natural history of these tumours. Everolimus and sunitinib can provide palliative benefit with prolongation of progression-free survival from 5.5 to 11 months and increased survival.

In patients with extensive liver metastasis, occlusion of the arterial blood flow by hepatic arterial embolization may control hormone-related symptoms. In most cases, the tumours are slowly progressive and may allow a reasonable quality of life for several years.

Epithelial Ovarian Cancer

Aetiology and pathology

There is uncertainty over the tissue of origin that gives rise to the 80% of all ovarian cancers that are epithelial (Box 17.56). The ovarian surface epithelium of the serosal peritoneum or the epithelial lining of the fallopian tube fimbriae are the most likely candidates. There is a
consistent relationship between the risk of epithelial ovarian cancer (EOC) and the frequency and duration of ovulation. While not mechanistically explained, this has provided a successful rationale for reducing the risk of EOC by up to one-third through early pregnancy and use of the oral contraceptive pill. The non-epithelial cancers are of germ cell or stromal origin, although molecular biological markers have shown that the category of mixed Müllerian carcinosarcoma is an entirely epithelial tumour with metaplastic stromal elements.

**Box 17.56**

**Ovarian cancer pathology**

- Serous cystadenocarcinoma
- Papillary cystadenocarcinoma
- Endometrioid cancer
- Adenocarcinoma
- Mucinous cancer
- Clear cell cancer
- Mixed mesodermal Müllerian tumours
- Germ cell cancers:
  - Dysgerminoma
  - Embryonal cancer
  - Endodermal sinus tumour
  - Choriocarcinoma
  - Teratoma – immature/mature
- Granulosa cell tumours
- Brenner, Sertoli–Leydig tumour, carcinoid tumours
- Other stromal cell tumours

*BRCA1* or *BRCA2* germline mutations (see **Box 17.47**) are present in 10% overall, except in those with a family history of breast or ovarian cancer. In high-grade serous histology, *BRCA* mutations are present in 23% of patients <50 years old, falling to 12% in those >50 years, despite a lack of family history in 40%.

**Clinical features**

Ovarian cancer typically causes few specific symptoms, often leading to late diagnosis; however, it is not silent (**Box 17.57**).
Symptoms associated with ovarian cancer that need investigation

- Persistent abdominal distension (women often refer to this as bloating)
- Feeling full when eating or early satiety and loss of appetite
- Pelvic or abdominal pain
- Increased urinary urgency or frequency

Sometimes, there is a sensation of a pelvic mass, which may become (acutely) painful; often, however, there is only vague abdominal distension and epigastric discomfort. Symptoms of irritable bowel syndrome can be confused with those of ovarian cancer but rarely present for the first time over the age of 50, when they should stimulate investigation for ovarian cancer.

On examination, the majority of patients present with a pelvic mass and advanced stage III (spread within the peritoneal cavity) or IV (extraperitoneal) disease. Screening (see p. 592) by serum CA125 tumour marker and transvaginal ultrasound scan does detect some early cancers with improved survival, but is being further refined with serial tests to avoid too many negative laparotomies and is thus still considered a research tool.

Investigations

Pelvic examination should be complemented by a serum CA125 tumour marker in primary care and transvaginal ultrasound. MRI is the definitive imaging technique for the pelvis, while CT-PET scans assist in staging the patient. A risk of malignancy index (RMI) of >250 (Box 17.58) should trigger investigation by a specialist gynaecological cancer team.

Box 17.58

Risk of ovarian malignancy index (RMI)

- RMI combines three pre-surgical features and is a product of the ultrasound scan score (U), the menopausal status (M) and the serum CA125 level (CA125):
  \[
  \text{RMI} = U \times M \times \text{CA125}
  \]
- The ultrasound result is scored as 1 point for each of the following characteristics:
  - multilocular cysts, solid areas, metastases, ascites and bilateral lesions: \( U = 0 \) (for an ultrasound score of 0), \( U = 1 \) (for an ultrasound score of 1), \( U = 3 \) (for an ultrasound score of 2–5).
- The menopausal status is scored as 1 = pre-menopausal and 3 = post-menopausal. The classification of ‘post-menopausal’ relates to women who have had no period for more than 1 year or women over the age of 50 who have had a hysterectomy.
- Serum CA125 is measured in IU/mL and can vary between 0 and hundreds or even thousands of units.
• If the RMI is >250, a strong suspicion of ovarian cancer should be maintained.

BRCA mutation status should be assessed in patients with a positive family history (see Box 17.46), and in those with high-grade serous adenocarcinoma histology under the age of 50 to identify the potential for targeted treatment with PARP inhibitors.

Prognosis

Histological subtype (clear cell and mucinous are worse), grade/differentiation, stage, extent of residual disease following surgery (macroscopic versus microscopic or none) and performance status are all significant independent prognostic factors for survival (Box 17.59).

Box 17.59

</tbody>
</table>

Five-year survival rates for stage III vary with BRCA mutational status: BRCA1 44% and BRCA2 61%, compared to BRCA-negative 25%. BRCA status is also a predictive marker for increased sensitivity to platinum and anthracycline cytotoxics, and to PARP inhibitors like olaparib.

Management
Debulking surgery (with total abdominal hysterectomy, bilateral salpingo-oophorectomy, omentectomy, and stripping of the sub-diaphragmatic peritoneum) has a major role in the treatment of ovarian cancer. When disease is confined to the ovary – that is, stage I – surgery can be curative in 80–90% if the histology is well to moderately differentiated. For patients with poorly differentiated or more advanced disease, and spread throughout the peritoneal cavity, surgery still has a major role in staging and in improving survival when it is possible to debulk optimally to no visible residual disease. Primary chemotherapy and delayed surgery is an alternative approach when disease is too advanced to permit optimal primary debulking surgery and is able to render approximately one-third of inoperable patients fit for optimal debulking surgery. Survival of patients with such advanced disease is equal, whether chemotherapy is given before or after surgery, but preoperative downstaging can avoid much surgical morbidity.

Carboplatin, which is associated with fewer side-effects than cisplatin, has become the mainstay of EOC chemotherapy. Response is achieved in approximately two-thirds of patients. Paclitaxel has been shown to increase the response rate and improve the survival of many patients when added to a platinum-based treatment. Adjuvant treatment with carboplatin and paclitaxel for stage I high-risk disease increases the absolute 5-year survival by 9%, from 70% to 79%, and for combined stages I–III completely debulked disease by 19%, from 60% to 79%, a relative risk reduction of 29%.

In more advanced disease, 75% of patients will respond to combination chemotherapy and the median survival is approximately 3 years. Treatment at recurrence may involve surgery for oligo-metastatic disease with a long treatment-free interval, but can also be delayed in advanced cases until the disease is symptomatic. Further palliative responses can be achieved with carboplatin and paclitaxel if the treatment-free interval is >6 months; liposomal doxorubicin, etoposide, gemcitabine and trabectedin are all active drugs for the palliation of recurrent disease. Up to 30% of those with metastatic disease may be alive after 5 years, although this falls to 5–10% if the cancer is not able to be debulked at operation or has spread outside the peritoneal cavity. It has proven difficult to develop more targeted biological agents for ovarian cancer, apart from olaparib for BRCA-mutated disease. Bevacizumab, when added to chemotherapy, has increased disease-free survival by 3–6 months without increasing overall survival, and has a limited role, except perhaps in platinum-resistant recurrent disease.

Stage III EOC tends to remain exclusively within the peritoneal cavity, which has led to new intraperitoneal routes of treatment administration with a 17% improved survival for those with minimal residual disease after surgery. However, at recurrence, bulk disease in the peritoneum commonly causes progressive bowel obstruction, which may require palliative operation or expert palliative care support to manage the terminal phases of the illness.

Further reading
Renal cell carcinoma

Clinical features and diagnosis

See page 791.

Investigations and management

At diagnosis, renal cancers are staged using CT and/or MRI scans to assess operability and the presence of distant metastases.

A nephrectomy is performed unless bilateral tumours are present or the contralateral kidney functions poorly, in which case conservative surgery, such as partial nephrectomy, may be indicated.

For patients with metastatic disease, prognosis is predicted on the basis of the Heng criteria (Karnofsky performance status score <80, haemoglobin below the lower limit of normal, neutrophils and platelets above the upper limit of normal, raised calcium, <6 months from diagnosis). Those with no risk factors are considered as having a favourable prognosis and 75% will be alive at 2 years; those with 1–2 risk factors are considered intermediate-prognosis (53% alive at 2 years); and those with 3 or more risk factors are considered poor-prognosis (7% survival at 2 years). If metastases are present and the patient is in the favourable or intermediate group, nephrectomy may still be warranted when the primary tumour constitutes the main bulk of disease, since regression of metastases has been reported after removal of the main tumour mass. Adjuvant treatments are unproven and under investigation. The 5-year survival rate is 60–70% with tumours confined to the renal parenchyma, 15–35% with lymph node involvement, and only approximately 5% in those who have distant metastases.

TKIs are the mainstay of treatment for metastatic renal cancer. Sunitinib has a 30–40% response rate and a median time to progression of 11 months. It is a toxic drug, with fatigue, diarrhoea, sore mouth and taste disturbance its main side-effects. It can also cause cardiac dysfunction with prolonged use. It is normally given for 28 days, followed by a 2-week break. Pazopanib, a related drug, is better tolerated and of similar efficacy. Patients who fall into the favourable-prognosis group may be treated with immunotherapy: for example, high-dose IL-2. Following failure of immunotherapy or a first-line TKI, the drug axitinib may be used; if that fails, some may respond to everolimus. Bevacizumab has activity and is sometimes combined with interferon. Isolated metastases – of brain or lung, for instance – may be suitable for excision.

Urothelial cancers
Clinical features and diagnosis

(See also pp. 791–792) Prognosis depends on the performance status of the patient, the TNM stage of the tumour (and whether it has penetrated the bladder muscle in bladder tumours, in particular), and its degree of differentiation. After surgery, the surgical margins, lymphovascular invasion and nodal involvement are further prognostic factors.

Management

Renal pelvis and ureteric tumours

Early-stage tumours are treated by nephro-ureterectomy. Adjuvant radiotherapy and chemotherapy appear to be of little or no value. The remainder of the urothelium is at risk of further primary transitional cell cancers (TCCs) in about half of patients and requires surveillance cystoscopy. Metastatic TCC is treated as for bladder tumours (see below).

Bladder tumours

Superficial bladder TCCs within the basement membrane are treated by transurethral resection or local diathermy. The risk of recurrence varies with the differentiation, and follow-up check cystoscopies and cytological examination of the urine are required. Recurrent superficial TCC can be treated with bladder instillation of BCG (bacille Calmette-Guérin) or, alternatively, with chemotherapy agents such as gemcitabine or mitomycin to delay further recurrence for 18 months on average.

Patients with muscle-invasive bladder tumours are treated with radical cystectomy if under 70 years, and radical radiotherapy if over 70 years, with salvage cystectomy for recurrences. In the absence of metastases and with adequate renal function (glomerular filtration rate >60 mL/min), surgery or radical radiotherapy should be preceded by neoadjuvant chemotherapy; this is cisplatin-based, with methotrexate, vinblastine and doxorubicin (MVAC) or cisplatin and gemcitabine. Neoadjuvant chemotherapy improves the absolute cure rate by 10%. The prognosis ranges from a 5-year survival rate of 80–90% for lesions not involving bladder muscle to 5% for those presenting with metastases.

Alternatively, those with T1 grade 3 to T4 tumours can be offered the chance of bladder preservation with chemo-radiotherapy using cisplatin and 5-FU. This can achieve complete response at subsequent transurethral resection in 66%, bladder preservation and a good quality of life in 67%, and a comparable long-term survival (30–50% at 5 years) to cystectomy. Cystectomy requires a new bladder to be made out of small bowel, joining this to the urethra if possible, or an ileal conduit.

Metastatic bladder cancer.

This is a chemosensitive cancer; it is usually a TCC, although other variants may occur, such as squamous tumours where schistosomiasis is endemic. Cisplatin-based treatment is the mainstay and response rates of 40–60% are seen. Approximately 5–10% are durable. Second-line
chemotherapy often produces responses in previously responsive tumours; combinations include carboplatin and paclitaxel. Targeting the PD-1/PD-L1 axis (see p. 601) is producing encouraging results and is likely to be used increasingly in management of this disease.

**Prostate cancer**

### Early prostate cancer

#### Clinical features and diagnosis

(See p. 792.) Diagnosis is usually made on a raised serum prostate-specific antigen (PSA), followed by a transrectal ultrasound-guided needle biopsy.

#### Prognosis

The histological appearances are graded and accorded a Gleason score; together with the height of the serum PSA, plus accurate staging of the local extent of disease with pelvic MRI (dynamic contrast) and transrectal ultrasound, this score can identify prognostic groups ([Box 17.60](#)). Treatment decisions must balance the age and performance status of the patient with the predicted behaviour of the cancer, which is becoming more objectively identifiable with advances in gene profiling. This allows the selection of patients with good prognosis for no active treatment; they may reasonably choose to be kept under surveillance and, like 75% of men over the age of 80, die with, but not because of, their prostate cancer.

### Box 17.60

**Prostate cancer: prognostic factors**

**At initial diagnosis**

- Clinical stage
- Biopsy Gleason grade
- Serum PSA level

**Post surgery**

- Surgical/pathological stage
- Surgical margins
- Extracapsular spread, extension to seminal vesicles or lymph nodes

**Metastatic hormone-resistant**

- Performance status
Management

(See also p. 793.) Patients with disease localized to the prostate requiring treatment can be managed by curative surgery (radical prostatectomy), external beam radiotherapy, or brachytherapy implants, which can achieve equivalent survival rates but differ in the spectrum of unwanted side-effects with respect to incontinence and sexual dysfunction. Radiotherapy tends to be used more frequently in older patients who wish to avoid surgery. In appropriately selected series of patients, a 5-year survival of 85% can be achieved. Adjuvant radiotherapy after radical prostatectomy can reduce PSA relapse but has not increased overall survival. Discussion between patient and clinician is vital to enable a treatment choice that is most appropriate to the patient's circumstances; many of these individuals are elderly and the side-effects of treatment are significant, often not leading to an improvement in mortality. For many patients (those with combined Gleason scores of 6 or below), localized prostate cancer may be managed expectantly using the strategy of watchful waiting, in which regular PSA tests are supplemented with repeat prostatic biopsies to establish whether the cancer is becoming more aggressive and thus warrants active therapy. Alternatively, they may be managed through a strategy of simple surveillance using changes in symptoms and PSA alone to guide therapy.

Endocrine therapy

Prostate cancer is the most hormone-sensitive malignancy. The androgen receptor (AR) plays a critical role; prostate cancer tissue is able to trap circulating androgens so that tissue levels of androgens are maintained, despite very low (castration) levels of circulating androgens. Resistance may involve receptor super-sensitivity and altered ligand binding, allowing other steroids to act as agonists and eventually bypassing the androgen receptor.

Androgen deprivation

• **GnRH agonists**, e.g. goserelin and leuprorelin, and orchidectomy are equally effective at lowering circulating androgens and inducing responses in prostate cancer. However, in the first week, GnRH agonists produce a rise in luteinizing hormone (LH) and testosterone, which can result in a tumour flare in metastatic disease; they must therefore be combined with an antiandrogen, e.g. flutamide, in the initial phases. An alternative is to use a gonadorelin antagonist, e.g. degarelix.

• **Androgen receptor blockers** include drugs such as bicalutamide and the more potent antagonist, enzalutamide.

• **Androgen synthesis inhibitors** such as abiraterone act by inhibiting CYP17.

• **Corticosteroids and oestrogens** may also be helpful in disease that has become refractory to
Hormonal agents may also be used after chemotherapy for prostate cancer, and both enzalutamide and abiraterone have been shown to prolong life in this situation. Adjuvant androgen deprivation treatment, such as monthly depot goserelin, has not improved survival following surgery, but when given before and during radiotherapy, can improve the overall survival at 3 years for T1–T3 tumours from 62% to 78%.

Advanced prostate cancer

Management

Locally advanced prostate cancer (T3 N0) without distant metastases is best treated with combined androgen deprivation and radiotherapy, which improves 10-year survival, compared with endocrine treatment alone, from 61% to 71%.

Metastatic prostate cancer is normally treated initially with androgen deprivation to achieve castration and effectively palliated in 70% of patients for a median duration of response of 2 years. Once this fails, the disease is termed castration-resistant and further palliative options are more potent hormonal drugs or chemotherapy, such as docetaxel. If chemotherapy fails, a return to hormonal therapy may prolong disease control. The timing of chemotherapy remains unclear; rather like in breast cancer, it may be deferred until all available hormonal therapy has failed or it may be used earlier.

Other non-hormonal approaches are frequently used: bone-targeted drugs such as alpharadin ($^{223}$radium), zoledronic acid and denosumab, as well as palliative radiotherapy for painful metastases.

Germ cell tumours

Testicular and ovarian germ cell tumours

Germ cell tumours are the most common cancers in men aged 15–35 years but comprise only 1–2% of all cancers. They are much less common in women. There are two main histological types: seminoma (dysgerminoma in women) and non-seminoma. Non-seminomas may be comprised of varying proportions of mature and immature elements; the mature elements are now known as teratoma (previously, this term referred to all non-seminomas). Teratomas in women present as dermoid cysts with low malignant potential. Germ cell tumours may rarely occur in extragonadal sites in the midline from pituitary, mediastinum or retroperitoneum but should be treated in a similar manner (Box 17.61).
Germ cell histology: WHO classification

- Seminoma
- Non-seminoma
  - Embryonal carcinoma
  - Choriocarcinoma
  - Yolk sac tumour
  - Teratoma

Clinical features

Most men present with a testicular mass, which is often painful; some have symptoms of metastases to the para-aortic lymph nodes with back pain and gynaecomastia if the tumour is hCG-secreting (Fig. 17.41). In women, the mass presents with vague pelvic symptoms but at a younger age than the more common epithelial ovarian cancers.

![Fig. 17.41](image.png)

**FIGURE 17.41** Gynaecomastia (arrowed) in a man with β-human chorionic gonadotrophin-secreting testicular cancer.

Investigations

- **Ultrasound or MRI scanning** of the testicle or ovary is required.
- **Assay of serum tumour markers** includes α-fetoprotein (AFP), β-human chorionic gonadotrophin (β-hCG) and lactate dehydrogenase (LDH). A urinary pregnancy test for hCG in the accident and emergency department has saved the lives of young men with metastatic germ cell cancer.
- **CT or MRI scan** is performed to seek distant metastases.

Treatment

- **Surgery for men** is by the inguinal approach to avoid spillage of highly metastatic tumour in
the scrotum.

- **Surgery in women** for diagnosis and staging should always be conservative, compared to the approach in epithelial ovarian cancer, with preservation of fertility because of the efficacy of chemotherapy.

## Management

### Seminomas

Seminomas are very radiosensitive and chemo-sensitive. They are associated with a raised serum LDH but only rarely a mildly raised β-hCG and never a raised AFP. Stage I disease limited to the gonad is associated with a 10–30% 5-year risk of recurrence with surgery alone. Adjuvant therapy, with either chemotherapy or radiotherapy to the para-aortic lymph nodes, is preferred as it leads to greater than 95% cure in early-stage disease. Carboplatin is the first choice because of convenience, reduced acute side-effects, and absence of the long-term risks of secondary malignancy that are associated with radiotherapy. Alternatively, intensive surveillance can be undertaken, with treatment reserved for those who relapse; this approach carries an equally high cure rate, since combination chemotherapy (e.g. cisplatin, etoposide and bleomycin, BEP) will cure 95% of those with visible metastatic disease.

### Non-seminomas

The risk of relapse with stage I disease varies from 5% to 50%, depending on the prognostic factors of histological differentiation, presence of embryonal elements, and extent of local and vascular invasion.

For those at moderate to high risk, adjuvant chemotherapy with a single cycle of BEP leads to a 95% cure rate. The option of primary retroperitoneal lymph node dissection in high-risk non-seminoma is now rarely taken up, as it is less likely to reduce the risk of recurrence.

Metastatic disease commonly involves para-aortic lymph nodes and lungs but may spread rapidly (especially if there are trophoblastic (β-hCG-producing) elements present) and cause life-threatening respiratory or other organ failure. A rapid diagnosis can be made in the presence of gynaecomastia and a positive urinary pregnancy test before the institution of potentially life-saving treatment. About 80% of teratomas will express either β-hCG or AFP, and almost all metastatic disease will be associated with an elevation of the less specific serum marker, LDH.

The percentage cure rate depends on the height of the tumour markers (AFP > 10000 and β-hCG > 100 000 IU/L) and the sites of metastases; it ranges from 50% to 95%. The most established regimen is BEP and 3–4 cycles are usually given.

Patients who relapse following initial chemotherapy may well be cured by subsequent chemotherapy with further cisplatin and ifosfamide, or high-dose chemotherapy with carboplatin and etoposide, and a stem cell transplant.

Although approximately 20% of men will be infertile due to azoospermia at the time of
diagnosis, the majority of the remainder will retain their fertility after chemotherapy and be able to father normal children. Similarly, most women retain their fertility, although less is known about the association with infertility at presentation owing to the much lower frequency of germ cell tumours in women.

**Further reading**

**Metastatic Cancer of Unknown Primary**

Patients presenting with symptoms of their metastases, or with an incidental finding on imaging without a clinically obvious primary after investigation, represent a common clinical problem and comprise 5–10% of patients in a specialist oncological centre. As a result of several systematic studies, some with postmortem follow-up, the following guidance should aid the choice of appropriate investigation and treatment. On the other hand, poor-prognosis patients identified by performance status, histology, site and extent of disease can be spared the discomfort of intensive investigation and given more appropriate palliative care.

**Diagnosis**

Diagnosis requires histology first and foremost, as it will lead to the identification of several distinct groups.

- *Squamous cancers* mostly present in the lymph nodes of the cervical region; 80% will be
associated with an occult head and neck primary, the remainder arising from the lung. Inguinal nodes usually point to a primary of the genital tract or anal canal. Treatment with radiotherapy and chemotherapy may have curative potential, especially in the head and neck area, and even in the absence of an identifiable primary on pan-endoscopy.

- **Poorly differentiated or anaplastic cancers** will include the majority of the curable cancers, such as high-grade lymphomas and germ cell tumours, and should be suspected in all young patients with midline masses. They are identifiable by their immunocytochemistry and tumour markers. Gene markers, such as ip12 for germ cell tumours and Bcl-2 for lymphomas, are increasingly available to aid this diagnosis. Treatment and prognosis are as outlined for lymphoma and germ cell tumours.

- **Adenocarcinomas** form the majority of cases. Their investigation should be guided by the desire to identify the most treatable options, and the knowledge that the largest proportion will have arisen from the lung or pancreas, with relatively poor treatment prospects.

  Tissue tumour markers can be helpful *(Box 17.62)* and, increasingly, gene profiles are able to identify the primary site of origin by gene expression microarray and RT-PCR.

</tbody>
</table>

Mutation analysis is more easily available to identify potential targets for treatment, such as RAS, EGFR and RET; however, clinical trials are still necessary to identify whether specific pathway inhibitors have a therapeutic effect when so identified.

Investigations should therefore always start with a review of the histology, a chest X-ray and a CT scan of chest, abdomen and pelvis; in men, they should include serum PSA and rectal ultrasound to identify prostate cancers, and in women, mammography and breast MRI to identify occult breast cancer, and pelvic MRI to identify ovarian cancer.

For good-prognosis patients wishing to have palliative chemotherapy, investigations such as
endoscopy to identify lung, colon or stomach primaries are indicated to guide the choice of chemotherapy agents, although the diagnostic yield of 4–5% must be set against the discomfort and risks. Serum tumour markers for other solid cancers, although highly sensitive, are too non-specific and unreliable to be useful as diagnostic aids in this situation.

Further investigation may require PET-CT for head and neck, lung and possibly other primaries, and radio-isotope scans for thyroid and carcinoid tumours. PET-CT may also be used to seek other metastatic sites if considering surgery for unifocal disease.

### Prognosis

The histological type and extent of the disease and performance status of the patient are the key factors. Most large series report an overall median survival of 12 weeks but considerably better survival amongst the special subgroups, such as patients presenting with isolated nodal metastases who have a significantly better prognosis than the majority with visceral and/or bone metastases and may warrant more extensive investigation.

### Management

If investigations have not identified a primary site, surgery may be considered for unifocal adenocarcinoma of unknown primary (ACUP) metastases in lymph nodes, lung, liver and brain, especially if due to melanoma and so having the potential for long-term survival.

In women, an isolated axillary lymph node metastasis should be treated as for lymph-node-positive breast cancer; this has a similar prospect for long-term cure, though without the need for breast surgery. Malignant ascites in women should be treated with a trial of chemotherapy, as for primary peritoneal, fallopian tube or epithelial ovarian cancer. The prognosis for those responding to the therapeutic trial is similar to that in the disease of known primary origin. Primary chemotherapy that achieves an excellent response by imaging and CA125 criteria should be followed by debulking surgery; if successful, it carries a median survival in excess of 4 years.

For men, the occasional occult prostatic cancer found from a raised serum PSA offers some palliative treatment prospects *(Box 17.63)*.

---

### Box 17.63

**Adenocarcinoma of unknown primary: where search for the primary is of therapeutic benefit**

- Breast, e.g. isolated axillary lymphadenopathy
- Ovary, e.g. peritoneal carcinomatosis
- Prostate, e.g. pelvic lymphadenopathy
- Colon, e.g. liver metastases
For the patient presenting with hepatic metastases, which are most commonly associated with an occult gastrointestinal primary, there is an increasing choice and efficacy of chemotherapy agents for gastrointestinal cancers that have the potential to improve their palliation.

If there is an excellent response, suitable patients may even be considered for hepatic ablation or resection. If, after all efforts, no primary has been identified, palliative chemotherapy treatment can achieve responses in 20–40% in highly selected series, with median survivals of 9–10 months, and 5–10% surviving to 5 years.

Miscellaneous arthropathies 705
Musculoskeletal problems, particularly pain, are common. They represent 20–30% of the workload of the primary care physician. They can be divided into three types

- **Pain arising from soft tissues around joints**, such as muscles and tendons. The joints themselves are normal. These are the most common locomotor problems, and are generally self-limiting or respond to simple analgesia, physiotherapy or exercise.

- **Diseases of the joints themselves**. Osteoarthritis is more common than inflammatory arthritis, especially in the elderly.

- **Autoimmune rheumatic diseases**. These include disorders such as systemic lupus erythematosus (SLE), where the locomotor symptoms are just one manifestation of a systemic disorder.

**Anatomy and Physiology of the Normal Joint**

A joint can be defined as a place where two or more bones meet. There are three types of joints: fibrous, fibrocartilaginous and synovial.

**Fibrous and fibrocartilaginous joints**

These include the intervertebral discs, the sacroiliac joints, the pubic symphysis and the costochondral joints. Skull sutures are fibrous joints. Little movement occurs at such joints.

**Synovial joints**

Synovial joints (Fig. 18.1) include the ball-and-socket joints (e.g. hip) and the hinge joints (e.g. interphalangeal). They are designed to allow movement, which is restricted to a required range, and stability is maintained during use. The load is distributed across the surface, thus preventing damage by overloading or disuse. Each structural component of a synovial joint plays a key functional role, and different components are affected in different disease processes.
Juxta-articular bone

Bone structure and physiology are discussed on page 707. The bone that abuts a joint (juxta-articular bone) is highly vascular and comprises a light framework of mineralized collagen enclosed in a thin coating of tougher, cortical bone. It withstands pressure poorly if the normal intra-articular covering of hyaline cartilage is worn away, as in osteoarthritis (OA; see pp. 667–671). This process can lead to abnormalities of bone growth and remodelling (see p. 668).

Articular cartilage

The hyaline cartilage lining the bones within a joint is called articular cartilage. It is avascular and derives nourishment from synovial fluid. It is predominantly composed of type II collagen, encoded by the COL2A1 gene, which forms a mesh-like network. Within the mesh are giant macromolecular aggregates of proteoglycan. These heterogeneous macromolecules comprise protein chains with side-chains of the carbohydrates keratan and chondroitin sulphate (aggrecans). These molecules have a negative charge and retain water in the structure by producing a dynamic tension between the retaining force of the collagen matrix and the expansive effect of osmotic pressure. Intermittent pressure from ‘loading’ of the joint is essential to normal cartilage function and encourages movement of water, minerals and nutrients between cartilage and synovial fluid. Chondrocytes secrete collagen and proteoglycans, and are embedded in the cartilage. They migrate towards the joint surface along with the matrix they produce. Defects in articular cartilage and underlying bone are features of osteoarthritis.

Synovium and synovial fluid

The joint capsule, which is connected to the periosteum, is lined with synovium, which is a few cells thick and vascular. Its surface is smooth and non-adherent, and is permeable to...
proteins and crystalloids. As there are no macroscopic gaps, it is able to retain normal joint fluid, even under pressure. Macrophages and fibroblast-like synoviocytes form the synovial layer by cell-to-cell interactions mediated by cadherin II. The synoviocytes release hyaluronan into the joint space, which helps to retain fluid in the joint. Synovial fluid is a highly viscous fluid secreted by the synovial cells and has a similar consistency to plasma. Glycoproteins ensure a low coefficient of friction between the cartilaginous surfaces. Tendon sheaths and bursae are also lined by synovium. Inflammation of the synovium is a feature of inflammatory arthritis.

Ligaments and tendons
These structures stabilize joints. Ligaments are variably elastic and this contributes to the stiffness or laxity of joints (see pp. 666–667). Tendons are inelastic and transmit muscle power to bones. The joint capsule is formed by intermeshing tendons and ligaments. The point where a tendon or ligament joins a bone is called an enthesis and may be the site of inflammation. Whereas most ligaments and tendons run outside the joints, some, like the supraspinatus tendon in the shoulder and the cruciate ligaments in the knee, run through the joint. Inflammation or trauma to these joints can cause severe joint symptoms.

Blood vessels and nerves
The ligaments, periosteum, synovial tissue and capsule of the joint are richly supplied by blood vessels and nerves. Pain usually derives from inflammation of these sites because the synovial membrane is relatively insensitive.

Enzymes and cytokines
Connective tissue constantly undergoes repair and remodelling. Degradation is mediated by enzymes such as aggrecanase and matrix metalloproteinases (MMPs), which require zinc and act at a neutral pH. There are several MMPs that act on different collagens, such as the gelatinases (MMP-2 and 9), which degrade denatured collagen. MMPs also act on non-collagen proteins: for example, the stromelysins (MMP-3, 10 and 11), which degrade proteoglycans and fibronectin.

The turnover of normal collagen is initiated by cytokines: for example, interleukin-1 (IL-1) synthesized by chondrocytes. Activation of latent MMPs and tissue plasminogen activator then occurs.

Two inhibitors, TIMP (tissue inhibitor of metalloproteinase) and plasminogen activator inhibitor-1 (PAI-1), inhibit degradation during matrix remodelling.

Skeletal muscle
This tissue consists of bundles of myocytes containing actin and myosin molecules. These molecules interdigitate and form myofibrils, which cause muscle contraction in a similar way to myocardial muscle (see p. 933). Bundles of myofibrils (fasciculi) are covered by connective tissue, the perimysium, which merges with the epimysium (covering the muscle)
and forms the tendon, which attaches to the bone surface (enthesis).

Though not strictly a component of the joint itself, muscles are so closely related to joints that strain and tension in muscles are commonly interpreted by patients as joint pain. Pain in muscles and ligaments (myofascial pain) is a very common cause of locomotor symptoms. Primary inflammatory disease of muscle (myositis) is far less common.

Clinical Approach to the Patient with Rheumatic Disease

Taking a musculoskeletal history

In most rheumatological disorders, the diagnosis is clinical: that is, made on the history and examination, and then supported by investigations. Taking a thorough history is therefore crucial, and the main points to consider are described below.

Who is the patient?

Age
Some diseases, such as OA, polymyalgia rheumatica and giant cell arteritis, present mainly in patients over the age of 50. Conversely, autoimmune rheumatic diseases and inflammatory arthritis frequently present in people under 50.

Gender
Most rheumatological diseases can occur in either gender, but rheumatoid arthritis (RA), SLE and systemic sclerosis are more common in women, whereas gout and ankylosing spondylitis are more common in men.

Ethnicity
SLE is more common in African–Caribbean people than in other ethnicities.

Job
Jobs that involve heavy use of one part of the body can lead to soft tissue pain and/or OA: for example, in the low back, hips and knees of people who do a lot of heavy lifting. Musculoskeletal pain may also affect people's ability to do their job, care for children or dependants, or enjoy social activities. It is important to assess these effects on quality of life.

Has something happened to the patient?

Physical trauma
Trauma to a particular region of the body may cause pain there and/or in related regions. Where an injury is associated with a legal or insurance claim, this process may affect longevity
Psychosocial stress and depression

The biopsychosocial model of disease holds that physical, psychological and social factors interact to contribute to symptoms. This model is used in musculoskeletal disorders, where pain may cause distress and poor sleep, which in turn build up muscle tension and worsen the pain (see pp. 663–665). Acute stressful events, such as bereavement, bullying, abuse and redundancy, may exacerbate these symptoms.

What are the symptoms?

Pain

• **Where is it? Is it localized or generalized?** The pattern of joint involvement is a useful clue to the diagnosis (e.g. distal interphalangeal joints in nodal OA).

• **Is it arising from joints, spine, muscles or bone, with local tenderness?** Soft tissue lesions and inflamed joints are locally tender.

• **Could it be referred from another site?** Joint pain is localized but may radiate distally – shoulder to upper arm; hip to thigh and knee.

• **Is it constant, intermittent or episodic?** How severe is it – aching or agonizing?

• **Are there aggravating or precipitating factors?** Is it made worse by activity and eased by rest (mechanical), or worse after rest (inflammatory).

• **Are there any associated neurological features?** Numbness, pins and needles and/or loss of power suggest ‘nerve’ involvement. The distribution of symptoms is a useful clue to the nerve or nerve root affected.

Stiffness

• **Is it generalized or localized?** Spine or joint stiffness is common after injury.

• **Does it affect the limb girdles or periphery?**

• **Is it worse in the morning and relieved by activity?**
  – Joint stiffness for more than 30 min each morning – think of inflammatory arthritis.
  – Morning spinal stiffness in younger adults – think of ankylosing spondylitis (see pp. 683–685).
  – Shoulder and pelvic girdle stiffness and pain in a patient over 55 years may be polymyalgia rheumatica (see p. 700).

Swelling

• **Does it affect one joint or several?** Look for symmetry or asymmetry, and/or a peripheral or proximal pattern. An acute monoarthritis may be due to trauma, gout, pseudogout or sepsis (fever or immunosuppression). A polyarthritis is more likely to be due to OA or RA.
• **Is it constant or does it come in short-lived or longer episodes?**
• **Is there associated inflammation** (redness and warmth)?

**Extra-articular symptoms**
Osteoarthritis and soft tissue problems are not usually associated with symptoms outside the joints. The presence of features such as rash, breathlessness, neurological symptoms or blood disorders suggests that the locomotor problems may be one facet of a more systemic disorder, such as RA, psoriatic arthritis or SLE.

**What medication is the patient taking?**
• **Could a drug be a cause?** Diuretics may precipitate gout in men and older women. Steroids can cause avascular necrosis. Some drugs cause a lupus-like syndrome (see p. 692).
• **Have the symptoms responded to medication?** A good response to a trial of steroids suggests an inflammatory or autoimmune problem.

**What is the family history?**
Does anyone in the family have a similar problem or another related disorder?

**Examination of the joints**
Always observe patients, looking for disabilities, as they walk into the room and sit down. General and neurological examinations are often necessary. Guidelines for rapid examinations of the limbs and spine are shown in **Box 18.1**.

---

**Box 18.1**

**Rapid examinations of the limbs and spine**

**Upper limbs**

• **Raise the arms sideways to the ears (abduction). Reach behind the neck and back.** Difficulties with these movements indicate a shoulder or rotator cuff problem.
• **Hold the arms forwards, with elbows straight and fingers apart, palm up and palm down.** Fixed flexion at the elbow indicates an elbow problem. Examine the hands for swelling, wasting and deformity.
• **Place the hands in the ‘prayer’ position with the elbows apart.** Flexion deformities of the fingers may be due to arthritis, flexor tenosynovitis or skin disease. Painful restriction of the wrist limits the person's ability to move the elbows out with the hands held together.
• **Make a tight fist.** Difficulty with this indicates a loss of flexion or grip. Grip strength can be measured.
**Lower limbs**

- **Ask the patient to walk** a short distance away from and towards you, and to stand still. Look for abnormal posture or stance.
- **Ask the patient to stand on each leg.** Severe hip disease causes the pelvis on the non-weight-bearing side to sag (positive Trendelenburg test).
- **Watch the patient stand and sit,** looking for hip and/or knee problems.
- **Ask the patient to straighten and flex each knee.**
- **Ask the patient to place each foot in turn on the opposite knee with the hip externally rotated.** This tests for painful restriction of the hip or knee. Abnormal hips or knees must be examined with the patient lying down.
- **Move each ankle up and down.** Examine the ankle joint and tendons, medial arch and toes while the patient is standing.

**Spine**

Stand behind the patient.

- **Ask the patient to (a) bend forwards to touch the toes with straight knees, (b) extend backwards, (c) flex sideways, and (d) look over each shoulder, flexing and extending and side-flexing the neck.** Observe abnormal spinal curves – scoliosis (lateral curve), kyphosis (forward bending) or lordosis (backward bending). A cervical and lumbar lordosis and a thoracic kyphosis are normal. Muscle spasm is worse whilst standing and bending. Leg length inequality leads to a scoliosis that decreases on sitting or lying (the lengths are measured with the patient lying down).
- **Ask the patient to lie supine.** Examine any restriction of straight-leg raising (see disc prolapse, below).
- **Ask the patient to lie prone.** Examine for anterior thigh pain during a femoral stretch test (flexing knee whilst prone), which indicates a high lumbar disc problem.
- **Palpate the spine and buttocks for tender areas.**

Examining an individual joint involves three stages: looking, feeling and moving *(Box 18.2).* A screening examination of the locomotor system, known by the acronym GALS (global assessment of the locomotor system), has been devised. Video demonstrations are available (see ‘Further reading’). GALS has been modified for examination of children.

---

**Box 18.2**

**Examination of the joint**

**Look at the appearance of the joint**

- Swelling – could be bony, fluid or synovial
Deformity:
- **Valgus**, where the distal bone is deviated laterally (e.g. knock-knees or genu valgum)
- **Varus**, where the distal bone is deviated medially (bow-legs or genu varum)
- Fixed flexion or hyperextension

Rash – especially psoriasis

Muscle wasting – easier to see in large muscles like the quadriceps

Scars – from surgery or trauma

Signs of inflammation

Symmetry:
- Are the right and left joints (e.g. hips, knees, any other paired joint) the same?
- If not, which do you think is abnormal?

**Feel**

Swelling:
- **Fluid swelling** (effusion) usually represents increased synovial fluid in inflammatory arthritis, but can be due to blood or pus
- **Synovial swelling** is rubbery or boggy and usually occurs in inflammatory arthritis
- **Bony swelling**, such as Heberden's nodes in the fingers, is usually seen in osteoarthritis

Warmth – a warm joint may be inflamed or infected

Tenderness – may represent joint inflammation, but many people have chronic tenderness all over the body (e.g. in fibromyalgia)

**Move**

Active movement:
- Is the range full and pain-free?
- Is the movement fluid?
- In the hands, can the patient perform fine movements?
- In the legs, can the patient walk properly?

Compare movements on the right and left sides – are they symmetrical?

Is there crepitus when the joint is moved?

If active movement is limited, try passive movement:
- In a joint problem both will usually be affected.
- In a muscle or nerve problem, passive movement may remain full.

**Investigation of rheumatic disease**

Investigations are unnecessary in many of the common musculoskeletal problems; the diagnosis is clear from the history and examination findings. Tests help to exclude another condition and to reassure the patient or their primary care physician.
Useful blood screening tests

• Full blood count:
  – **Haemoglobin.** Normochromic, normocytic anaemia suggests chronic inflammatory and autoimmune diseases. Hypochromic, microcytic anaemia indicates iron deficiency, sometimes due to non-steroidal anti-inflammatory drug (NSAID)-induced gastrointestinal bleeding.
  – **White cell count.** Neutrophilia is seen in bacterial infection (e.g. septic arthritis). It also occurs with corticosteroid treatment. Lymphopenia is found in viral illnesses or SLE. Neutropenia may reflect drug-induced bone marrow suppression. Eosinophilia is seen in eosinophilic granulomatosis with polyangiitis (see p. 1121).
  – **Platelets.** Raised platelets occur with any chronic inflammation. Thrombocytopenia is seen in drug-induced bone marrow suppression and may be a feature of SLE.

• **Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP).** An increase in these reflects inflammation. Plasma viscosity is also raised in inflammatory disease.

• **Bone and liver biochemistry.** A raised serum alkaline phosphatase may indicate liver or bone disease. A rise in liver enzymes is seen with drug-induced toxicity. For other investigations of bone, see pages 708–711.

Other blood and urine tests

• Protein electrophoretic strip (and/or immunofixation), serum free light chain testing and urinary Bence Jones protein – to exclude myeloma as a cause of a raised ESR.

• Serum uric acid – for gout.

• Antistreptolysin O titre – in rheumatic fever.

Serum autoantibody studies

• **Rheumatoid factors (RFs)** (see also pp. 674–675). Rheumatoid factors are detected by enzyme-linked immunosorbent assay (ELISA). RFs are antibodies (usually immunoglobulin (Ig) M, but also IgG or IgA) against the Fc portion of IgG. They are detected in 70% of people with RA, but are not diagnostic. RFs are detected in many autoimmune rheumatic disorders (e.g. SLE), in chronic infections, and in asymptomatic older people (Box 18.3).

**Box 18.3**

**Conditions in which rheumatoid factor (RF) is found in the serum**

- **Anti-citrullinated peptide antibodies (ACPA).** These antibodies are directed against citrullinated antigens, vimentin, fibrinogen, alpha enolase and type II collagen. They are measured by an ELISA technique and are present in up to 80% of people with RA. They have a high specificity for RA (90%, with a sensitivity of 60%). They are helpful in early disease when the RF is negative, to distinguish it from acute transient synovitis (see Box 18.26). Positivity for RF and/or ACPA is associated with a worse prognosis and an increase in the likelihood of bony erosions in people with RA.

- **Antinuclear antibodies (ANAs).** These are detected by indirect immunofluorescent staining of fresh frozen sections of rat liver or kidney or Hep-2 cell lines. Different patterns reflect a variety of antigenic specificities that occur with different clinical pictures (see Box 18.36). ANA is used as a screening test for SLE and systemic sclerosis – a negative ANA makes either condition highly unlikely – but low titres occur in RA and chronic infections and in normal individuals, especially the elderly (Box 18.4).

- **Anti-double-stranded DNA (dsDNA) antibodies.** These are usually detected by a precipitation test (Farr assay), ELISA or an immunofluorescent test using *Crithidia luciliae* (which contains dsDNA). Raised anti-dsDNA is highly specific for SLE; the levels usually rise and fall in parallel with disease activity so can be used to monitor the level of treatment required.

- **Anti-extractable nuclear antigen (ENA) antibodies** (see Box 18.36). These produce a speckled ANA fluorescent pattern, and can be identified by ELISA. The most commonly measured ENAs are:
  - **anti-Ro and anti-La,** which occur in Sjögren syndrome and SLE
  - **anti-Sm,** which is highly specific for SLE
  - **anti-Jo-1,** which is the most common of the anti-tRNA synthetase enzymes that occur in some people with dermatomyositis or polymyositis
  - **anti-topoisomerase I (anti-Scl 70),** which is specific for systemic sclerosis
  - **anti-RNA polymerase I and III,** which occur in systemic sclerosis and are associated with pulmonary fibrosis.

- **Anti-neutrophil cytoplasmic antibodies (ANCAs)** (see p. 702). These are predominantly IgG autoantibodies directed against the primary granules of neutrophil and macrophage lysosomes. They are strongly associated with small-vessel vasculitis. Two major clinically relevant ANCA patterns are recognized on immunofluorescence:
  - **proteinase 3 (PR3-ANCA),** also called cytoplasmic or cANCA, producing a granular immunofluorescence and seen in granulomatosis with polyangiitis (GPA)
  - **myeloperoxidase (MPO-ANCA),** also called perinuclear or pANCA, producing a perinuclear stain and seen in microscopic polyarteritis (polyangiitis) and eosinophilic
• **Antiphospholipid antibodies** (see p. 695). These are detected in the antiphospholipid syndrome (see p. 695).

• **Immune complexes.** Immune complexes are infrequently measured, largely because of variability between assays and difficulty in interpreting their meaning. Assays based on the polyethylene glycol (PEG) precipitation method or C1q binding are available commercially.

• **Complement.** Low complement levels indicate consumption and suggest an active disease process in SLE.

### Joint aspiration and examination of synovial fluid

Examination of joint (or bursa) fluid is used mainly to diagnose septic, reactive or crystal arthritis. The appearance of the fluid is an indicator of the level of inflammation. The procedure is often undertaken in combination with injection of a corticosteroid. Aspiration alone is therapeutic in crystal arthritis (*Box 18.5*).

---

**Box 18.5**

**Joint aspiration**

*This is a sterile procedure that should be carried out in a clean environment.*

1. Explain the procedure to the patient; obtain consent.
2. Clean the skin and your hands scrupulously. Remove rings and wristwatch. Put on gloves.
3. Draw up local anaesthetic (and corticosteroid if it is being used) and then use a new needle.
4. Warn the patient. Insert the needle, injecting local anaesthetic as it advances; if a joint effusion is suspected, attempt to aspirate as you advance it.
5. If fluid is obtained, change syringes and aspirate fully.
6. Examine the fluid in the syringe and decide whether or not to proceed with a corticosteroid injection (if fluid is clear or slightly cloudy) or send for microbiological tests.
7. Cover the injection site and advise the patient to rest the affected area for a few days. Warn the patient that the pain may increase initially but to report urgently if this persists beyond a few days, if the swelling worsens or if they become febrile, since this might indicate an infected joint.

---

Aspiration and analysis of synovial fluid are always indicated when septic or crystal-induced arthritis is suspected, particularly a monoarthritis. Normal fluid is clear and straw-coloured, and contains <3000 white blood cells (WBC)/mm³. Inflammatory fluid is cloudy and contains >3000 WBC/mm³. Septic fluid is opaque and less viscous, and contains up to 75...
There is much overlap.

Polarized light microscopy is performed for crystals:

- **gout**: negatively bi-refringent, needle-shaped crystals of sodium urate
- **calcium pyrophosphate deposition arthropathy**: rhomboidal, weakly positively bi-refringent crystals of calcium pyrophosphate.

**Gram staining** is essential if septic arthritis is suspected and may identify the organism immediately. Joint fluid should be cultured and antibiotic sensitivities requested.

**Diagnostic imaging and visualization**

- **X-rays** can be diagnostic in certain conditions (e.g. established RA) and are the first investigation in many cases of trauma. X-rays can detect joint space narrowing, erosions in RA, calcification in soft tissue, new bone formation, e.g. osteophytes, and decreased bone density (osteopenia) or increased bone density (osteosclerosis):
  - In acute low back pain (see pp. 656–657), X-rays are indicated only if the pain is persistent, recurrent, associated with neurological symptoms or signs, or worse at night or associated with symptoms such as fever or weight loss.
  - Radiological changes are common in older people and may not indicate symptomatic OA or spondylosis.
  - X-rays are of little diagnostic value in early inflammatory arthritis but are useful as a baseline from which to judge later change.

- **Ultrasound** is particularly useful for periarticular structures, soft tissue swellings and tendons, and for detecting active synovitis in inflammatory arthritis. It is increasingly used to examine the shoulder and other structures during movement, e.g. shoulder impingement syndrome (see pp. 653–654). Doppler ultrasound measures blood flow and hence inflammation. Ultrasound may be used to guide local injections.

- **Magnetic resonance imaging (MRI)** shows bone changes and intra-articular structures in striking detail. Visualization of particular structures can be enhanced with different resonance sequences. \(T_1\)-weighted MRI is used for anatomical detail, \(T_2\)-weighted for fluid detection and short tau inversion recovery (STIR) for the presence of bone marrow oedema. MRI is more sensitive than X-rays in the early detection of articular and periarticular disease. Gadolinium injection enhances inflamed tissue. MRI is especially useful for detection of damage to non-bony tissues in or near joints, e.g. meniscal tears in the knee and torn rotator cuff muscles in the shoulder; detection of nerve root compression in the spine; detection of inflamed muscle in myositis; and early detection of synovitis in inflammatory arthritis.

- **Computerized axial tomography (CT)** is useful for detecting changes in calcified structures but the dose of irradiation is high.

- **Bone scintigraphy** utilizes radionuclides, usually \(^{99m}\)Tc, and detects abnormal bone turnover and blood circulation; although non-specific, it helps in detecting areas of inflammation, infection or malignancy. It is best used in combination with other anatomical imaging
techniques.

• **Dual-energy X-ray absorptiometry (DXA) scanning** uses very low doses of X-irradiation to measure bone density and is used in the screening and monitoring of osteoporosis.

• **Positron emission tomography (PET) scanning** uses radionuclides, which decay by emission of positrons. $^{18}$F-Fluorodeoxyglucose uptake indicates areas of increased glucose metabolism. PET is used to locate tumours and demonstrate large-vessel vasculitis, e.g. Takayasu's arteritis (see pp. 1054–1055). PET scans are combined with CT to improve anatomical details.

• **Arthroscopy** is a direct means of visualizing a joint, particularly the knee or shoulder. Biopsies can be taken, surgery performed in certain conditions (e.g. repair or trimming of meniscal tears), and loose bodies removed.

• **Nerve conduction studies and electromyography** are used to diagnose nerve entrapment syndromes (such as carpal or tarsal tunnel) and to distinguish myositis from neuropathies.

### Further reading

### Common Regional Musculoskeletal Problems

See *Figure 18.2*. 

Pain in the neck and shoulder

See Box 18.6.

### Box 18.6

**Pain in the neck and shoulder**

- Trauma (e.g. a fall)
- Mechanical or muscular neck pain
- Whiplash injury
- Disc prolapse – nerve root entrapment
- Ankylosing spondylitis
- Shoulder lesions:
  - Rotator cuff tendonitis
  - Calcific tendonitis or bursitis
– Impingement syndrome or rotator cuff tear
– Adhesive capsulitis (true ‘frozen’ shoulder)
– Inflammatory arthritis or osteoarthritis
  • Polymyalgia rheumatica
  • Fibromyalgia (chronic widespread pain)
  • Chronic (work-related) upper limb pain syndrome
  • Tumour

### Mechanical or muscular neck pain (shoulder girdle pain)

Unilateral or bilateral muscular-pattern neck pain is common and usually self-limiting. It can follow injury, falling asleep in an awkward position, or prolonged keyboard working. Chronic burning neck pain occurs because of muscle tension from anxiety and stress.

Spondylosis seen on X-ray increases after the age of 40 years but it is not always related to pain. Spondylosis can, however, cause stiffness and increases the risk of mechanical or muscular neck pain. Muscle spasm is palpable and tender, and may lead to abnormal neck posture (e.g. acute torticollis). Muscular-pattern neck pain is not localized but affects the trapezius muscle, the C7 spinous process and the paracervical musculature (shoulder girdle pain). Pain often radiates upwards to the occiput and is commonly associated with tension headaches. These features are also seen in chronic widespread pain (see pp. 664–665).

### Management

Patients are given short courses of analgesic therapy, along with reassurance and explanation. Physiotherapists can help to relieve spasm and pain, teach exercises and relaxation techniques, and improve posture. An occupational therapist can advise about the ergonomics of the workplace if the problem is work-related (see p. 665).

### Nerve root entrapment

This is caused by an acute cervical disc prolapse or pressure on the root from spondylothotic osteophytes narrowing the root canal.

Acute cervical disc prolapse presents with unilateral pain in the neck, radiating to the interscapular and shoulder regions. This diffuse, aching, dural pain is followed by sharp, electric shock-like pain down the arm, in a nerve root distribution, often with pins and needles, numbness, weakness and loss of reflexes (Box 18.7).

Cervical spondylosis occurs in the older patient with posterolateral osteophytes compressing the nerve root and causing root pain (see Fig. 21.64), commonly at C5/C6 or C6/C7; it is seen on oblique radiographs of the neck. An MRI scan clearly distinguishes facet joint OA, root canal narrowing and disc prolapse.

### Management

A support collar, rest, analgesia and sedation are used initially as necessary. Patients should be advised not to carry heavy items. They usually recover in 6–12 weeks. MRI is the investigation of choice if surgery is being considered or the diagnosis is uncertain (Fig. 18.3). A cervical root block, administered under direct vision by an experienced pain specialist, may relieve pain while the disc recovers. Neurosurgical referral is recommended if the pain persists or if the neurological signs of weakness or numbness are severe or bilateral. Bilateral root pain, with or without long track symptoms or signs, is a neurosurgical emergency because a central disc prolapse may compress the cervical spinal cord. Posterior osteophytes may cause spinal claudication and cervical myelopathy.
Whiplash injury

Whiplash injury results from acceleration–deceleration forces applied to the neck, usually in a road traffic accident when the car of a person wearing a seat belt is struck from behind. A simple decision plan based on clinical criteria helps to distinguish those most at risk and who warrant radiography. There is a low probability of serious bony injury if there is:

- no midline cervical tenderness
- no focal neurological deficit
- normal alertness
- no intoxication
- no other painful distracting injury.

CT scans are reserved for those with bony injury. MRI scans occasionally show severe soft tissue injury. Whiplash injuries may lead to litigation or insurance claims.

Whiplash injury is a common cause of chronic neck pain, although most people recover within a few weeks or months. Delayed recovery depends, in part, on the severity of the initial injury. The pattern of chronic neck pain is often complex, involving pain in the neck, shoulder and arm. It may be accompanied by subjective symptoms, such as headache, dizziness and poor concentration. The subjective nature of these symptoms has led to controversy about their cause. The problem is more commonly seen in industrialized countries, where the conflictive nature of the compensation process may actually delay recovery. Non-conflictive means of compensation may lead to a better prognosis.
Management

Management is with reassurance (the patient is often distressed and anxious), analgesia, a short-term support collar and physiotherapy. Pain may take a few weeks or months to settle and the patient should be warned of this. Clinical trial evidence shows no benefit with prolonged physiotherapy.

Pain in the shoulder

The shoulder is a shallow joint with a large range of movement. The humeral head is held in place by the rotator cuff (Fig. 18.4), which is part of the joint capsule. It is comprised of the tendons of infraspinatus and teres minor posteriorly, supraspinatus superiorly, and teres major and subscapularis anteriorly. The rotator cuff (particularly supraspinatus) prevents the humeral head from blocking against the acromion during abduction; the deltoid pulls up and the supraspinatus pulls in to produce a turning movement, and the greater tuberosity glides under the acromion without impingement. Shoulder pathology restricts or is made worse by shoulder movement. Specific diagnoses are difficult to make clinically but that may not matter for pain management.

![FIGURE 18.4](image)

Pain in the shoulder can sometimes be due to problems in the neck; the differential diagnosis is shown in Box 18.8. Adhesive capsulitis (true frozen shoulder) is uncommon (see below). Early inflammatory arthritis and polymyalgia rheumatica in the elderly may present with shoulder pain. Shoulder pain is more common in diabetic patients than in the general population.
**Box 18.8**

**Differential diagnosis of ‘shoulder’ pain**

- Rotator cuff tendonitis pain is worse at night and radiates to the upper arm.
- Painful shoulders produce secondary muscular neck pain.
- Muscular neck pain (also known as shoulder girdle pain) does not radiate to the upper arm.
- Cervical nerve root pain is usually associated with pins and needles or neurological signs in the arm.

---

**Rotator cuff (supraspinatus) tendonosis**

This condition is a common cause of shoulder pain at all ages. It follows trauma in 30% of cases and is bilateral in under 5%. The pain radiates to the upper arm and is made worse by arm abduction and elevation, which are often limited. The pain is often worse during the middle of the range of abduction, reducing as the arm is raised fully; a so-called ‘painful arc syndrome’. When examined from behind, the scapula rotates earlier than usual during elevation. Passive elevation reduces impingement and is less painful. Severe pain virtually immobilizes the joint, although some rotation is retained (compare adhesive capsulitis; see below). There is also painful spasm of the trapezius. There may be an associated subacromial bursitis. Isolated subacromial bursitis occurs after direct trauma, falling on to the outstretched arm or elbow. Acromioclavicular osteophytes increase the risk of impingement and may need to be removed surgically.

X-ray or ultrasound is necessary only when rotator cuff tendonosis is persistent or the diagnosis is uncertain.

---

**Management**

Analgesics, NSAIDs and/or physiotherapy may suffice, but severe pain responds to an injection of corticosteroid into the subacromial bursa (*Fig. 18.4*). Patients should be warned that 10% will develop worse pain for 24–48 hours after injection. Some 70% improve over 5–20 days and mobilize the joint themselves. Physiotherapy helps persistent stiffness. Further ultrasound-guided corticosteroid injections may be needed but the long-term benefit is unclear.

---

**Torn rotator cuff**

This condition is caused by trauma but also occurs spontaneously in the elderly and in RA. It prevents active abduction of the arm but patients learn to initiate elevation using the unaffected arm. Once elevated, the arm can be held in place by the deltoid muscle. In younger people, the tear is repaired surgically but this is rarely possible in the elderly or in RA. Some patients require arthroscopic surgery.
Calcific tendonosis and bursitis

Calcium pyrophosphate deposits in the tendon are visible on X-ray but they are not always symptomatic. The pathogenesis is unclear, although ischaemia may play a part. The deposit is usually just proximal to the greater tuberosity. It may lead to acute or chronic recurrent shoulder pain and restriction of movement. A local corticosteroid injection may relieve the pain. The calcification may persist or resolve. Aspiration or breaking up of the deposit under ultrasound control may be required for persistent pain. Rarely, arthroscopic removal is necessary.

Shedding of crystals into the subacromial bursa causes a bursitis with severe pain and shoulder restriction. The shoulder feels hot and is swollen, and an X-ray shows a diffuse opacity in the bursa. The differential diagnosis of calcific bursitis is gout, pseudogout or septic arthritis. Aspiration and injection with corticosteroid can help.

Adhesive capsulitis (true ‘frozen’ shoulder)

This condition is uncommon but can develop with rotator cuff lesions, or following hemiplegia, chest or breast surgery, or myocardial infarction. Initially, it causes severe shoulder pain and a gradually reducing range of movement, leading to a ‘frozen’ phase where there is loss of all shoulder movements but little pain. NSAIDs and intra-articular injections of local anaesthetic and corticosteroids are helpful in the painful phase. Subsequently, there is usually a gradual improvement in function over weeks to months. Therapeutic exercises and physiotherapy help in later phases. Once the pain settles, arthroscopic release speeds functional recovery.

Pain in the elbow

Pain in the elbow can be due to epicondylitis, inflammatory arthritis or, occasionally, OA.

Epicondylitis

Two common sites where the insertions of tendons into bone become inflamed (enthesitis) are the common wrist extensor origin at the lateral humeral epicondyle (‘tennis elbow’) and the common wrist flexor origin at the medial epicondyle (‘golfer’s elbow’). Despite the names, both conditions are usually unrelated to either sport!

There is local tenderness. Pain radiates into the forearm on using the affected muscles – typically, gripping or holding a heavy bag in tennis elbow or carrying a tray in golfer's elbow. Pain at rest also occurs.

Management

Advise rest and arrange review by a physiotherapist. A local injection of corticosteroid at the
point of maximum tenderness is helpful when the pain is severe but needs physiotherapy follow-up to prevent recurrences (Fig. 18.5). Avoid the ulnar nerve when injecting golfer's elbow. Both conditions settle spontaneously eventually, but occasionally persist and require surgical release.

![Common extensor origin](image)

**FIGURE 18.5** Injection for tennis elbow.

**Pain in the hand and wrist**

(See Box 18.9.) Hand pain is commonly caused by injury or repetitive, work-related activities. When associated with pins and needles or numbness, it suggests a neurological cause arising at the wrist, elbow or neck. Pain and stiffness that are worse in the morning are due to tenosynovitis or inflammatory arthritis. The distribution of hand pain often indicates the diagnosis.

**Box 18.9**

**Causes of pain in the hand and wrist**

**All ages**

- Trauma/fractures
- Tenosynovitis:
  - Flexor with/without triggering
  - Dorsal
  - De Quervain's
- Carpal tunnel syndrome
• Ganglion
• Inflammatory arthritis
• Raynaud syndrome (see p. 1054)
• Chronic regional pain syndrome type I (see p. 665)

**Older patients**

• Nodal OA:
  – DIPs (Heberden's nodes)
  – PIPs (Bouchard's nodes)
  – First carpometacarpal joint
• Trauma – scaphoid fracture
• Pseudogout
• Gout:
  – Acute
  – Tophaceous
  DIPs/PIPs, distal/proximal interphalangeal joints.

---

**Tenosynovitis**

The finger flexor tendons run through synovial sheaths and under loops that hold them in place. Inflammation occurs with repeated or unaccustomed use, or in inflammatory arthritis. The thickened sheaths are often palpable.

*Flexor tenosynovitis* causes finger pain when gripping and stiffness of the fingers in the morning. Occasionally, a tendon causes a trigger finger, when the finger remains flexed in the morning or after gripping, and has to be pulled straight. A tender tendon nodule is palpable, usually in the distal palm. Trigger finger or thumb is more common in diabetic patients.

*Dorsal tenosynovitis* is less common, except in RA. The hourglass swelling extends from the back of the hand and under the extensor retinaculum.

*De Quervain's tenosynovitis* causes pain and swelling around the radial styloid, where the abductor pollicis longus tendon is held in place by a retaining band. There is local tenderness, and the pain at the styloid is worsened by flexing the thumb into the palm.

---

**Management**

Resting, splinting and NSAIDs may help. Local corticosteroids injected alongside the tendon under low pressure (not into the tendon itself) are helpful. Occasionally, surgery is needed if symptoms persist.

---

**Carpal tunnel syndrome**
This condition arises due to median nerve compression in the limited space of the carpal tunnel. Thickened ligaments, tendon sheaths or bone enlargement can cause it, but it is usually idiopathic. (Causes are discussed on p. 882.) The history is usually typical and diagnostic, the patient waking with numbness, tingling and pain in a median nerve distribution. The pain may radiate to the forearm. The fingers feel swollen but usually are not. Wasting of the abductor pollicis brevis develops with sensory loss in the radial three and a half fingers. The pain may be produced by tapping the nerve in the carpal tunnel (Tinel's sign) or by holding the wrist in flexion (Phalen's test).

Management
Management is with a splint to hold the wrist in dorsiflexion overnight, which relieves the symptoms and is diagnostic; used nightly for several weeks, it may produce full recovery. If it does not, a corticosteroid injection into the carpal tunnel (avoid the nerve!) helps in about 70% of cases, although it may recur. Persistent symptoms or nerve damage produce prolonged latency across the carpal tunnel on nerve conduction studies and require surgical decompression.

Other conditions causing pain

Inflammatory arthritis
This may present with pain, swelling and stiffness of the hands. In RA, the wrists, proximal interphalangeal (PIP) joints and metacarpophalangeal (MCP) joints are affected symmetrically. In psoriatic arthritis and reactive arthritis, a finger may be swollen (dactylitis), or the distal interphalangeal (DIP) joints and nails are affected asymmetrically.

Nodal osteoarthritis
This affects the DIP and less commonly PIP joints, which are initially swollen and red. The inflammation and pain settle but bony swellings remain (see pp. 669–670).

First carpometacarpal osteoarthritis
This causes pain at the base of the thumb when gripping, or painless stiffness at the base of the thumb, often in people with nodal OA.

Scaphoid fractures
These cause pain in the anatomical snuffbox. They are not seen immediately on X-ray; if there is clinical suspicion, a cast is necessary. Untreated scaphoid fractures can eventually cause pain because of failed union.

Ganglion
A ganglion is a jelly-filled, often painless swelling caused by a partial tear of the joint capsule
or tendon sheath. The wrist is a common site. Treatment is not essential, as many resolve or cause little trouble; otherwise, surgical excision is the best option.

**Dupuytren's contracture**

This condition is a painless, palpable fibrosis of the palmar aponeurosis, with fibroblasts invading the dermis. It causes puckering of the skin and gradual fixed flexion, usually of the ring and little fingers. It is more common in males, Caucasians, individuals with diabetes mellitus, and those who overuse alcohol. A similar fibrosis occurs in the feet and is often more aggressive. It is also associated with Peyronie's disease of the penis – a painful inflammatory disorder of the corpora cavernosa, leading eventually to painless fibrosis and angulation of the penis during erection. Intraleisonal steroid injections may help in early disease and some advocate transcutaneous needle aponeurotomy. Percutaneous collagenase injection into the lesion has been shown to be effective in several studies and is now first-line treatment used before surgery. Surgical release of the contracture is restricted to those with severe deformity of the fingers.

**Pain in the lower back**

Low back pain is a common symptom. It is often traumatic and work-related, although lifting apparatus, other mechanical devices and improved office seating help to avoid it. Episodes are generally short-lived and self-limiting, and patients attend a physiotherapist or osteopath more often than a doctor. Chronic back pain is the cause of 14% of long-term disability in the UK. The causes are listed in *Box 18.10*.

---

**Box 18.10**

**Causes of pain in the back (lumbar region)**

**Mechanical**

- Trauma
- Muscular and ligamentous pain
- Fibrositic nodulosis
- Postural back pain (sway back)
- Lumbar spondylosis
- Facet joint syndrome
- Lumbar disc prolapse
- Spinal and root canal stenosis
- Spondylolisthesis
- Disseminated idiopathic skeletal hyperostosis (DISH)
- Fibromyalgia, chronic widespread pain (see pp. 664–665)

**Inflammatory**
- Infective lesions of the spine
- Ankylosing spondylitis/sacroiliitis (see pp. 683–685)

**Metabolic**
- Osteoporotic spinal fractures (see pp. 711–715)
- Osteomalacia (see pp. 717–718)
- Paget's disease (see pp. 715–717)

**Neoplastic (see p. 749)**
- Metastases
- Multiple myeloma
- Primary tumours of bone

Referred pain

The majority of cases of low back pain are uncomplicated and arise from mechanical causes. Management of this type of back pain is summarized in **Box 18.11**.

**Box 18.11**

**Management of back pain**
- Most back pain presenting to a primary care physician needs no investigation
- Pain between the ages of 20 and 55 years is likely to be mechanical and is managed with analgesia, brief rest if necessary and physiotherapy
- Patients should stay active within the limits of their pain
- Early treatment of the acute episode, advice and exercise programmes reduce long-term problems and prevent chronic pain syndromes
- Physical manipulation of uncomplicated back pain produces short-term relief and enjoys high patient satisfaction ratings
- Psychological and social factors may influence the time of presentation
- Appropriate early management reduces long-term disability

One should be alert to clues in the history and examination that could suggest more serious causes of low back pain, as summarized in **Figure 18.6**.
In investigations

- **Spinal X-rays** *(Fig. 18.7)* are required only if the pain is associated with certain ‘red flag’ symptoms or signs, which indicate a high risk of more serious underlying problems:
  - starts before the age of 20 years or after 50
  - is persistent and a serious cause is suspected
  - is worse at night or in the morning, when an inflammatory arthritis (e.g. ankylosing spondylitis), infection or a spinal tumour may be the cause
  - is associated with a systemic illness, fever or weight loss
  - is associated with neurological symptoms or signs.
• **MRI (Fig. 18.8)** is preferable to CT scanning when neurological signs and symptoms are present. CT scans demonstrate bony pathology better. Interpretation of the relevance of the findings may require a specialist opinion.

  ![Figure 18.7](image1.png)

  **FIGURE 18.7** Spinal metastasis in L2. The patient had severe back pain and weight loss, and prior carcinoma of the breast.

  ![Figure 18.8](image2.png)

  **FIGURE 18.8** Magnetic resonance image of the lumbar spine. A large disc prolapse is shown at the L4/L5 level and a smaller prolapse at L5/S1 (arrowed). The signal from all the lumbar discs indicates dehydration.

• **Bone scans** are useful in infective and malignant lesions but are also positive in degenerative lesions.

• **Full blood count, ESR and biochemical tests** are required only when the pain is likely to be
due to malignancy, infection or a metabolic cause. Normal ESR and CRP distinguish mechanical back pain from polymyalgia rheumatica, a likely differential in the elderly.

**Mechanical low back pain**

Mechanical low back pain starts suddenly, may be recurrent and is helped by rest. It is often precipitated by an injury and may be unilateral or bilateral. It is usually short-lived.

**Examination**

The back is stiff and a scoliosis may be present when the patient is standing. Muscular spasm is visible and palpable, and causes local pain and tenderness. It lessens when sitting or lying. Excessive rest should be avoided. Once a patient develops low back pain, although the episode itself is usually self-limiting, there is a significantly increased risk of further back pain episodes. Risk factors for recurrent back pain include:

- female sex
- increasing age
- pre-existing chronic widespread pain (fibromyalgia)
- psychosocial factors, such as high levels of psychological distress, poor self-rated health and dissatisfaction with employment.

Chronic low back pain is a major cause of disability and time off work and is reduced by appropriate early management.

**Spinal movement** occurs at the disc and the posterior facet joints, and stability is normally achieved by a complex mechanism of spinal ligaments and muscles. Any of these structures may be a source of pain. An exact anatomical diagnosis is difficult but some typical syndromes are recognized (see below). They are often associated with, but not necessarily caused, by radiological spondylosis (see pp. 886–888).

**Postural back pain** develops in individuals who sit in poorly designed, unsupportive chairs.

**Lumbar spondylosis**

The fundamental lesion in spondylosis occurs in an intervertebral disc, a fibrous structure whose tough capsule inserts into the rim of the adjacent vertebrae. This capsule encloses a fibrous outer zone and a gel-like inner zone. The disc allows rotation and bending.

Changes in the discs occasionally start in teenage years or early twenties and often increase with age. The gel changes chemically, breaks up, shrinks and loses its compliance. The surrounding fibrous zones develop circumferential or radial fissures. In the majority, this is initially asymptomatic but visible on MRI as decreased hydration. Later, the discs become thinner and less compliant. These changes cause circumferential bulging of the intervertebral ligaments.
Reactive changes develop in adjacent vertebrae; the bone becomes sclerotic and osteophytes form around the rim of the vertebra (Fig. 18.8). The most common sites of lumbar spondylosis are L5/S1 and L4/L5.

In young people, disc prolapse through an adjacent vertebral end-plate produces a Schmorl's node on X-ray. This process is painless but may accelerate disc degeneration.

Spondylosis may be symptomless but can cause:

- episodic mechanical spinal pain
- progressive spinal stiffening
- facet joint pain
- acute disc prolapse, with or without nerve root irritation
- spinal stenosis
- spondylolisthesis.

**Facet joint syndrome**

Lumbar spondylosis also causes secondary OA of the misaligned facet joints. Pain is typically worse on bending backwards and when straightening from flexion. It is lumbar in site, unilateral or bilateral, and radiates to the buttock. The facet joints are well seen on MRI and may show OA, an effusion or a ganglion cyst. Direct corticosteroid injections into the joints under imaging may help but their long-term value is unclear. Physiotherapy to reduce hyperlordosis and weight reduction are helpful.

**Fibrositic nodulosis**

This condition causes unilateral or bilateral low back and buttock pain. There are tender nodules in the upper buttock and along the iliac crest. Such nodules are relevant only if they are tender. They are probably traumatic. Local, intralesional corticosteroid injections may help. No imaging is required.

**Postural back pain and sway back of pregnancy**

Low back pain is common in pregnancy and reflects altered spinal posture and increased ligamentous laxity. There is usually a hyperlordosis on examining the patient standing. Weight control and pre- and postnatal exercises are helpful, and the pain usually settles after delivery. Analgesics and NSAIDs are best avoided during pregnancy and breast-feeding. Epidurals during delivery are not associated with an increased incidence of subsequent back pain. Poor posture causes a similar syndrome in the non-pregnant, owing to obesity or muscular weakness. Poor sitting posture at work is a frequent cause of chronic low back pain.

**Management of mechanical back pain**

Adequate analgesia to allow normal mobility and avoidance of bed rest is best, combined with physical treatments such as physiotherapy, back muscle training regimens and manipulation.
Manipulation produces more rapid pain relief in some patients. Acupuncture may help. Re-education in lifting and exercises help to prevent recurrent attacks of pain. Most episodes recover, irrespective of the treatment given. A positive approach probably reduces the development of chronic pain. A comfortable sleeping position should be adopted using a mattress of medium (not hard) firmness.

## Acute lumbar disc prolapse

The central disc gel may extrude into a fissure in the surrounding fibrous zone and cause acute pain and muscle spasm. These events are often self-limiting. A disc prolapse occurs when the extrusion extends beyond the limits of the fibrous zone (Fig. 18.8). The weakest point is posterolateral, where the disc may impinge on emerging spinal nerve roots in the root canal.

The episode often starts dramatically during lifting, twisting or bending, and produces a typical combination of low back pain and muscle spasm, and severe, lancinating pains, paraesthesia, numbness and neurological signs in one leg (rarely both). The back pain is diffuse and usually unilateral, and radiates into the buttock. The muscle spasm leads to a scoliosis that reduces when lying down. The nerve root pain develops with, or soon after, the onset. The site of the pain and other symptoms are determined by the root affected (Box 18.12). A central high lumbar disc prolapse may cause spinal cord compression and long tract signs (i.e. upper motor neurone). Below L2/L3, it produces lower motor neurone lesions.

### Examination

On examination, the back often shows a marked scoliosis and muscle spasm. The straight-leg-raising test, whilst the patient is lying, is positive in a lower lumbar disc prolapse – raising the straight leg beyond 30° produces pain radiating down the leg further than the knee. Slight limitation or pain in the back limiting this movement is seen with mechanical back pain. Pain in
the affected leg produced by a straight raise of the other leg suggests a large or central disc prolapse. Look for perianal sensory loss and urinary retention or incontinence, which indicate a cauda equina lesion – a neurosurgical emergency (see p. 888). An upper lumbar disc prolapse produces a positive femoral stretch test: pain in the anterior thigh when the knee is flexed in the prone position.

**Management**

Advise a short period (2–3 days) of bed rest, lying flat for a lower disc but semi-reclining for a high lumbar disc, and prescribe analgesia and muscle relaxants. Once the pain is tolerable, encourage the patient to mobilize and refer them to a physiotherapist for exercises and preventative advice. The investigation of choice is MRI, which identifies the abnormal disc and any compressed nerves. An imaging-guided epidural or nerve root canal injection reduces pain rapidly, although the evidence that it speeds resolution or prevents surgery is unclear. Caudal epidural injections are less effective than lumbar ones. Resuscitation equipment must be available for these procedures. Referral to a surgeon for possible microdiscectomy or hemi-laminectomy is necessary if the neurological signs are severe, if the pain persists and is severe for more than 6–10 weeks, or if the disc is central. If bladder or anal sphincter tone is affected, it becomes a neurosurgical emergency.

**Spinal and root canal stenosis**

Progressive loss of disc height, OA of the facet joints, posterolateral osteophytes and buckling of the ligamentum flavum all contribute to root canal stenosis. These changes cause nerve root pain or spinal root claudication – pain and paraesthesia in a root distribution brought on by walking and relieved slowly by rest. The associated sensory symptoms, slower recovery when the patient rests, and presence of normal foot pulses distinguish this from peripheral arterial claudication. Severe cervical spondylosis may also produce spinal claudication, often with arm symptoms and signs.

The investigation of choice to identify the location and extent of stenosis is MRI. Spinal canal stenosis at more than one level is often associated with severe spondylosis and/or a congenitally narrow spinal canal. It causes buttock and bilateral leg pain, ‘heaviness’, paraesthesiae and numbness when walking. Rest helps, as does bending forwards, a manoeuvre that opens the spinal canal. Specialist surgical advice is necessary.

**Spondylolisthesis**

This condition occurs in adolescents and young adults when bilateral congenital pars interarticularis defects cause instability and permit a vertebra to slip, with or without preceding injury. Rarely, a cauda equina syndrome develops, with loss of bladder and anal sphincter control, and saddle-distribution anaesthesia. It is diagnosed radiologically and can be seen on plain radiographs, though MRI may be necessary if entrapment of nerve roots or
cauda equina syndrome is suspected. Low back pain in adolescents warrants investigation, and spondylolisthesis requires orthopaedic assessment. It needs careful monitoring during the growth spurt.

A degenerative spondylolisthesis may also develop in older people with lumbar spondylosis and OA of the facet joints.

**Diffuse idiopathic skeletal hyperostosis**

Diffuse idiopathic skeletal hyperostosis (DISH, or Forestier's disease) affects the spine and extraspinal locations. It causes bony overgrowths and ligamentous ossification, and is characterized by flowing calcification over the anterolateral aspects of the vertebrae. The spine is stiff but not always painful, despite the dramatic changes seen on plain radiographs, which are the imaging investigation of choice. Ossification at muscle insertions around the pelvis produces radiological ‘whiskering’. Similar changes occur at the patella and in the feet. It is more common in people with metabolic syndrome (high body mass index (BMI), diabetes mellitus, hypertension and dyslipidaemia; see p. 209).

**Management** is with analgesics or NSAIDs for pain, and exercise to retain movement and muscle strength.

**Osteoporotic crush fracture of the spine**

Osteoporosis is asymptomatic but leads to an increased risk of fracture of peripheral bones, particularly neck of femur and wrist, and thoracic or lumbar vertebral crush fractures. Such vertebral fractures develop without trauma, after minimal trauma, or as part of a major accident. They may develop painlessly or cause agonizing localized pain that radiates around the ribs and abdomen. Multiple fractures lead to an increased thoracic kyphosis. They cause disability and reduced quality of life. The diagnosis is confirmed by X-rays, showing loss of anterior vertebral body height and wedging, with sparing of the vertebral end-plates and pedicles. Bone oedema on MRI indicates that a fracture is recent. An underlying tumour and pathological fracture need to be excluded.

**Management**

Advise bed rest and analgesia until the severe pain subsides over a few weeks, then gradual mobilization. It may warrant hospitalization, and the prescription of intravenous bisphosphonates or subcutaneous or nasal calcitonin to relieve pain. There may be some residual pain and deformity.

The role of percutaneous vertebroplasty and balloon kyphoplasty remains unclear; there are no randomized controlled trials (RCTs) showing any benefit. Both involve inserting a needle through a pedicle into the affected vertebral body under CT guidance with the aim of stabilizing the fracture. Kyphoplasty involves inflating a balloon filled with methyl methacrylate cement in order to restore vertebral shape. Vertebroplasty is the injection of
cement alone, without restoring vertebral shape. Pain relief is usual with both but the risks are higher with vertebroplasty. Deciding when to intervene is complicated by the spontaneous recovery that many experience.

Bone density measurement and preventative treatment of osteoporosis are essential (see pp. 713–715).

### Septic discitis

Septic discitis may cause severe pain and rapid adjacent vertebral destruction. It is seen on MRI and requires urgent neurosurgical referral.

### Ankylosing spondylitis

Buttock pain and low back stiffness in a young adult suggest ankylosing spondylitis (see pp. 683–685), especially if they are worse at night and in the morning.

### Pain in the hip

‘Hip’ refers to a wide area between the upper buttock, trochanter and groin. It is useful to ask the patient to point to the site of pain and its field of radiation. Pain arising from the hip joint itself is felt in the groin, lower buttock and anterior thigh, and may radiate to the knee. Occasionally and inexplicably, hip arthritis causes pain only in the knee (Box 18.13).

### Osteoarthritis of the hip
OA (see pp. 667–671) is the most common cause of hip joint pain in a person over the age of 50 years. It gives rise to pain in the buttock and groin on standing and walking. Stiff hip movements cause difficulty in putting on a sock and may produce a limp. Sudden-onset pain may be associated with an effusion on MRI and can be treated by an ultrasound-guided steroid injection. Severe hip OA is characterized by pain and limitation even at rest and abnormal gait. In severe cases, total hip replacement is the only successful therapy.

**Lateral hip pain syndrome: trochanteric bursitis and gluteus medius tendonopathy**

This syndrome may be due to trochanteric bursitis and caused by trauma or unaccustomed exercise. It also occurs in inflammatory arthritis. The pain over the trochanter is worse on going up stairs, lying on that side in bed and crossing the legs. The best management is unclear but exercises help, as may a local corticosteroid injection, although the evidence base for treatment is poor. Surgery is rarely necessary. Lateral hip pain may be referred from the upper lumbar spine. A tear of the gluteus medius tendon at its insertion into the trochanter causes a similar syndrome but does not respond to injection. MRI scans have demonstrated this new syndrome.

**Meralgia paraesthetica**

This condition causes numbness and burning dysesthesia (increased sensitivity to light touch) over the anterolateral thigh, and may be precipitated by a sudden increase in weight, an injury or pelvic surgery. It is usually self-limiting but can be helped by amitriptyline or gabapentin at night.

**Fracture of the femoral neck**

This fracture usually occurs after a fall, occasionally spontaneously. There is pain in the groin and thigh, weight-bearing is painful or impossible, and the leg is shortened and externally rotated. Occasionally, a fracture is not displaced and remains undetected. X-rays are diagnostic. Anyone with a hip fracture, especially after minimal trauma, should be reviewed for osteoporosis (see pp. 711–715).

**Avascular necrosis (osteonecrosis) of the femoral head**

This condition is uncommon but occurs at any age. (Risk factors are discussed on p. 715.) There is severe hip pain. X-rays are diagnostic after a few weeks, when a well-demarcated area of increased bone density is visible at the upper pole of the femoral head. The affected bone may collapse. Early, the X-ray is normal but bone scintigraphy or MRI demonstrates the lesion and shows bone marrow oedema.
**Inflammatory arthritis of the hip**

Inflammatory arthritis produces pain in the groin and stiffness, which is worse in the morning. RA rarely presents with hip pain, although the hip is involved eventually in severe RA. Ankylosing spondylitis and other seronegative spondyloarthropathies cause inflammatory hip arthritis in younger people.

**Polymyalgia rheumatica**

Bilateral hip, buttock and thigh pain and stiffness that are worse in the morning in an elderly patient may be attributable to polymyalgia rheumatica (see p. 700). Neck and shoulder pain and stiffness are usually also present.

**Pain in the knee**

The knee depends on ligaments and quadriceps muscle strength for stability. It is frequently injured, particularly during sports. Trauma or overuse of the knee leads to a variety of peri- and intra-articular problems. Some are self-limiting; others require physiotherapy, local corticosteroid injections or surgery.

Painful knee problems can be divided into those that arise within the joint and those that arise in the soft tissues around the joint (Box 18.14). Only problems arising within the joint are likely to cause accumulation of fluid (effusion). Identification and aspiration of fluid from effusions are important diagnostic procedures.

---

**Box 18.14**

**Pain in the knee**

**Trauma and overuse**

Problems arising within the joint
- Osteoarthritis
- Inflammatory arthritis
- Meniscal tear
- Cruciate ligament tear
- Chrondromalacia
- Osteochondritis dissecans
- Spontaneous osteonecrosis of the knee

Problems arising in tissues around the joint

**Medial**
• Medial ligament strain
• Anserine bursitis

**Anterior**
• Pre-patellar bursitis
• Infrapatellar bursitis
• Quadriceps tendon enthesitis
• Osgood–Schlatter disease

**Posterior**
• Popliteal (Baker's) cyst

**Other**
• Hypermobility syndrome
• Referred from hip joint

---

### Knee joint effusions

An effusion of the knee causes swelling, stiffness and pain. The pain is more severe with an acute onset and with increasing inflammation because the capsule that contains the pain receptors is stretched. A full clinical history must include a past medical, family and drug history.

### Examination

A large and tense effusion is easily seen and felt on each side of the patella and in the suprapatellar pouch, and is fluctuant. The effusion delays the patella tapping against the femur when it is pressed firmly and quickly with the knee held straight and relaxed (the ‘patellar tap’ sign). Small effusions also demonstrate the ‘bulge’ sign when the patient is lying with the quadriceps relaxed. For this test, apply a gentle sweeping pressure, first to the medial side of the joint and then, watching the medial dimple, to the lateral side. Slightly delayed bulging of the medial dimple indicates fluid in the joint.

### Investigations

These are:
• blood tests (urate, blood cultures)
• aspiration *(Fig. 18.9)* and examination of the knee effusion.
The basic technique of aspiration is described in **Box 18.5**. If the fluid obtained is very cloudy, septic arthritis (or occasionally gout) is the likeliest diagnosis. Slightly cloudy or blood-stained fluid that does not clot is likely to indicate pseudogout. Frank blood that clots suggests a haemarthrosis. Fluid should be sent for Gram stain and culture if sepsis is suspected. It should be sent for polarized light microscopy if looking for crystals (see p. 651).

### Pain arising from within the knee

#### Osteoarthritis of the knee

Minor radiographic changes of OA (see **Fig. 18.16**) are very common in the over-fifties and do not usually cause pain, which is more likely to arise from surrounding soft tissues. X-ray appearances and the degree of pain felt in OA of the knee are not closely correlated. Marked valgus, varus or fixed flexion deformities suggest severe OA. For severe cases, surgery, usually total knee replacement, is the treatment of choice. In milder cases, pain relief, physiotherapy and, sometimes, intra-articular corticosteroid injections may help.

#### Inflammatory arthritis of the knee

Monoarthritis of the knee, associated with severe pain and marked redness, may be due to septic arthritis, gout or pseudogout. A cool, clear, viscous effusion is seen in elderly people with moderate or severe symptomatic OA (see pp. 667–671). RA rarely presents with knee involvement alone, though seronegative spondyloarthritis may do so.

#### Haemarthrosis of the knee

This condition is caused by:

- trauma: meniscal, cruciate or synovial lining tear
• clotting or bleeding disorders, e.g. haemophilia, sickle cell disease or von Willebrand's disease.

Torn meniscus
The menisci are partially attached fibrocartilages that stabilize the rounded femoral condyles on the flat tibial plateaux. In the young, they are resilient, but this decreases with age. They can be torn by an injury, commonly in sports that involve twisting and bending. The history is usually diagnostic. There is immediate medial or lateral knee pain and swelling within a few hours. The affected side is tender. If the tear is large, the knee may lock flexed. The immediate treatment is to apply ice. MRI demonstrates the tear (Fig. 18.10). In most circumstances, especially in active sportsmen and sportswomen, early arthroscopic repair or trimming of the torn meniscus is essential. Surgical intervention reduces recurrent pain, swelling and locking but not the risk of secondary OA. In older patients with OA plus meniscal tear, surgery is no more effective than physiotherapy alone. The long-term benefit of early repair of tears is not yet known. Post-surgical quadriceps exercises aid a return to sport and other activities.

![FIGURE 18.10](image) Magnetic resonance image of a knee. A complete tear of the posterior horn of the medial meniscus is shown, extending to its lower surface (arrowed).

Torn cruciate ligaments
Torn cruciate ligaments account for around 70% of knee haemarthroses in young people. They often coexist with a meniscal tear. Partial cruciate tears are difficult to diagnose clinically. On flexing the knee to 90°, a torn anterior cruciate allows the tibia to be pulled forwards on the femur. MRI is the investigation of choice. Such injuries need urgent orthopaedic referral, reconstructive surgery usually being necessary in young active adults. There is a significant incidence of secondary OA.

Chondromalacia patellae
This diagnosis is made arthroscopically. The retropatellar cartilage is fibrillated. In most
cases, the pain settles eventually. When there is patellar misalignment, it may need surgery, as does recurrent patellar dislocation in adolescent girls.

**Osteochondritis dissecans**

This condition occasionally causes knee pain and swelling in adolescents and young adults, more commonly males. It is probably traumatic, possibly with hereditary predisposing factors. A fragment of bone and its attached cartilage detach by shearing, most commonly from the lateral aspect of the medial femoral condyle.

There is aching pain after activity and, if the fragment becomes loose, locking or ‘giving way’ occurs. The lesion is seen on a tunnel-view X-ray but MRI is more sensitive, especially if the fragment is undisplaced. Undisplaced lesions are treated with rest, then isometric quadriceps exercises. Loose fragments can be fixed arthroscopically or removed. A similar lesion affecting the lateral femoral condyle occurs in older people.

**Spontaneous osteonecrosis of the knee**

Osteonecrosis may occur spontaneously or after injury. There is local pain and there are marked bone marrow changes on MRI (Fig. 18.11A) or single-photon emission computed tomography (SPECT; Fig. 18.11B). In particular, weight-bearing must be avoided. Pamidronate by infusion is sometimes used. Spontaneous osteonecrosis of the knee (SONK) may progress to bone infarction and require replacement surgery.

**FIGURE 18.11** Spontaneous osteonecrosis of the knee. A. Magnetic resonance image showing a high signal in the posterior aspect of the femoral condyle, a small effusion and a popliteal cyst. B. Single-photon emission computed tomography (SPECT) image showing a high signal in the posterior medial femoral condyle.

---

**Pain from structures around the knee**

**Medial knee pain**
There may be medial or lateral ligament strain but the medial ligament is more commonly affected. There is pain at the ligament's insertion into the upper medial tibia, which is worsened by standing or stressing the affected ligament.

Anserine bursitis causes pain and localized tenderness 2–3 cm below the posteromedial joint line in the upper part of the tibia at the site of the bursa. It occurs in obese women, often with valgus deformities, and in breast-stroke swimmers.

**Management** is with physiotherapy and a local corticosteroid injection.

### Anterior knee pain

Anterior knee pain is common in adolescence. In many cases, no specific cause is found, despite investigation. This is called ‘anterior knee pain syndrome’ and settles with time. Isometric quadriceps exercises and avoidance of high heels both help the condition. Patients and parents often need firm reassurance. Abnormal patellar tracking may be a cause and may need surgical treatment. Hypermobility of joints causes joint pain, maltracking and, rarely, recurrent patellar dislocation (see also p. 704).

### Pre- and infrapatellar bursitis

This can occur in patients whose jobs involve frequent kneeling (‘housemaid’s knee’, ‘clergyman’s knee’, ‘carpet-layer’s knee’). There is local pain, tenderness and sometimes swelling. Avoidance of kneeling and a local corticosteroid injection are helpful. Septic bursitis can occur.

### Osgood–Schlatter disease

Osgood–Schlatter disease (see p. 704) causes pain and swelling over the tibial tubercle. It is a traction apophysitis of the patellar tendon and occurs particularly in teenage sports players.

### Enthesitis

This may occur at the patellar end of the quadriceps tendon (jumper's knee).

### Posterior knee pain

**Popliteal cyst (Baker's cyst)**

In approximately 5% of people with a knee effusion, a swollen, painful popliteal cyst develops. The semi-membranosus bursa in some individuals has a valve-like connection to the knee, allowing the effusion to flow into the bursa but not back. The cyst is best seen and felt in the popliteal fossa with the patient standing.

### Ruptured popliteal cyst

Fluid escapes into the soft tissue of the popliteal fossa and upper calf, causing sudden and severe pain, swelling and tenderness of the upper calf. Dependent oedema of the ankle develops, and the knee effusion reduces dramatically in size and may be undetectable.
A history of previous knee problems and the sudden onset of pain and tenderness high in the calf suggest a ruptured cyst rather than a deep vein thrombosis (DVT). However, the diagnosis is often missed and treated inappropriately with anticoagulants. A diagnostic ultrasound examination distinguishes a ruptured cyst from a DVT (see p. 1055). Analgesics or NSAIDs, rest with the leg elevated, and aspiration and injection with corticosteroids into the knee joint are required.

**Pain in the shin, calf and ankle**

**Sever's disease**

This is a traction apophysitis of the Achilles tendon in young people (compare Osgood–Schlatter disease, p. 704).

Pain at the insertion of the Achilles tendon into the calcaneum is an enthesitis. This is traumatic or it can complicate spondyloarthritis. Raising the shoe heel reduces pain. Occasionally, a low-pressure corticosteroid injection near the enthesis is necessary.

**Achilles tendonosis**

This causes a painful, tender swelling a few centimetres above the tendon's insertion. Advise against walking barefoot and jumping. Tendon damage or rupture can occur with quinolone, e.g. ciprofloxacin therapy. Therapeutic ultrasound is helpful. (*Caution*: a local injection may cause the tendon to rupture.) Autologous platelet concentrates are used but evidence of efficacy is poor.

**Achilles bursitis**

This lies clearly anterior to the tendon and can be safely injected with corticosteroid.

**Compartment syndromes**

The muscles of the lower leg are enclosed in fascial compartments, with little room for expansion to occur. Compartment syndromes can be acute and severe, such as following exercise.

In the *anterior tibial syndrome*, there is severe pain in the front of the shin, occasionally with foot drop. Immediate surgical decompression to prevent muscle necrosis is sometimes required.

*Chronic compartment syndrome* produces pain in the lower leg that is aggravated by exercise and may therefore be mistaken for a vascular or neurological disorder.

**Pain in the foot**
(See Box 18.15). The feet are subjected to extreme pressures by weight-bearing and inappropriate shoes. They are commonly painful. Broad, deep, thick-soled shoes are essential for sporting activities, prolonged walking or standing, and in people with congenitally flat or arthritic feet.

**Box 18.15**

**Pain in the foot and heel: causes**

- Structural – flat (pronated) or high-arched (supinated)
- Hallux valgus/rigidus (± osteoarthritis)
- Metatarsalgia
- Morton's neuroma
- Stress fracture
- Inflammatory arthritis
- Acute, monoarticular – gout
- Chronic, polyarticular – rheumatoid arthritis
- Chronic, pauciarticular – spondyloarthritis
- Tarsal tunnel syndrome
- Heel pain
- Plantar fasciitis: below heel
- Plantar spur: below heel
- Achilles tendonitis/bursitis: behind heel
- Sever's disease: behind heel
- Arthritis of ankle/subtaloid joints

There are two common types of foot deformity:

- **Flat feet.** These stress the ankle and throw the hindfoot into a valgus (everted) position. A flat foot is rigid and inflexible.

- **High-arched feet.** These place pressure on the lateral border and ball of the foot.

The foot is affected by a variety of inflammatory arthritic conditions. After the hand, the foot joints are the most commonly affected by RA. The diagnosis depends on careful assessment of the distribution of the joints affected, the pattern of other joint problems or the finding of an associated condition (e.g. psoriasis; see pp. 1353–1356).

**Hallux valgus**

The big toe migrates laterally. In the congenital form, the first metatarsal bone is displaced
medially (metatarsus primus varus). The shape of modern shoes causes later onset of hallux valgus. It is a common complication of RA.

### Hallux rigidus

OA of the first metatarsophalangeal (MTP) joint in a normally aligned or valgus joint causes hallux rigidus: a stiff, dorsiflexed and painful big toe. Careful choice of footwear and the help of a podiatrist suffice for most cases but some require surgery.

### Metatarsalgia

This is common, especially in women who wear high heels, after trauma and in those with hammer toes. The ball of the foot is painful to walk and stand on. Callosities and pressure-induced bursae develop under the metatarsal heads. RA causes misalignment of the metatarsal bones and severe metatarsalgia.

**Management** is with podiatry and the wearing of appropriate shoes. Surgery is occasionally needed, particularly in the rheumatoid forefoot.

### Morton's neuroma

This usually occurs between the third and fourth metatarsal heads. It causes pain, burning and numbness in the adjacent surfaces of the affected toes when walking. It is helped by wearing wider, cushion-soled shoes. Occasionally, a steroid injection or excision is necessary.

### Stress fractures of the metatarsals

These cause sudden, severe, weight-bearing pain in the distal shaft of the fractured metatarsal bone. They occur after unaccustomed walking or with new shoes. There is local tenderness and swelling, but initially X-rays are normal and diagnosis delayed *(Fig. 18.12)*. A radioisotope bone scan or MRI reveals the fracture earlier than X-rays. Reduced weight-bearing for a few weeks usually suffices. Underlying osteoporosis may be a cause.
Tarsal tunnel syndrome

This is an entrapment neuropathy of the posterior tibial nerve at the medial malleolus. It produces burning, tingling and numbness of the toes, sole and medial arch. The nerve is tender below the malleolus and, when tapped, produces a shock-like pain (Tinel's sign). A local steroid injection under the retinaculum, between the medial malleolus and calcaneum, is helpful.

Pain under the heel

See Box 18.15.

Plantar fasciitis

This is an enthesitis at the insertion of the plantar fascia into the calcaneum. It produces localized pain under the heel when standing and walking, and local tenderness. It occurs alone or in spondyloarthritis. Obesity, particularly in flat-footed people who walk a lot, can predispose to plantar fasciitis.

Plantar spurs

These are traction lesions at the insertion of the plantar fascia in older people and are usually
asymptomatic. They become painful after trauma.

**Calcaneal bursitis**

This is a pressure-induced (adventitious) bursa that produces diffuse pain and tenderness under the heel. Compression of the heel pad from the sides is painful, which distinguishes it from plantar fascia pain.

**Clinical features and management of heel pain**

Whatever the cause, heel pain is always worse in the morning as soon as weight is placed on the foot.

All of these lesions are treated with heel pads, and reduced walking; they are often self-limiting. A dorsiflexion splint at night to stretch the plantar fascia is worth trying. When an injection is necessary, a medial approach is used, rather than advancing through the heel pad, often under ultrasound guidance.

**Pain in the chest**

Musculoskeletal conditions are sometimes a cause of chest pain. An example is Tietze's disease. In this condition, pain arises from the costosternal junctions. It is usually unilateral and affects one, two or three ribs. There is local tenderness, which helps to make the diagnosis. The condition is benign and self-limiting. It often responds well to anti-inflammatory drugs. Other causes of chest wall pain include rib fractures due to trauma, osteoporosis or a malignant deposit. Costochondral pain occurs in ankylosing spondylitis (see pp. 683–685). In people with heart disease, costochondral pain may cause severe anxiety but it is not like angina and the patient should be reassured.

**Pain associated with sport and the performing arts**

Pain in muscles and soft tissues is common after sport or associated with performing arts, such as dancing or playing musical instruments. General advice, such as warming up properly and using appropriate supportive footwear for running, can help. However, in cases of prolonged pain or where the person suffering pain is a professional sportsperson or performer, referral to a sports medicine specialist is advisable.

**Further reading**

Chronic Pain Syndromes

Chronic pain is defined as pain lasting more than 3 months (the natural tissue-healing time). Many rheumatological illnesses (e.g. RA and OA) cause pain of such duration but are not considered as chronic pain syndromes. In chronic pain syndromes, the pain generally has no clear structural cause or curative treatment and is often combined with psychological distress, poor sleep and altered use of the muscles due to the pain (called fear-avoidance behaviour or abnormal pain behaviour). This altered behaviour can lead to more stress and tension in the muscles, exacerbating the pain (Fig. 18.13).

The pain suffered by these patients is neither imaginary nor artefactual, even though there may be no structural abnormality in the painful area. There is a problem with the pain processing system in the nervous system, leading to amplification of pain signals. Psychological factors often contribute to this amplification, and the pain can make
psychological distress worse in a vicious circle. The combination of physical pain and psychological distress makes these syndromes difficult to manage.

Living with chronic pain is difficult. Patients may become anxious, depressed or socially isolated, and their quality of life is reduced. There are often adverse effects on employment, personal relationships and dependence on others. Consultations need to address these issues, as well as the pain itself, to be effective. In chronic pain syndromes, patients need help to lead a more normal life despite their pain, and are best referred to a specialist, multidisciplinary pain service. Medications alone are not the answer.

These syndromes can be conveniently subdivided into chronic widespread pain (above and below the waist and on both sides of the body) and chronic regional pain (any other distribution). Both are very common. Epidemiological studies show that the prevalence of chronic widespread pain is 10–11% and that of chronic regional pain 20–30%.

### Chronic widespread pain

Pain that starts in a single area can spread to other areas of the body, as more muscles become tense and tender. Conversely, patients with chronic widespread pain can develop new, localized causes of pain (e.g. appendicitis, OA) that can be treated successfully. It should not be assumed that every pain in these patients is always due to the same chronic problem.

Two of the main causes of chronic widespread pain are fibromyalgia and joint hypermobility syndrome (see pp. 666–667).

#### Fibromyalgia

Fibromyalgia is not a diagnosis of exclusion. It can occur in patients who have other illnesses like RA and SLE. Individuals suffer chronic widespread pain with disrupted and unrefreshing sleep, constant tiredness, and tender points detectable on pressing their muscles (Fig. 18.14). Multiple other symptoms, such as irritable bowel syndrome (IBS), tension headaches, dysmenorrhoea, atypical facial or chest pain and forgetfulness, often coexist. It occurs in about 1 in 50 people, can develop at any age and affects women more than men (2 : 1). The diagnosis is clinical, and blood tests and imaging are normal. These tests may be requested to exclude other causes of pain.
Management

(See p. 901.) A clear explanation of the diagnosis is critically important. While being honest about the fact that there is no cure for fibromyalgia, it is also necessary to reassure the patient that it is not arthritis and that the pain is not causing damage to joints or muscles. Many patients have never had an explanation of the cause of their symptoms, which leads to fear and doubt. Treatment options that can be offered to help (not cure) are described below.

Drugs

There is evidence from clinical trials for use of analgesics, anticonvulsants and antidepressants. Commonly used drugs include amitriptyline (which may also improve sleep), pregabalin, paracetamol, tramadol and gabapentin. Benefits, however, are often short-term and adverse effects common.

Non-drug therapies

A sympathetic, psychosocial, multidisciplinary approach is appropriate. A graded, supervised aerobic exercise regimen over 3 months is safe and effective. When depression is present, it should be treated. Cognitive behavioural therapy can help the person to pace their life more effectively and to cope better. Pain management programmes, combining psychology with physiotherapy, are designed to improve physical function and quality of life but do not reduce.
pain intensity. Acupuncture can lessen pain in some cases but the effect is usually transient.

**Chronic regional pain**

**Chronic (work-related) upper-limb pain syndrome**

This name is preferred to ‘repetitive strain injury’ (RSI). The predominant symptoms are pain in all or part of one or both arms. A specific lesion, such as tennis elbow or carpal tunnel syndrome, or muscular-pattern neck pain often develops first, and early recognition and treatment may prevent chronicity. After a variable period, the pain becomes more diffuse and no longer simply work-related, and there is often severe distress. It is seen in keyboard workers and in musicians. When it arises at work, it is often at a time of changing work practices, shortage of staff or disharmony. Middle managers find it difficult to deal with and this compounds the stress.

**Management**

If possible, there should be a brief period off work and a gradual return to activity as the pain settles. Use of analgesia and NSAIDs, with physiotherapy, is helpful during the initial phase to prevent a vicious circle developing. Amitriptyline or pregabalin is helpful for some patients.

A review of working practices and the positioning of screen, keyboard and chair are essential, as is support of the patient by their manager. Musicians are helped by expert advice on playing technique and should reduce playing times temporarily, but not stop completely.

**Temporomandibular pain dysfunction syndrome**

This pain syndrome is a disorder of the temporomandibular joint that is associated with nocturnal tooth grinding or abnormalities of bite. It occurs in anxious people. It gives rise to pain in one or both temporomandibular joints.

Dental correction of the bite helps a few, but when no dental cause is found, low-dose tricyclic antidepressant therapy is used. Many patients are made worse by unnecessary dental treatment.

**Complex regional pain syndrome**

Complex regional pain syndrome (CRPS) is a rare condition (prevalence 20 : 100 000), in which regional neuropathic pain is associated with abnormal sensory, autonomic, motor and/or trophic changes. There are two types. In CRPS type I, there is no identifiable overt nerve lesion, whereas such a lesion is identifiable in CRPS type II. CRPS usually occurs after trauma but the pain is disproportionate in time or intensity to that usually caused by such an injury. It may also develop after central nervous system lesions (e.g. strokes) or without cause.

Its features are pain and other sensory abnormalities, including hyperaesthesia; and
autonomic vasomotor dysfunction, leading to abnormal blood flow and sweating; and motor system abnormalities, leading to structural changes of superficial and deep tissues (trophic changes). Not all components need be present. The sensory, motor and sympathetic nerve changes are not restricted to the distribution of a single nerve and may be remote from the site of injury. The early phase, with pain, swelling and increased skin temperature, is difficult to diagnose but potentially reversible.

After a period of weeks or months, a second, still painful, dystrophic phase develops, characterized by articular stiffness, cold skin and trophic changes, often with localized osteoporosis.

A late phase involves continued pain, skin and muscle atrophy, and muscle contractures, and is extremely disabling.

Diagnosis is clinical – a high index of suspicion and recognition of the unusual distribution of the pain. There are no specific or sensitive investigations, though demineralization may be seen on X-ray. Bone scan and MRI are not required to make the diagnosis.

**Management**

Management is difficult and the problem often very disabling. The evidence base for treatment is poor. Early diagnosis, effective pain relief and general care of the patient are essential. NSAIDs, tricyclic antidepressants, serotonin–norepinephrine reuptake inhibitors, and pregabalin or gabapentin are used in the early phase, together with active exercise of the limb, encouraged by a physiotherapist. Intravenous bisphosphonates can also be effective. Referral to a specialist pain clinic is essential. Nerve blocks were used in the past but are less common now. Intravenous immunoglobulins have been used in clinical trials but are not yet an accepted therapy.

<sup>a</sup> In order of potency.

<sup>b</sup> COX-2-specific NSAID (coxib).

### Simple and compound analgesic agents

Simple agents, such as paracetamol, aspirin or codeine compounds (or combination preparations), used when necessary or regularly, relieve pain and improve function. Sleep may also be improved. Side-effects are relatively infrequent, although drowsiness and constipation occur with codeine preparations, especially in the elderly.

Stronger analgesics, such as dihydrocodeine, tramadol or morphine derivatives, should be used only with severe pain.

### Non-steroidal anti-inflammatory drugs

Non-steroidal anti-inflammatory drugs (NSAIDs) have anti-inflammatory and centrally acting analgesic properties. They inhibit cyclo-oxygenase (COX), a key enzyme in the formation of prostaglandins, prostacyclins and thromboxanes (see *Fig. 24.30*). There are two specific cyclo-oxygenase enzymes:

- **COX-1** is the constitutive form present in many normal tissues.
- **COX-2** is the form mainly induced in response to pro-inflammatory cytokines and is not found in most normal tissues (except the kidney). It is associated with oedema and the nociceptive
and pyretic effects of inflammation.

**Effects and side-effects**

Most of the older NSAIDs are non-specific and block both enzymes but with variable specificity (‘non-specific NSAIDs’, or nsNSAIDs). Their therapeutic effect depends on blocking COX-2 and their side-effects mainly on blocking COX-1. COX-1 protects the gastric mucosa and blocking it accounts for the majority of upper gastrointestinal side-effects.

The most common side-effects with non-specific NSAIDs are indigestion or skin rashes. More serious upper gastrointestinal side-effects are gastric erosions and peptic ulceration with perforation and bleeding. These occur more frequently in the elderly, in whom mortality is higher, in long-term use, and in those with high risk factors: a history of ulcers, *Helicobacter pylori*, and concurrent corticosteroid or anticoagulant therapy. Ibuprofen, in combination with low-dose aspirin, significantly increases the risk of severe gastrointestinal bleeding. Practice guidelines recommend proton pump inhibitors in high-gastrointestinal-risk patients on non-specific NSAIDs. H₂ blockers are less effective as gastroprotective agents. Prostaglandin E₂ analogues, such as misoprostol, reduce ulcer complications and are popular, but may cause nausea and diarrhoea. Lower gastrointestinal side-effects of non-specific NSAIDs are becoming more common.

COX-2 inhibitors (‘coxibs’) produce fewer gastrointestinal side-effects but these still occur. Coxibs are used in patients who have a high risk of gastrointestinal disease but no cardiovascular risk. People with a high risk of both may be better off taking an NSAID (ibuprofen or naproxen) or a coxib with a proton pump inhibitor.

Coxibs and NSAIDs may reduce renal function, especially in the elderly (see Box 20.20). Coxibs and all NSAIDs except naproxen, if used in high dose for long periods, cause a small increase in risk of vascular events, such as myocardial infarction or stroke. All these drugs, including naproxen, increase the risk of heart failure.

**Uses**

- **In musculoskeletal pain and in OA and spondylosis**, short courses of NSAIDs or coxibs are used but simple analgesia is often more appropriate.
- **In crystal synovitis**, NSAIDs and coxibs have a true anti-inflammatory effect.
- **In chronic inflammatory synovitis**, NSAIDs and coxibs do not alter the chronic inflammatory process or decrease the risk of joint damage, but they do reduce pain and stiffness.
- **In inflammatory arthritis and situations where more constant pain control is needed**, slow-release preparations are useful.
- **In chronic arthritis**, NSAID gels have some value.

The standard advice is to use NSAID in the lowest dose possible for the shortest time necessary to control pain. Be aware of the patient's gastrointestinal and cardiac risks before prescribing NSAIDs or coxibs.
Disorders of collagen

Collagen is responsible for many of the structural, tensile and load-bearing properties in the various tissues where it is found. The structure of collagen is discussed on page 647. Thirty or more dispersed genes encode for more than 19 different types of collagen (Box 18.17).

Joint hypermobility syndrome (Ehlers–Danlos syndrome type III)

These two terms describe the same syndrome. Inheritance appears to be autosomal dominant but the underlying genetic abnormality is unknown. Hypermobility itself is very common (15–20% of adults); it may be demonstrated by showing increased flexibility in the thumbs, little fingers, elbows, knees and lumbar spine, and quantified using the Beighton score (Box 18.18). The majority of hypermobile people suffer no adverse effects from the hypermobility but in some it can cause recurrent subluxations of individual joints and/or persistent widespread musculoskeletal pains. These people are said to have joint hypermobility syndrome. Other symptoms, such as bowel disturbance, easy scarring and faintness on standing (postural orthostatic tachycardia syndrome, or POTS), can also occur and the combination can be very disruptive to normal life. Treatment of the musculoskeletal symptoms relies on specialist physiotherapy to advise on exercises that take the patient’s hypermobility into account. Pain management programmes can be helpful in more severe cases. It is usually better to avoid surgery due to difficulties in healing.

<sup>a</sup>
Other forms of Ehlers–Danlos syndrome

Ehlers–Danlos syndrome (EDS) is a heterogeneous group of disorders of collagen. Ten different types have been recognized with varying degrees of skin fragility, skin hyperextensibility and joint hypermobility.

- **Types I and II** (classic EDS) are inherited in an autosomal dominant fashion. Mutations in COL5A1 and COL5A2 result in abnormal type V collagen.
- **Type IV** (vascular type) is also autosomal dominant and involves arteries, bowel and uterus, as well as skin. Mutations in the COL3A1 gene produce abnormalities in structure, synthesis or secretion of type III collagen.
- **Type VI** is a recessively inherited disorder and results from a mutation in the gene that encodes lysyl hydroxylase.
- **Type VII** is an autosomal dominant disorder in which there is a defect in the conversion of procollagen to collagen; COL1A1 and COL1A2 mutations delete the N-proteinase cleavage sites.

Type III EDS was described above. The other forms of EDS are very rare and their defects have not been elucidated here. The clinical features are described on page 1378.

Marfan syndrome

This condition is described on pages 1028–1029.

Osteogenesis imperfecta

This is a heterogeneous group of disorders inherited mainly in autosomal dominant fashion with mutations in COL1A1 and COL1A2 genes. There are four main types of osteogenesis imperfecta and clinical subtypes are also described (V, VI and VII). The major clinical feature is bone fragility but other collagen-containing tissues are also involved, such as tendons, skin and eyes.

- **Type I**: mild bony deformities, blue sclerae, defective dentine, early-onset deafness, hypermobility of joints and heart valve disorders
- **Type II**: death in the perinatal period
• **Type III**: severe bone deformity and blue sclerae

• **Type IV**: fewer fractures, normal sclerae, normal lifespan but can also be severe, as in type III.

**Management** with daily oral risedronate in children improves BMD and reduces fracture risk. Intravenous pamidronate is another option. Prognosis is variable, depending on the severity of the disease. Stem cell therapy is being used.

**Achondroplasia**

Achondroplasia (‘dwarfism’) is diagnosed in the first years of life. The disease is inherited in an autosomal dominant manner and is caused by a defect in the fibroblast growth factor receptor-3 gene. The trunk is of normal length but the limbs are very short and broad due to abnormal endochondral ossification. The vault of the skull is enlarged, the face is small and the nose bridge is flat. Intelligence is normal.

**Further reading**

**Osteoarthritis**

Osteoarthritis (OA) is the most common type of arthritis and is no longer viewed as a simple degenerative process due to ageing. It is now recognized to occur as a result of damage to articular cartilage induced by a complex interaction of genetic, metabolic, biochemical and biomechanical factors, leading to an inflammatory response affecting cartilage, subchondral bone, ligaments, menisci, synovium and capsule. It is the subject of intense investigation to develop disease-modifying therapies, with limited success so far.

**Epidemiology**

The prevalence of OA rises with age, being uncommon before 50 years of age and increasing, so that most people over 60 years will have some radiological evidence of it, although only a quarter of these are symptomatic. It occurs worldwide with a variable distribution. For instance, hip OA is less common and knee OA more common in Asians than in Europeans. Beyond 55 years of age, women are affected more commonly than men, with a familial pattern of inheritance in nodal and primary generalized forms of OA. It has a variable distribution (**Fig. 18.15**) and resulting disabilities have major socioeconomic resource implications, particularly in the developed world. OA is the most common cause of disability in the Western
world in older adults.

**Aetiology and pathogenesis**

Cartilage is a matrix of collagen fibres, enclosing a mixture of proteoglycans and water (see p. 647); it has a smooth surface and is shock-absorbing. Under normal circumstances, there is a dynamic balance between cartilage degradation by wear and its production by chondrocytes. Early in the development of OA, this balance is lost and, despite increased synthesis of extracellular matrix, the cartilage becomes oedematous. Subsequently, focal erosion of cartilage develops, chondrocytes die and, although repair is attempted from adjacent cartilage, the process is disordered, leading to a failure of synthesis of extracellular matrix so that the surface becomes fibrillated and fissured. Cartilage ulceration exposes underlying bone to increased stress, producing microfractures and cysts. The bone attempts repair but produces abnormal sclerotic subchondral bone and overgrowths at the joint margins, called osteophytes (**Fig. 18.16**). There is some secondary inflammation. This process produces a spectrum of OA,
ranging from atrophic disease in which cartilage destruction occurs without any subchondral bone response, to hypertrophic disease in which there is massive new bone formation at the joint margins.

Joint specific genetic factors are involved in the pathogenesis of OA. Polymorphisms in the gene for human aggrecan have been correlated with OA of the hand in older men, and familial concordance for hip and knee OA is greater in surgically defined than in radiographically defined disease. There is no single gene, however, that associates with all patterns of OA, and several other mechanisms have been suggested:

• *Abnormal stress and loading*, leading to mechanical cartilage damage, play a role in
secondary OA.

- **Obesity** is a risk factor for developing OA of the hand and knee, but not the hip, in later life. Increased skeletal mass increases cartilage volume.

- **Collagenases** (MMP-1 and MMP-13) cleave collagen, and other metalloproteinases, such as stromelysin (MMP-3) and gelatinases (MMP-2 and MMP-9), are also present in the extracellular matrix. MMPs are secreted by chondrocytes in an inactive form. Extracellular activation then leads to the degradation of both collagen and proteoglycans around chondrocytes.

- **Tissue inhibitors of metalloproteinases** (TIMPs) regulate the MMPs. Disturbance of this regulation may lead to an increase in cartilage degradation over synthesis and contribute to the development of OA. TIMPs have not yet proven to be of therapeutic value.

- **Osteoprotegerin (OPG), RANK and RANK ligand** (RANKL) control subchondral bone remodelling. Their levels are significantly different in OA chondrocytes. Inhibition of RANKL is being investigated as a new therapeutic approach in OA.

- **Aggrecanase** production is stimulated by pro-inflammatory cytokines, and aggrecan (the major proteoglycan) levels fall.

- **Synovial inflammation** is present in OA, and CRP in the serum may be raised. Interleukin-1 (IL-1) and tumour necrosis factor alpha (TNF-α) release stimulates metalloproteinase production, and IL-1 inhibits type II collagen production. IL-6 and IL-8 may also be involved. Anti-cytokine therapy has not yet been tested in OA. The production of cytokines by macrophages and that of MMPs by chondrocytes in OA are dependent on the transcription factor nuclear factor kappa B (NF-κB). Inhibition of NF-κB may have a therapeutic role in OA.

- **IL-1 receptor antagonist** genes are associated with radiographic severity of knee OA.

- **Growth factors**, including insulin-like growth factor 1 (IGF-1) and transforming growth factor beta (TGF-β), are involved in collagen synthesis, and their deficiency may play a role in impairing matrix repair. Paradoxically, increased TGF-β may also cause increased subchondral bone density.

- **Cartilage breakdown products** lead to macrophage infiltration and vascular hyperplasia, and IL1-β and TNF-α may contribute to further cartilage degradation.

- **Vascular endothelial growth factor** (VEGF) from macrophages is a potent stimulator of angiogenesis and may contribute to inflammation and neovascularization in OA. Innervation can accompany vascularization of the articular cartilage.

- **A strong hereditary element** underlying OA is suggested by twin studies. The influence of genetic factors is estimated at 35–65%. Mutations in the gene for type II collagen (COL2A1) have been associated with early polyarticular OA. Large genome-wide association studies (GWAS) of subjects undergoing total knee replacement have identified the strongest association on chromosome 3 with rs6076, which is in perfect linkage disequilibrium with rs11177. This single nucleotide polymorphism (SNP) encodes a missense polymorphism
within the nucleostemin encoding gene, GNL3.

- **In the Caucasian population**, there is an inverse relationship between the risk of developing OA and osteoporosis.

- **Gender.** In women, weight-bearing sports produce a two- to threefold increase in risk of OA of the hip and knee. In men, there is an association between hip OA and certain occupations: farming and labouring. OA may flare after the female menopause or after cessation of hormone replacement therapy.

- **Periarticular enthesitis** has been proposed as a factor in the pathogenesis of nodal generalized OA (NGOA) and is the subject of investigation.

The term **primary OA** is sometimes used when there is no obvious known predisposing factor.

**Box 18.19** shows some of the predisposing factors for the development of OA, and **Box 18.20** lists other conditions that sometimes cause secondary arthritis.

---

**Box 18.19**

**Factors predisposing to osteoarthritis (OA)**

- **Obesity:** This predicts a later risk of radiological and symptomatic OA of the hip and hand in population studies
- **Heredity:** There is a familial tendency to develop nodal and generalized OA
- **Gender:** Polyarticular OA is more common in women; a higher prevalence after the menopause suggests a role for sex hormones
- **Hypermobility** (see p. 704): Increased range of joint motion and reduced stability lead to OA
- **Osteoporosis:** There is a reduced risk of OA
- **Diseases:** See Box 18.20
- **Trauma:** A fracture through any joint predisposes. Meniscal and cruciate ligament tears cause OA of the knee
- **Congenital joint dysplasia:** This alters joint biomechanics and leads to OA. Mild acetabular dysplasia is common and leads to earlier onset of hip OA
- **Joint congruity:** Congenital dislocation of the hip or a slipped femoral epiphysis or Perthes' disease predispose; osteonecrosis of the femoral head (see p. 659) in children and adolescents causes early-onset OA
- **Occupation:** Miners develop OA of the hip, knee and shoulder, cotton workers OA of the hand, and farmers OA of the hip
- **Sport:** Repetitive use and injury in some sports cause a high incidence of lower-limb OA
Box 18.20

Causes of osteoarthritis

Primary OA
• No known cause

Secondary OA
Pre-existing joint damage
• Rheumatoid arthritis
• Gout
• Spondyloarthritis
• Septic arthritis
• Paget's disease
• Avascular necrosis, e.g. corticosteroid therapy

Metabolic disease
• Cartilage calcification
• Hereditary haemochromatosis
• Acromegaly

Systemic disease
• Haemophilia – recurrent haemarthrosis
• Haemoglobinopathies, e.g. sickle cell disease
• Neuropathies

Clinical features

OA affects many joints, in diverse clinical patterns, typically causing mechanical pain with movement and/or loss of function. Hip and knee OA are major causes of disability. Early OA is rarely symptomatic, however, unless accompanied by a joint effusion, whilst advanced radiological and pathological OA is not always symptomatic.

Symptoms are usually gradual in onset and progressive. Episodic disease flare-ups may be inflammatory in nature, with an associated slight rise in ESR or CRP. Focal synovitis is caused by fragments of shed bone or cartilage. Radiological OA is usually, but not inevitably, progressive. This progression may be stepwise or continual. Radiological improvement is uncommon but has been observed, suggesting that repair is possible.

Symptoms
• Joint pain with movement and/or weight-bearing.
• Short-lived morning joint stiffness.
• Functional limitation.

Signs
• Crepitus.
• Restricted movement.
• Bony enlargement.
• Joint effusion and variable levels of inflammation.
• Bony instability and muscle wasting.

Clinical subsets

Localized OA

Nodal OA
In nodal OA (Box 18.21), joints of the hand are usually affected one at a time over several years, with the DIPs more frequently involved than the PIPs. Nodal OA often begins around the female menopause, with inflammation causing painful, tender, swollen interphalangeal joints and impairment of hand function. At this stage, enthesitis can be seen on MRI. Intra-articular corticosteroid injections may be helpful at this stage. The inflammatory phase settles after some months or years, leaving painless bony swellings posterolaterally: Heberden's nodes (DIPs) and Bouchard's nodes (PIPs), along with stiffness and deformity (Fig. 18.17). Functional impairment is usually limited, although PIP OA restricts grip more than DIP involvement. On X-ray, the nodes are marginal osteophytes and there is joint space loss.

Box 18.21
Features of nodal osteoarthritis
• Demonstrates a familial nature
• Has a higher incidence in women
• Shows a typical pattern of polyarticular involvement of the hand joints
• Develops in late middle age and around female menopause
• Has a generally good long-term functional outcome
• Is associated with osteoarthritis of the knee, hip and spine (nodal generalized osteoarthritis)
Severe nodal osteoarthritis. The distal interphalangeal joints (DIPs) demonstrate Heberden's nodes (arrowed). The middle finger DIP joint is deformed and unstable. The thumb is adducted and the bony swelling of the first carpometacarpal joint is clearly shown – ‘the squared hand of nodal osteoarthritis’.

Thumb-base OA coexists with nodal OA and causes pain and disability, which decrease as the joint stiffens. The ‘squared’ hand in OA (Fig. 18.17) is caused by bony swelling of the first carpometacarpal joint and fixed adduction of the thumb. Function is rarely severely compromised.

Polyarticular hand OA is associated with a slightly increased frequency of OA at other sites.

**Hip OA**

Hip OA affects 7–25% of adult Caucasians but is significantly less common in black African and Asian populations. There are two major subgroups defined by the radiological appearance. The most common is **superior-pole hip OA**, where joint space narrowing and sclerosis predominantly affect the weight-bearing upper surface of the femoral head and adjacent acetabulum. This finding is most common in men and unilateral at presentation, although both hips may become involved in progressive disease. Early onset of hip OA is associated with acetabular dysplasia or labral tears. Less commonly, **medial cartilage loss** occurs. This appearance is seen most commonly in women and is associated with hand involvement (NGOA), and is usually bilateral. It is more rapidly disabling.

**Knee OA**
The prevalence of symptomatic knee OA is 40% in individuals over 75 years of age and is more common in women. There is a strong relationship with obesity. The disease is generally bilateral and strongly associated with nodal OA of the hand in elderly women, or is seen as part of generalized OA. The medial compartment is most commonly affected, leading to a varus (bow-legged) deformity. Often, retropatellar OA is also present. Previous trauma and meniscal and cruciate ligament tears are risk factors for developing knee OA. Bone marrow lesions seen on MRI predict disease progression and eventual joint replacement.

**Primary generalized OA**

This condition is rare and usually seen in combination with NGOA. Other affected areas include the knees, first MTP, hip and intervertebral (spondylosis) joints. Its onset is often sudden and severe. There is a female preponderance and a strong familial tendency. Periarticular ligamentous pathology may have an important role in the phenotypic expression of NGOA.

**Erosive OA**

In this rare subgroup, the DIPs and PIPs are inflamed and equally affected, with a poor functional outcome. Radiologically, there is marked osteolysis. Destructive phases are followed by phases of remodelling.

**Crystal-associated OA**

This condition most commonly occurs with calcium pyrophosphate deposition (CPPD) in the cartilage. It increases in frequency with age and causes cartilage calcification (CC) on over 40% of knee X-rays in the over-eighties, but is usually asymptomatic. The joints most frequently affected are the knees (hyaline cartilage and fibrocartilage) and wrists (triangular fibrocartilage; see *Fig. 18.15*). There is patchy linear CC on X-ray (*Fig. 18.18*).
A chronic arthropathy (pseudo-OA) occurs, predominantly in elderly women with severe CC. There is a florid inflammatory component and marked osteophyte and cyst formation visible on X-rays. The joints affected differ from those in NGOA, being predominantly the knees, then wrists and shoulders. CC is associated with CPPD crystal-induced arthritis (see p. 689).

A rare, rapidly destructive arthritis in elderly women, affecting shoulders, hips and knees, is associated with the finding of crystals of calcium apatite in a bloody joint effusion. The outlook is poor and joints require early surgical replacement.

**Investigations**

- **Blood tests.** There is no specific test; the ESR is usually normal, although high-sensitivity CRP may be slightly raised. Rheumatoid factor and antinuclear antibodies are negative.
- **X-rays.** These are abnormal only when the damage is advanced. They are useful in preoperative assessments. For knees, a standing X-ray (stressed) is used to assess cartilage loss, and ‘skyline’ views in flexion are used for patello-femoral OA.
- **MRI.** This demonstrates meniscal tears, early cartilage injury and subchondral bone marrow changes (osteochondral lesions).
- **Arthroscopy.** This reveals early fissuring and surface erosion of the cartilage.
- **Aspiration of synovial fluid** (if there is a painful effusion). This shows a viscous fluid with few leucocytes (see p. 651).

**Management**

The guiding principle is to treat the symptoms and disability, not the radiological appearances;
depression and poor quadriceps strength are better predictors of pain than radiological severity in OA of the knee. Patient education about the disease and its effects reduces pain, distress and disability, and increases compliance with treatment. Psychological or social factors alter the impact of the disease.

**Physical measures**

Weight loss and exercises for strength and stability are useful. Hydrotherapy helps, especially in lower-limb OA. Local heat, ice packs, massage, and rubefacients or local NSAID gels are all used. Insoles for flat feet and a walking stick held on the contralateral side to the affected lower limb joint are useful.

There is increasing evidence that acupuncture helps knee OA. Other forms of complementary medicine are commonly used, despite lack of scientific evidence that they have any effect.

**Medication**

Potential benefit must be balanced against potential side-effects, especially in the elderly. Paracetamol is used but its value has been questioned (see Box 18.16). NSAIDs or coxibs should be used intermittently when possible. Opioids are a last resort and should be used cautiously in older patients.

Intra-articular corticosteroid injections produce short-term improvement when there is a painful joint effusion. Frequent injections into the same joint should be avoided. Heterogeneity of relevant studies means that the potential role of intra-articular hyaluronan preparations is not effective in general.

Glucosamine and chondroitin (sold as food supplements) have no clinically relevant effect on joint pain or joint space narrowing.

There are no proven agents that halt or reverse OA, although they are greatly needed. The role of bisphosphonates in reducing bone changes is unclear. The role of drugs that block tissue metalloproteinases or cytokines (see pathogenesis, above) is also unclear.

**Surgery**

Arthroscopy for knee OA is rarely beneficial. Replacement arthroplasty, however, has transformed the management of severe OA. More than 1 million hip arthroplasties are being performed worldwide each year, predominantly for OA, and this number is projected to double in the next two decades. Furthermore, there has been a significant fall in 90-day mortality from 0.56% in 2003 to 0.29% in 2018. The safety of hip and knee replacements is now equal, with a complication rate of about 1%, loosening and late blood-borne infection being the most serious. These slight but definite risks make it essential for the patient to be certain that surgery is necessary. Resurfacing hip surgery has become popular but may have higher complication rates in women, particularly with metal on metal resurfacing. Uni-compartmental knee replacement is a less major procedure and may be appropriate in some cases. For most patients, a total hip or knee replacement reduces pain and stiffness, and greatly increases function, mobility and – particularly significant for the elderly – independence.
Other surgical procedures include re-alignment osteotomy of the knee or hip, excision arthroplasty of the first MTP and base of the thumb, and fusion of a first MTP joint.

Further reading

Inflammatory Arthritis
Inflammatory arthritis includes a large number of diseases in which the predominant feature is synovial inflammation. The three main subgroups of inflammatory arthritis are rheumatoid arthritis (RA), spondyloarthritis and crystal arthritis (Box 18.22). The diagnosis of these conditions is helped by distinguishing:

• the pattern of joint involvement (symmetrical or asymmetrical, large or small) (Box 18.23)
• presence of any non-articular disease
• a past and family history
• periodicity of the arthritis (single acute, relapsing, chronic and progressive).

Box 18.22
The three main subgroups of inflammatory arthritis

1. Rheumatoid arthritis (associated with antibodies)
2. Spondyloarthritis (associated with human leucocyte antigen (HLA)-B27)
3. Metabolic arthritis (e.g. associated with crystals)

Box 18.23
Pattern of joint involvement in inflammatory arthritis

Diseases presenting as an inflammatory monoarthritis

• Crystal arthritis, e.g. gout, CPPD
• Septic arthritis
• Palindromic rheumatism
• Traumatic ± haemarthrosis
• Arthritis due to juxta-articular bone tumour
• Occasionally, psoriatic, reactive, rheumatoid may present as monoarthritis

**Diseases presenting as an inflammatory polyarthritis**

• Rheumatoid arthritis
• Reactive arthritis
• Spondyloarthritis associated with psoriasis or ankylosing spondylitis
• Postviral arthritis
• Lyme arthritis
• Enteropathic arthritis
• Arthritis associated with erythema nodosum
  CPPD, calcium pyrophosphate deposition arthropathy.

Certain non-articular diseases, such as psoriasis, iritis, IBS, non-specific urethritis or recent dysentery, suggest spondyloarthritis. There may be evidence of recent viral illness (rubella, hepatitis B or erythrovirus), rheumatic fever, or a tick bite and skin rash (Lyme disease). In early arthritis, it may not be possible to make a specific diagnosis until the disease has evolved from an undifferentiated arthritis into a chronic form.

There is a distinct genetic separation of rheumatoid-pattern synovitis and spondyloarthritis; RA (see below) is associated with a genetic marker in the class II major histocompatibility complex (MHC) genes, whilst spondyloarthritis shares certain alleles in the B locus of class I MHC genes, usually B27 (see p. 683).

In general, the pain and stiffness of inflammatory arthritis are worse in the morning, often lasting for several hours and improving with activity, in contrast with the much shorter morning stiffness and mechanical pain with activity of OA. Inflammatory markers (ESR and CRP) are often raised in inflammatory arthritis, and there is often a normochromic, normocytic anaemia. Specific types of arthritis are discussed below.

**Early inflammatory polyarthritis**

Undifferentiated polyarthritis requires urgent referral to a rheumatologist for diagnosis and treatment, including the early introduction of disease-modifying agents when indicated (see p. 680). In persistent inflammatory arthritis, sustained remission depends on rapid diagnosis and intensive treatment. Poor prognostic features for undifferentiated polyarthritis are:

• polyarticular onset
• positive anti-citrullinated peptide antibodies (ACPA)
• positive rheumatoid factor
• joint erosion on X-ray at presentation
• disease >3–6 months.

**Rheumatoid arthritis**

RA is an autoimmune disease associated with autoantibodies to the Fc portion of immunoglobulin G (rheumatoid factor) and to citrullinated cyclic peptide. There is persistent synovitis, causing chronic symmetrical polyarthritis with systemic inflammation. Genetically, RA is a heterogeneous group of diseases.

**Epidemiology**

RA has a worldwide distribution affecting 0.5–1% of the population (with a female preponderance of 3 : 1). The prevalence is low in black Africans and Chinese people. The incidence is falling. RA remains a significant cause of disability and mortality and carries a high socioeconomic cost. It presents from early childhood (when it is rare) to late old age. The most common age of onset is between 30 and 50 years.

**Aetiology and pathogenesis**

There has been a greater understanding of genetic and environmental factors in the last two decades.

- **Gender.** Women, before the menopause, are affected three times more often than men. Post-menopause, the frequency of onset is similar between the sexes; thus sex hormones may be important in the pathogenesis. A meta-analysis of the use of the oral contraceptive pill has shown no effect on RA overall, but it may delay the onset of disease.

- **Genetic factors.** There is an increased incidence in first-degree relatives and a high concordance amongst monozygotic twins (up to 15%) and dizygotic twins (3.5%). Overall, genetic factors account for about 60% of disease susceptibility. There is a strong association between susceptibility to RA and certain human leucocyte antigen (HLA) haplotypes: HLA-DR4, which occurs in 50–75% of patients and correlates with a poor prognosis, as does possession of certain shared alleles of HLA-DRB1*04. The possession of these shared epitope alleles in HLA-DRB1 (S2 and S3P) increases susceptibility to RA and may predispose to ACPA directed against citrullinated antigens. Citrullination is a process that modifies antigens, allowing them to fit into the shared epitope on HLA alleles. In a genome-wide association study in ACPA-positive RA, an association was found with loci near HLA-DRB1 and PTPN22 in people of European descent. These genes affect the presentation of autoantigens (HLA-DRB1), T-cell receptor signal transduction (PTPN22) and targets of ACPA (PAD14).

- **Environment.** Smoking and other forms of bronchial stress increase the risk of RA with HLA-DR4 and acts synergistically with HLA-DRB1 to increase the risk of having ACPA. Environmental stress, such as smoking, is thought to promote post-translational modifications,
leading to citrullination of mucosal proteins in pulmonary tissue. A loss of tolerance at other mucosal sites is suggested by the association of periodontal disease and alterations in the gut microbiome with RA.

**Immunology**

RA is primarily a synovial disease, and synovitis occurs when chemoattractants produced in the joint recruit circulating inflammatory cells. Over-production of tumour necrosis factor alpha (TNF-α) leads to synovitis and joint destruction. Interaction of macrophages and T and B lymphocytes drives this over-production. TNF-α stimulates over-production of IL-6, as well as other cytokines. The increased understanding of the immunopathogenesis of this disease has informed the development of targeted biological therapies *(Fig. 18.19)*. Blockade of TNF-α and IL-6 has produced marked improvement in synovitis and systemic malaise, indicating the pivotal role of these cytokines in the chronic synovitis (see pp. 680–682).
An imbalance in the number of certain cell types appears to be central to immune regulation and its dysfunction.

- **Synovial cells** in chronic rheumatoid synovitis are predominantly fibroblast-like synoviocytes, and macrophage-like synoviocytes that produce pro-inflammatory cytokines. Abnormal fibroblast-like synoviocytes circulate between joints and may be the trigger for polyarthritis.

- **Osteoclasts** cause bone and cartilage destruction.

- **Synovial B cells**, activated by cytokine-activated macrophages and T cells, produce autoantibodies, of which IgM and IgA RF are the most typical in RA. As RFs bind the Fc portion of IgG, they have the potential for self-aggregation and immune complex formation in
the synovium. These may then trigger macrophages via IgG Fc receptors to produce even more cytokines, including IL-1, IL-8, TNF-α and granulocyte–macrophage colony-stimulating factor, and fibroblasts to produce IL-6.

• **CD20-positive B-cell ablation** (a technique used for treating B-cell lymphomas) induces temporary remission, reinforcing the central role of B cells in the chronic inflammation of RA. As the B cells return, the CRP rises and the disease flares again.

• **Synovial fibroblasts** have high levels of the adhesion molecule, vascular cell adhesion molecule (VCAM-1, a molecule that supports B-lymphocyte survival and differentiation), decay accelerating factor (DAF, a factor that prevents complement-induced cell lysis) and cadherin II (which mediates cell-to-cell interactions). These molecules may facilitate the formation of ectopic lymphoid tissue in synovium. Mice deficient in cadherin II are resistant to a form of inflammatory arthritis.

• **T cells** can be a part of the destructive process. T cell-associated cytokines, such as IL-2 and IL-4, however, are not present in high amounts. Th17 helper cells (see pp. 131–132), which produce IL-17A, 17F, 21 and 22, and TNF-α, may cause inflammation. The normal regulatory T cells are suppressed by TGF-β and interleukins (produced by macrophages and dendritic cells), allowing the Th17 helper cells to increase.

  **The role of innate immunity** in RA pathogenesis and in predisposing the joint to inflammation is still unknown (see pp. 123–128).

  The **triggering antigen**, which leads to self-maintained inflammation in RA, remains unclear. Triggers for ACPA production include filaggrin, type II collagen and vimentin. There is little evidence that type II collagen is the triggering antigen, although it is a cause of arthritis in animal models of RA. Smoking is a potential trigger, particularly in ACPA-positive RA (see p. 675).

### Pathology

RA is typified by widespread, persistent synovitis of joints, tendon sheaths or bursae. Normal synovium is thin, comprising a lining layer a few cells thick that contains fibroblast-like synoviocytes and macrophages overlying loose connective tissue. The synoviocytes play a central role in synovial inflammation. In RA, the synovium becomes greatly thickened, causing ‘boggy’ swelling around joints and tendons, with proliferation of the synovium into folds and fronds, and infiltration by a variety of inflammatory cells, including polymorphs, which transit through the tissue into the joint fluid, and lymphocytes and plasma cells. There are disorganized lymphoid follicles. The normally sparse surface layer of lining cells becomes hyperplastic and thickened (**Fig. 18.20**). There is marked vascular proliferation. Increased permeability of blood vessels and the synovial lining layer leads to joint effusions that contain lymphocytes and dying polymorphs.
The hyperplastic synovium spreads from the joint margins onto the cartilage surface. This ‘pannus’ of inflamed synovium damages the underlying cartilage by blocking its normal route for nutrition and by the direct effects of cytokines on the chondrocytes. The cartilage becomes thinned and the underlying bone exposed. Local cytokine production and joint disuse combine to cause juxta-articular osteoporosis during active synovitis.

Fibroblasts from the proliferating synovium also grow along the course of blood vessels between the synovial margins and the epiphyseal bone cavity, and damage the bone. This process is shown by MRI to occur in the first 3–6 months following onset of the arthritis before the diagnostic, ill-defined, juxta-articular bony ‘erosions’ appear on X-ray (Fig. 18.21). This early damage justifies the use of disease-modifying anti-rheumatic drugs (DMARDs; see p. 680) within 3 months of onset of the arthritis to try to induce disease remission. Low-dose steroids delay, and anti-TNF-α agents halt and occasionally reverse, erosion formation. Erosions lead to a variety of deformities and contribute to long-term disability.
Rheumatoid factors and anti-citrullinated peptide antibodies (ACPA)

Transient production of RF (see pp. 650–651) is an essential part of the body's normal mechanism for removing immune complexes, but in RA they show a much higher affinity and their production is persistent and occurs in the joints. They are of any immunoglobulin class (IgM, IgG or IgA), but the most common tests employed clinically detect IgM RF. Around 70% of people with polyarticular RA have IgM rheumatoid factor in the serum. Positive titres can predate the onset of RA.

The term ‘seronegative RA’ is used when the standard tests for IgM RF are persistently negative. These patients tend to have a more limited pattern of synovitis.

IgM RF is not diagnostic of RA and its absence does not rule the disease out; however, it is a useful predictor of prognosis. A persistently high titre in early disease implies more persistently active synovitis, more joint damage and greater disability eventually, and justifies earlier use of DMARDs.

ACPAs (see p. 650) are usually present with RF in RA. They are better predictors of a transition from early transient inflammatory arthritis to persistent synovitis and early RA. RF
and ACPA together are even more specific.

**Clinical features**

**Typical presentation**

RA typically presents (approximately 70% of cases) as a progressive, symmetrical, peripheral polyarthritis, evolving over a period of a few weeks or months in patients between 30 and 50 years of age, although the disease can occur at any age. Less commonly (15%), a rapid onset can occur over a few days (or explosively overnight), with a severe symmetrical, polyarticular involvement, especially in the elderly. Factors indicating a poor prognosis are listed in Box 18.24. The differential diagnosis of early RA is shown in Box 18.25.

---

**Box 18.24**

**Factors predicting a poor prognosis for progression in early rheumatoid arthritis**

- Older age
- Female sex
- Symmetrical small joint involvement
- Morning stiffness >30 min
- >4 swollen joints
- Cigarette smoking
- Co-morbidity
- C-reactive protein >20 g/dL
- Positive rheumatoid factor and anti-citrullinated peptide antibodies
**Box 18.25**

**Differential diagnosis of early rheumatoid arthritis**

- Postviral arthritis: rubella, hepatitis B or erythrovirus
- Seronegative spondyloarthropathies
- Polymyalgia rheumatica
- Acute nodal osteoarthritis (proximal and distal interphalangeal joints involved)

Revised classification (American College of Rheumatology, ACR) criteria from 2010 are more suitable for assessing and diagnosing early arthritis than previous versions because they do not rely on later changes, such as erosions and extra-articular disease to distinguish RA (Box 18.26).

**Box 18.26**

**ACR/EULAR 2010 criteria for rheumatoid arthritis**

*The cut-off point for RA is at ≥6 points. Patients can also be classified as having RA if they have both typical erosions and longstanding disease previously satisfying the classification criteria. ACPA, anti-citrullinated peptide antibody; ACR,*
In early RA, the combination of at least one swollen joint for more than 6 weeks with no prior injury, no associated history or family history of spondyloarthritis or associated conditions such as psoriasis (see pp. 1353–1356), and a positive ACPA test is the best way to select patients for earlier treatment to avoid joint damage. This benefit of earlier treatment is evidence-based and has been shown to reduce the risk of the development of damage and permanent joint deformities.

Symptoms and signs of early RA
The majority of patients complain of pain and stiffness of the small joints of the hands (MCPs, PIPs) and feet (MTPs). The DIPs are usually spared. The wrists, elbows, shoulders, knees and ankles are also affected. In most cases, many joints are involved, but 10% of patients present with a monoarthritis of the knee or shoulder or with carpal tunnel syndrome.

Fatigue is a common complaint. The pain and stiffness are significantly worse in the morning. Sleep is disturbed.

The joints are usually warm and tender with some joint swelling. There is limitation of movement and muscle wasting. Deformities and non-articular features develop if the disease cannot be controlled (see below).

RA in the older patient may mimic polymyalgia rheumatica; the synovitis becomes apparent as the corticosteroid dose is reduced.

Other presentations
The presentation and progression of RA are variable. Presentations are shown in Box 18.27. Relapses and remissions occur either spontaneously or on drug therapy. In some patients, the disease remains active, producing progressive joint damage. Rarely, the process may cease (‘burnt-out RA’).

Box 18.27
Presentations of rheumatoid arthritis

- **Palindromic.** Palindromic monoarticular attacks last 24–48 h; 50% progress to other types of RA.

- **Transient.** Disease is self-limiting, lasting <12 months and leaving no permanent joint damage. It is usually seronegative for IgM RF and ACPA. Some of these patients may have undetected postviral arthritis.

- **Remitting.** There is a period of several years during which the arthritis is active but then
remits, leaving minimal damage.

- **Chronic, persistent.** This is the most typical form; it may be seropositive or seronegative for IgM RF. The disease follows a relapsing and remitting course over many years. Seropositive (plus ACPA) patients tend to develop greater joint damage and long-term disability. They warrant earlier and more aggressive treatment with disease-modifying agents.

- **Rapidly progressive.** The disease progresses remorselessly over a few years and leads rapidly to severe joint damage and disability. It is usually seropositive (plus ACPA), has a high incidence of systemic complications and is difficult to treat.

ACPA, anti-citrullinated peptide antibody; RF, rheumatoid factor.

**Seronegative RA** initially affects the wrists more often than the fingers and has a less symmetrical joint involvement. It has a better long-term prognosis but some cases progress to severe disability. This form can be confused with psoriatic arthropathy, which has a similar distribution (see pp. 685–686).

**Palindromic rheumatism** is unusual (5%) and consists of short-lived (24–48-hour) episodes of acute monoarthritis. The joint becomes acutely painful, swollen and red, but resolves completely. Further attacks occur in the same or other joints. About 50% of patients go on to develop typical chronic rheumatoid synovitis after a delay of months or years. The rest remit or continue to have acute episodic arthritis. The detection of RF or ACPA predicts conversion to chronic, destructive synovitis.

**Complications**

**Septic arthritis**

This complication is serious and has significant morbidity and mortality. In immunosuppressed patients, the affected joints may not display the typical signs of inflammation with accompanying fever found in patients with an intact immune system. There is usually a neutrophil leucocytosis. Any effusion, particularly of sudden onset, should be aspirated. *Staphylococcus aureus* is the most common organism. Blood cultures are often positive. Treatment is with systemic antibiotics (see p. 690) and drainage.

**Amyloidosis**

Amyloidosis (see pp. 1288–1289) is found in a very small number of people with uncontrolled RA. RA is the most common cause of secondary AA amyloidosis. AL amyloidosis causes a polyarthritis that resembles RA in distribution and is also often associated with carpal tunnel syndrome and subcutaneous nodules.

**Joint involvement in RA**

The changes described below are seen in established disease or when early drug treatment has
been ineffective.

**Hands and wrists**

The impact of RA on the hands is severe. In early disease, the fingers are swollen, painful and stiff. Inflamed flexor tendon sheaths increase functional impairment and may cause a carpal tunnel syndrome. Joint damage causes:

- **A combination of ulnar drift and palmar subluxation of the MCPs** *(Fig. 18.22)*. This change leads to unsightly deformity, but function may be preserved once the patient has learned to adapt and pain is controlled.

  ![Ulnar deviation](image1)

  ![Boutonnière deformity](image2)

  ![Swan-neck deformity](image3)

  **FIGURE 18.22** Rheumatoid arthritis. A. Characteristic hand deformities. B. Early rheumatoid arthritis – dorsal tenosynovitis of the right wrist and small joints of both hands with spindling of the fingers.

- **Fixed flexion** (buttonhole or boutonnière deformity) or **fixed hyperextension** (swan-neck deformity) of the PIP joints, which impairs hand function.

- **Swelling and dorsal subluxation of the ulnar styloid**, which causes wrist pain and may cause rupture of the finger extensor tendons, leading in turn to a sudden onset of finger drop of
the little and ring fingers predominantly; this needs urgent surgical repair.

**Shoulders**

RA commonly affects the shoulders. Initially, the symptoms mimic rotator cuff tendonosis (see p. 654) with a painful arc syndrome and pain in the upper arms at night. Further joint damage leads to global stiffening; rotator cuff tears become more common (see p. 654) and interfere with dressing, feeding and personal toilet.

**Elbows**

Synovitis of the elbows causes swelling and a painful fixed flexion deformity. In late disease, flexion may be lost and severe difficulties with feeding result, especially combined with shoulder, hand and wrist deformities.

**Feet**

One of the earliest manifestations of RA is painful swelling of the MTP joints.
- The foot becomes broader and a hammer-toe deformity develops.
- Exposure of the metatarsal heads to pressure by the forward migration of the protective fibrofatty pad *(Fig. 18.23)* causes pain.

![FIGURE 18.23](image_url) The toes in rheumatoid arthritis. There is exposure of the metatarsal heads with forward migration of the soft tissue pad.
Ulcers or calluses may develop under the metatarsal heads and over the dorsum of the toes.

- Mid- and hindfoot RA causes a flat medial arch and loss of flexibility of the foot.
- The ankle often assumes a valgus position.

Appropriate broad, deep, cushioned shoes are essential but rarely wholly adequate, and walking is often painful and limited. Podiatry helps and surgery may be required.

**Knees**

Massive synovitis and knee effusions occur but respond well to aspiration and steroid injection (see p. 660). A persistent effusion increases the risk of popliteal cyst formation and rupture (see p. 662). In later disease, erosion of cartilage and bone causes loss of joint space on X-ray and damage to the medial and/or lateral and/or retropatellar compartments of the knees. Depending on the pattern of involvement, the knees may develop a varus or valgus deformity. Secondary OA follows. Total knee replacement is often the only way to restore mobility and relieve pain.

**Hips**

The hips are occasionally affected in early RA but less commonly so than the knees at all stages of the disease. Pain and stiffness are accompanied by radiological loss of joint space and juxta-articular osteoporosis. The latter may permit medial migration of the acetabulum (protrusio acetabulae). Later, secondary OA develops. Hip replacement is usually necessary.

**Cervical spine**

Painful stiffness of the neck in RA is often muscular, but it may be due to rheumatoid synovitis affecting the synovial joints of the upper cervical spine and the bursae, which separate the odontoid peg from the anterior arch of the atlas and its retaining ligaments. This synovitis leads to bone destruction, damages the ligaments and causes atlantoaxial or upper cervical vertebral instability. Subluxation and local synovial swelling may damage the spinal cord, producing pyramidal and sensory signs. MRI is the imaging of choice, but lateral flexed and extended neck X-rays can demonstrate instability. In late RA, difficulty walking that cannot be explained by articular disease, weakness of the legs or loss of control of bowel or bladder may be due to spinal cord compression and is a neurosurgical emergency.

Imaging of the cervical spine in flexion and extension is recommended in patients with RA before surgery or upper gastrointestinal endoscopy to check for instability and reduce the risk of cord injury during intubation.

**Other joints**

The temporomandibular, acromioclavicular, sternoclavicular, cricoarytenoid and any other synovial joint can be affected.

**Non-articular manifestations**
Soft tissue surrounding joints

Subcutaneous nodules are firm and intradermal, generally occurring over pressure points: typically, the elbows, the finger joints and the Achilles tendon in patients with seropositive erosive disease. They can be removed surgically but they tend to recur.

The olecranon and other bursae may be swollen (bursitis).

Tenosynovitis of flexor tendons in the hand can cause stiffness and occasionally a trigger finger. Swelling of the extensor tendon sheath over the dorsum of the wrist is common.

Muscle wasting around joints is common. Corticosteroid-induced myopathy occurs. Osteoporosis is more common in poorly controlled RA.

Less common non-articular manifestations

Non-articular complications are becoming less common, probably because of more effective disease control.

Lungs

Findings in the lungs (see pp. 1121–1122) include:

• airways disease: a spectrum from predominant bronchiectasis (cough and daily sputum) to
predominant obliterative bronchiolitis (progressive breathlessness)
• disease of the pleura: pleural effusion (asymptomatic to mildly breathless) and thickening
• interstitial lung disease: a combination of inflammation and basal lung fibrosis
• peripheral, intrapulmonary nodules: asymptomatic but may cavitate, especially with pneumoconiosis (Caplan syndrome)
• infective lesions, e.g. tuberculosis in patients on biological DMARDs.

**Vasculitis**
Vasculitis (see pp. 699–702) caused by immune complex deposition in arterial walls is uncommon. Smoking is a risk factor. Findings include:
• nail-fold infarcts due to cutaneous vasculitis
• widespread cutaneous vasculitis with necrosis of the skin (seen in people with very active, strongly seropositive disease)
• mononeuritis multiplex (see p. 883).

**Heart and peripheral vessels**
Poorly controlled RA with a persistently raised CRP and high cholesterol is a cardiovascular risk factor, independent of traditional risk factors (i.e. high cholesterol and hypertension). Other cardiovascular problems include:
• pericarditis, which is rarely symptomatic
• endocarditis and myocardial disease, rarely symptomatic, found at postmortem in approximately 20% of cases
• Raynaud syndrome, rarely (see p. 1054).

**Nervous system**
• Peripheral sensory neuropathies: mononeuritis multiplex or symmetrical, peripheral – due to vasculitis of the vasa nervorum.
• Compression neuropathies: carpal or tarsal tunnel syndrome – due to synovitis.
• Cord compression: due to atlantoaxial subluxation (see above).

**Eyes**
• Sicca syndrome causes dry mouth and eyes (see Sjögren syndrome, p. 698).
• Scleritis and episcleritis occur in severe, seropositive disease, resulting in painful red eye.
• Scleromalacia perforans is a rare feature.

**Kidneys**
Amyloidosis causes proteinuria, nephrotic syndrome and chronic kidney disease. It occurs rarely in severe, longstanding rheumatoid disease and is due to the deposition of highly stable
serum amyloid A protein (SAP) in the intercellular matrix of a variety of organs. SAP is an acute-phase reactant, produced normally in the liver.

**Spleen, lymph nodes and blood**

*Felty syndrome* is splenomegaly and neutropenia in a patient with RA. Leg ulcers and sepsis are complications. HLA-DR4 is found in 95% of patients, compared with 50–75% of people with RA alone.

Lymph nodes may be palpable, usually proximal to affected joints. There may be peripheral lymphoedema of the arm or leg.

*Anaemia* is almost universal and is usually normochromic and normocytic. It may be iron-deficient owing to gastrointestinal blood loss from NSAID ingestion, or rarely haemolytic (Coombs-positive). There may be a pancytopenia due to hypersplenism in Felty syndrome or as a complication of DMARD treatment. A high platelet count occurs with active disease.

### Diagnosis and investigations

Diagnosis relies on the clinical features described above. The predictors of poor prognosis arthritis are listed in *Box 18.24*. Initial investigations include:

- **Blood count** may show a normochromic, normocytic anaemia.
- **ESR and/or CRP** are raised in proportion to the activity of the inflammatory process and are useful in monitoring treatment.
- **Serology** reveals ACPA positivity (see p. 650). This is present earlier in the disease (and may predate it by many years), and in early inflammatory arthritis indicates the likelihood of progressing to RA. RF is present in approximately 70% of cases and ANA at low titre in 30%.
- **X-rays** show soft tissue swelling in early disease, but ultrasound and MRI (*Fig. 18.25*) are useful to demonstrate synovitis and early erosions.
Aspiration of the joint may be needed if an effusion is present. The aspirate looks cloudy owing to white cells. In a suddenly painful joint, septic arthritis should be suspected (see p. 690).

Doppler ultrasound is a very effective way of demonstrating persistent synovitis when deciding on the need for DMARDs or assessing their efficacy.

Other investigations will depend on the clinical picture, as outlined above. In severe disease, extensive imaging of joints may be required. MRI is the technique of choice, especially for the knee and cervical spine.

Management

(See Box 18.28.) The diagnosis of RA inevitably causes concern and fear in the patient and requires explanation and reassurance. Anyone with early inflammatory arthritis should be referred to a specialist arthritis clinic within 3 months of onset.

Box 18.28

Management of rheumatoid arthritis

- Establish the diagnosis clinically.
- Use NSAIDs and analgesics to control symptoms.
- Try to induce remission with i.m. depot methylprednisolone 80–120 mg if synovitis persists beyond 6 weeks.
- If synovitis recurs, refer to a rheumatologist to start DMARDs and consider combinations of sulfasalazine, methotrexate and hydroxychloroquine. Give a second dose of i.m. depot
methylprednisolone or oral steroids.
- Refer for physiotherapy and general advice through a specialist team.
- As improvement occurs, as measured by less pain, less morning stiffness and reduced acute-phase response, tail off steroids and possibly reduce drugs.
- If no better, use anti-TNF-α therapy or other biological agent.

DMARDs, disease-modifying anti-rheumatic drugs; TNF-α, tumour necrosis factor alpha.

The doctor should have a positive approach and remind the patient that, with the help of drugs, most people continue to lead a more or less normal life, as the aim of therapy is disease remission; 25% will recover completely. The earliest years are often the most difficult and people should be helped and encouraged to stay at work, as 30% lose their job within 2 years of diagnosis. Patients adjust and cope remarkably with time and support from the specialist team in a rheumatology unit (including doctors, nurses, physiotherapists, podiatrists and psychologists) and from leaflets, websites and local patient groups.

Patients from socially deprived backgrounds and smokers have a worse prognosis. Consideration must also be given to reducing the increased prevalence of cardiovascular risk that occurs in RA; statins are thought to be beneficial in this respect, although more clinical studies are required.

Drug therapy

There is no curative agent available for RA but early recognition and intensified treatment, with regular review until remission occurs, reduces disability. Less frequent review is then continued to assess disease activity, damage, function and co-morbidities.

The disease activity score DAS28 is widely used to measure disease activity in RA by counting the number of tender and swollen joints in 28 joints in the upper limbs and knees, combining these values with the ESR and the patient's assessment of their general health on a visual analogue scale to generate a numerical score (Fig. 18.26). A DAS28 score of greater than 5.1 implies active disease, less than 3.2 low disease activity and less than 2.6 remission. Data now support the use of multiple traditional DMARDs (started sequentially as ‘step-up’ or together) as combination therapy early in the disease to prevent the long-term irreversible damaging effects of joint inflammation. Biological therapies (known as biologics) are recombinant proteins: most commonly, monoclonal IgG1 antibodies directed against specific immunological targets or fusion proteins containing the Fc portion of IgG1 joined to receptor-blocking proteins. These drugs are increasingly used earlier in disease to reduce disease activity and damage. Searching for persistent synovitis in patients in apparent remission using Doppler ultrasound leads to more intensive therapeutic regimes to reduce longer-term disability.
Non-steroidal anti-inflammatory drugs and coxibs

Most people with RA are unable to cope without an NSAID to relieve night pain and morning stiffness in addition to disease-modifying drugs. The individual response to NSAIDs varies greatly, so several different drugs may have to be tried for at least a week for a particular patient to find the most effective (see Box 18.16), starting with an inexpensive NSAID with few side-effects. The major side-effects of NSAIDs and the use of coxibs are discussed on page 666. If gastrointestinal side-effects are prominent, or the patient is over 65 years of age, add a proton pump inhibitor. For additional relief, a simple analgesic is taken as required (e.g. paracetamol or a combination of codeine or dihydrocodeine and paracetamol).

Corticosteroids

The early use of corticosteroids slows down the course of the disease but intensive short courses in very early arthritis do not appear to stop progressive disease. Corticosteroids are the most common cause of secondary osteoporosis and the risk of fracture is increased by as
much as 75% within the first 3 months of treatment. Therefore, concomitant vitamin D and bisphosphonates are necessary to reduce fracture risk in patients expected to be on corticosteroid therapy for more than 3 months’ duration.

**Intra-articular injections** with semi-crystalline steroid preparations have a powerful but sometimes only short-lived effect.

**Intramuscular depot injections** (40–120 mg depot methylprednisolone) are used to help induce remission whilst waiting for DMARDs to work and to control severe disease flares.

**Oral corticosteroids** are powerful disease-controlling drugs but cause a number of problems ([Box 18.29](#); see also [Box 26.39](#)); they are best avoided in the long term because side-effects are inevitable. Early intensive short-term regimens are often used to help induce remission. Doses of 5–7.5 mg daily as maintenance therapy are used in some centres. Corticosteroids are invaluable to people with severe disease who have extra-articular manifestations such as vasculitis.

### Box 18.29

**Problems associated with the use of corticosteroids**

- Patients are increasingly anxious about the use of corticosteroids because of adverse publicity about their potential side-effects. This must be discussed frankly and the risks of not using corticosteroids in treatment should be described and balanced against the risks posed by the drugs themselves.
- Patients must be warned to avoid sugars and saturated fats, and to eat less because of the risk of weight gain.
- The skin becomes thin and easily damaged.
- Patients should be monitored for diabetes and hypertension.
- Cataract formation may be accelerated.
- Osteoporosis develops within 3 months on doses above 7.5 mg daily. Monitor with DXA scan and treat with calcium, vitamin D and bisphosphonate ([Box 18.31](#)).

**Disease-modifying anti-rheumatic drugs**

Traditional disease-modifying anti-rheumatic drugs (DMARDs) are synthetic small-molecule drugs; they are listed in [Box 18.30](#). Despite their mechanism of action being incompletely understood, they have been shown to reduce inflammation, joint swelling and plasma acute-phase reactants, and to slow the development of joint erosions as well as irreversible damage. Their beneficial effect is not immediate, taking 2–3 months to become apparent. As monotherapy, traditional DMARDs often have only a partial effect, achieving between 20% and 50% improvement by ACR criteria for disease remission ([Box 18.31](#)), and are more effective used in combination.
### Box 18.30

**Disease-modifying anti-rheumatic drugs (DMARDs)**

**Cytokine modulators**

**TNF-α blockers**

- **Etanercept (alone or with methotrexate)**: s.c. 25 mg x 2-weekly or 50 mg weekly
  - Injection site reactions, Infections, e.g. tuberculosis and sepsis/ciaema, Hypersensitivity reactions, Heart failure, Rare – demyelination and autoimmune syndromes, Reversible lupus-like syndrome, Infections, Hypersensitivity reactions
  - Baseline CXR, hepatitis B and C, HIV, FBC, U&Es, LFTs, if indicated
  - Monitor as per concomitant DMARD; if monotherapy, repeat FBC, U&Es and LFTs 6-monthly
  - As per etanercept

- **Adalimumab (with methotrexate)**: s.c. 40 mg alternate weeks
  - Injection site reactions, Infections, e.g. tuberculosis and sepsis/ciaema, Hypersensitivity reactions, Heart failure, Rare – demyelination and autoimmune syndromes, Reversible lupus-like syndrome, Infections
  - Baseline CXR, hepatitis B and C, HIV, Igs, CD19, FBC, U&Es, LFTs, if indicated

**Other biological agents (used with methotrexate)**

- **Rituximab**: I.v. 500–1000 mg
  - Hypo-hypertension, Skin rash, Nausea, Pruritus, Back pain, Rare – toxic epidermal necrolysis
  - Baseline CXR, hepatitis B and C, HIV, Igs, CD19, FBC, U&Es, LFTs, if indicated
  - Monitor as per concomitant DMARD; if monotherapy, repeat FBC, U&Es and LFTs 6-monthly

- **Abatacept**: I.v. 10 mg/kg on days 1, 15, 30 and then monthly s.c. preparations available
  - Nausea, vomiting, Headache, Rare – hypersensitivity
  - Baseline CXR, hepatitis B and C, HIV, FBC, U&Es, LFTs, if indicated

- **Tocilizumab**: I.v. 8 mg/kg infusion
  - Headache, Skin eruption, Stomatitis, Fever, Anaphylactic reactions
  - As per abatacept plus baseline and 6-monthly lipids

CD19, cluster of differentiation 19; CXR, chest X-ray; FBC, full blood count; HIV, human immunodeficiency virus; Igs, immunoglobulins; i.v., intravenous; LFTs, liver function tests; NICE, National Institute for Health and Care Excellence; s.c., subcutaneous; TNF-α, tumour necrosis factor alpha; U&Es, urea and electrolytes.
Early intervention with traditional DMARDs within 6 weeks to 6 months of disease onset improves the outcome. Combinations of three or four drugs (steroids, sulfasalazine, methotrexate and hydroxychloroquine) in early RA are increasingly common; the number of agents is reduced once remission has been achieved. Several DMARDs are contraindicated in pregnancy (see Box 29.10). Effective treatment with DMARDs including TNF-α blockers reduces the increased cardiovascular risk in RA.

**Methotrexate**

Methotrexate remains the anchor drug in RA therapy, although it should not be used in pregnancy and conception should be delayed until women have been off the drug for 6 weeks. A screening history, chest X-ray and an interferon gamma release assay (IGRA) in high-risk patients are performed to exclude tuberculosis. Initial pneumococcal and annual influenza vaccinations are given. The starting *weekly* dose of 7.5–10 mg orally is increased up to 15–25 mg as necessary to reduce disease activity. It is well tolerated, although nausea or poor absorption may limit its efficacy, in which case it is given by subcutaneous injection. Oral folic acid reduces side-effects but may also lessen efficacy. Full blood counts and liver biochemistry should be monitored. Methotrexate usually works within 1–2 months. More patients remain on this agent than on most other DMARDs, indicating that it is effective and has relatively few side-effects.

**Sulfasalazine**

Sulfasalazine is a combination of sulfapyridine and 5-amino-salicylic acid. Sulfapyridine is probably the active component. It is well tolerated and can be used during pregnancy. The usual starting dose of 500 mg per day is increased to a maintenance dose of 2–3 g per day. Around 50% of patients respond in the first 3–6 months, but efficacy can be lost. Blood monitoring is obligatory because of the risk of leucopenia and thrombocytopenia.

**Hydroxychloroquine**

---

**Box 18.31**

**The 2011 ACR/EULAR definitions for disease remission in rheumatoid arthritis clinical trials**

- Tender joint count (including feet and ankles) ≥1
- Swollen joint count (including feet and ankles) ≥1
- C-reactive protein ≥1 mg/L
- Patient global assessment ≥1 (on a 10-cm visual analogue scale)

ACR, American College of Rheumatology; EULAR, European League Against Rheumatism.
A dose of 200–400 g daily is well tolerated. It is used alone in mild disease or commonly as an adjunct to other DMARDs. Retinopathy is extremely rare (about 1 in 2000 patients). Some rheumatologists arrange an initial check of macular function with an Amsler chart and further reviews annually, as retinopathy is irreversible.

**Leflunomide**

This DMARD exerts an immunomodulatory effect by preventing pyrimidine production in proliferating lymphocytes through blockade of the enzyme dihydro-orotate dehydrogenase, thus blocking clonal expansion of T cells. Most other cells are able to bypass this blockade. It has a long half-life of 4–28 days. A dose of 20 mg daily (10 mg if diarrhoea is a problem) is used. Diarrhoea diminishes with time. Blood monitoring is obligatory (full blood count, platelets, liver biochemistry). The onset of action is 4 weeks with some further improvement sustained at 2 years. Leflunomide works in some patients who have failed to respond to methotrexate. Its long half-life means that it is best avoided in women planning a family.

**Biological therapies**

**TNF-α blockers**

These agents are more expensive than traditional DMARDs so they are used after at least two DMARDs (usually sulfasalazine and methotrexate) have failed. They represent a major therapeutic advance, particularly in the number of combination therapies that are now available to treat RA, although not all patients respond and there is loss of efficacy in some responders. They are usually given in combination with methotrexate to reduce loss of efficacy due to anti-drug antibody formation.

- **Etanercept** is a fully humanized p75 TNF-α receptor IgG1 fusion protein given by self-administered subcutaneous injection. Around 65% of patients respond well. Some develop an injection reaction.

- **Adalimumab** is a fully human monoclonal antibody against TNF-α, given along with methotrexate.

- **Infliximab** is a monoclonal antibody against TNF-α, given intravenously and co-prescribed with methotrexate to prevent loss of efficacy because of antibody formation.

- **Certolizumab pegol** is an Fab fragment of a humanized TNF-α inhibitor monoclonal antibody. It is pegylated: that is, polyethylene glycol groups are added to reduce its immunogenicity and prolong its half-life. The lack of an Fc portion on the antibody aims to reduce the risk of complement-dependent, as well as antibody-dependent, cytotoxicity and may reduce placental transfer. It is useful with or without methotrexate for severe active RA.

- **Golimumab** is a human IgG1-κ monoclonal antibody against TNF, which is given by subcutaneous injection once monthly for severe RA.

These products slow or halt erosion formation in up to 70% of people with RA and produce healing in a few. Malaise and tiredness improve in a manner that is not seen with other
DMARDs. Secondary failure may occur with all in the first year; changing to another anti-TNF agent is justified and often regains control of the disease. Potential biomarkers for responsiveness are being studied. Failure to respond to one does not predict failure to others.

**Safety data.**

To answer questions regarding rare or delayed onset of adverse events, as well as long-term outcomes and problems arising from biological therapies, national registers have been set up in different countries. These longitudinal, observational cohort studies are mostly focused on TNF-α blockers but are expanding to include other biological therapies.

To date, the results are reassuring. Infection rates are increased with TNF-α blockers, particularly in the first few months of treatment, but the rate then declines. There is a known association between RA and non-Hodgkin's lymphoma (NHL) but, overall, registers have not shown an increased risk of NHL in patients with RA treated with TNF-α blockers, although mean follow-up is relatively short at 5 years. There is no convincing evidence of any increased risk of other cancers. Reactivation of old tuberculosis may occur but is probably less common with etanercept. A pre-treatment chest X-ray is recommended, with a specialist review for high-risk groups. Tuberculosis should be treated before these agents are prescribed, and a course of prophylaxis is used in latent disease. Hepatitis B and C infection requires careful risk analysis and regular aminotransferase monitoring if anti-TNF agents are prescribed. They should not be used in patients who have severe cardiac failure.

These agents are extremely expensive when compared with traditional DMARDs but they may save costs in the longer term by reducing disability and the need for hospitalization. To date, there is no evidence of an adverse effect on pregnancy outcome but care is essential (see Box 29.10).

**Other biological agents**

- **Rituximab** is a chimeric monoclonal antibody (see pp. 146–147), directed against the CD20 receptor expressed on pre-B and mature B cells that is not present on stem cells and is lost before differentiation into plasma cells. Rituximab produces significant improvement in RF-positive RA for 8 months to several years when used alone or in combination with corticosteroids and/or methotrexate. This clinical improvement is associated with a 6–9-month B-cell lymphopenia and little change in circulating immunoglobulins. A re-flare is often accompanied by a return of peripheral B lymphocytes and rise in CRP. Rituximab can be re-used as the disease flares. Repeated courses are well tolerated and around 80% of RF-positive patients respond, with 50–60% showing persistent disease control; however, immunoglobulin levels should be monitored, as they may fall with repeated treatments. Rituximab is mainly used in patients who have failed to respond to anti-TNF agents.

- **Abatacept** is a recombinant fusion protein of CTLA4 and the Fc portion of IgG1, which selectively modulates T-cell activation by co-stimulation blockade. It may be used in patients who do not respond to anti-TNF regimens.

- **Tocilizumab** is a humanized monoclonal anti-IL-6 receptor antibody; it is used with
methotrexate for moderate to severe RA, usually after at least one other biologic has failed, but it may also be considered as a first-line biological therapy.

- **Anakinra** is a human recombinant IL-1 receptor antagonist; it is recommended for use in combination with methotrexate but is not often given in RA, as it is less efficacious than other biologics.

- **Tofacitinib** is oral Janus kinase (JAK) inhibitor, which selectively blocks JAK3/1 receptors that inhibit cytokine (IL-2, 4, 7, 9, 15 and 21) signalling. Three phase 3 studies have shown improvements with tofacitinib compared with placebo, methotrexate and adalimumab. There remain concerns, however, regarding infection and cardiovascular risk (due to raised lipids), as well as abnormal liver biochemistry. Therefore, the drug has not been approved in Europe, although it has been approved by the Food and Drug Administration (FDA) in the United States.

### Drugs used less commonly

**Gold, azathioprine, cyclophosphamide and ciclosporin**

These drugs are very rarely used to treat RA because of the availability of other agents with more favourable risk–benefit profiles. Gold (sodium aurothiomalate) is given by deep intramuscular injection and can induce remission. Due to side-effects or lack of effect, however, few patients remain on it beyond 2 years. Azathioprine and cyclophosphamide may be given when extra-articular features, particularly vasculitis, are severe. Ciclosporin is only used when conventional therapy has been ineffective and may cause a rise in creatinine level and hypertension.

### Physical measures

Input is required from the multidisciplinary team. Physiotherapists advise a combination of rest for active arthritis and exercises to maintain joint range and muscle power. Exercise in a hydrotherapy pool is popular and effective. Occupational therapists help to manage activities of daily living despite the arthritis and provide functional adaptations in the home or at work. Family and friends should be involved. Podiatry, footwear advice and psychological support should also be offered to all people with RA.

### Surgery

Surgery has a useful role in the long-term approach to patient management but is less frequently needed as therapeutic disease control becomes more effective. Its main objectives are prophylactic, to prevent joint destruction and deformity, and reconstructive, to restore function. Single-joint disease can be treated by surgical synovectomy to reduce the bulk of inflamed tissue and prevent damage. Excision arthroplasty of the ulnar styloid reduces pain and the risk of extensor tendon damage. Excision arthroplasties of the metatarsal heads reduce metatarsal pain and relieve pressure points. The major surgical advance has been the development of total replacement arthroplasty of the hip, knee, finger joints, elbow and shoulder. Such procedures
need careful planning and the expected outcomes and risks should be explained to the patient.

**Prognosis**

A poor prognosis is indicated by:

- **a clinical picture** of an insidious rather than an explosive onset of RA, female sex, increasing number of peripheral joints involved and the level of disability at the onset
- **blood tests** showing a high CRP/ESR, normochromic normocytic anaemia, and high titres of ACPA and of RF
- **X-rays** with early erosive damage *(note: ultrasound and MRI can show cartilage and bone damage prior to conventional X-rays).*

Prognosis can be altered dramatically with early DMARD therapy under expert supervision.

**Spondyloarthritis**

Spondyloarthritis (SpA) is an umbrella term for a group of conditions that affects the spine and peripheral joints with familial clustering and a link to certain type 1 HLA antigens *(Box 18.32).* Joint involvement is different from that seen in RA, as it is usually more limited and has a different distribution and associated extra-articular features. These diseases occasionally present in childhood.

**Box 18.32**

**Spondyloarthritis**

- Axial spondyloarthritis, including ankylosing spondylitis
- Psoriatic arthritis
- Reactive arthritis (sexually acquired)
- Post-dysenteric reactive arthritis
- Enteropathic arthritis (ulcerative colitis/Crohn's disease)

They may also be categorized according to their predominant clinical manifestation of axial (sacroiliac and/or spine) or peripheral (arthritis, enthesitis and/or dactylitis) disease with possible overlap. The Assessment of Spondyloarthritis International Society has developed classification criteria for both axial and peripheral SpA, which were developed to enhance diagnosis, treatment and design of clinical trials. Despite this, distinct SpA conditions exist, as shown in **Box 18.32.**

Histologically, the synovitis itself is similar to that of RA, but there is no production of rheumatoid factor (RF) or anti-citrullinated peptide antibody (ACPA). Inflammation of the enthesis (junction of ligament or tendon and bone) and joint ankylosis develop more commonly
than in RA. All are associated with an increased frequency of sacroiliitis and HLA-B27.

**Aetiology**

The common aetiological thread linking these disorders is their striking association with HLA-B27, particularly ankylosing spondylitis (AS). HLA type B27 is present in >90% of Caucasians with AS but only 8% of controls. HLA-B27 exhibits a number of unusual characteristics, including a high tendency to misfold. The role of class I HLA antigens in pathogenesis is supported by the fact that HLA-B27 transgenic mice spontaneously develop arthritis and skin, gut and genitourinary lesions.

Infections have been postulated to be involved, possibly by molecular mimicry, with parts of the organism that are structurally similar to the HLA molecule triggering cross-reactive antibody formation, although this hypothesis is unproven. The acquired immunodeficiency syndrome (AIDS) is increasing the prevalence of reactive arthritis and spondylitis in sub-Saharan Africa, even in the absence of HLA-B27. The explanation for this changing epidemiology is unclear.

The types of arthritis that follow a precipitating infection are called reactive arthritis (see p. 686).

The specialized immune systems of the gut and genitourinary mucous membranes may also play a causal role, perhaps reacting to local infections or to antigens, which cross the damaged mucosa.

**Axial spondyloarthritis**

Axial spondyloarthritis occurs in 1% of the general population. It is an inflammatory disorder primarily affecting fibrous and synovial joints of the spine. Sacroiliac joint changes are seen only on MRI. When radiographic changes at the sacroiliac joints are present, the term ankylosing spondylitis (AS) is used.

**Ankylosing spondylitis**

It is now recognized that AS forms part of the spectrum of axial spondyloarthritis. It presents with inflammatory back pain and sacroiliac inflammation. It is seen in 0.2–0.5% of the population in Northern Europe and approximately 0.5% in the USA, affecting mainly young adults (late teens to early thirties) and occurring worldwide, with a male to female ratio of 3: 1. Women present later and are under-diagnosed. The frequency of axial spondyloarthritis in different populations is roughly paralleled by the incidence of HLA-B27; Africans and Japanese have a low incidence of both HLA-B27 and AS, while the North American Haida Indians have a high incidence of both.
This is probably a combination of genetic and environmental features:

- There are at least 24 subtypes of HLA-B27 (B*2701 to B*2724). Some appear to increase risk; others have a protective role. Twin studies indicate a much higher disease concordance in HLA-B27-positive monozygotic twins (up to 70%) than in dizygotic twins (about 20–25%).

- Other genes lying within the major histocompatibility complex (the IL-1 gene cluster and CYP2D6) also influence susceptibility to AS but the disease is polygenic and genome-wide association studies have identified significant associations with the endoplasmic reticulum aminopeptidase (ERAP)-1 and IL-23 genes.

- The association of ERAP-1 with axial spondyloarthritis may support the arthritogenic peptide hypothesis, whereby disease is triggered by presentation of peptide by HLA-B27 to cytotoxic CD8-positive T cells. Furthermore, misfolding of HLA-B27 leads to the production of IL-23, and T cells resident in entheses promote inflammation characteristic of spondyloarthritis in response to IL-23.

- The interaction of environmental factors has been proposed, but although Gram-negative organisms, such as Yersinia, Klebsiella, Salmonella and Shigella, can cause a reactive arthropathy, there is no conclusive evidence for their involvement in the pathogenesis of axial spondyloarthritis.

- Lymphocyte and plasma cell infiltration occurs with local erosion of bone at the attachments of the intervertebral and other ligaments (enthesitis), which heals with new bone (syndesmophyte) formation.

### Clinical features

Initially, the diagnosis is often missed because the patient is asymptomatic between episodes and radiological abnormalities are absent.

- **Back pain** with episodic inflammation of the sacroiliac joints in the late teenage years or early twenties is the first manifestation of axial spondyloarthritis.

- **Pain in one or both buttocks** and low back pain and stiffness are typically worse in the morning and relieved by exercise.

- **Retention of the lumbar lordosis during spinal flexion** is an early sign. Later, paraspinal muscle wasting develops.

  **Criteria for classifying inflammatory back pain** as axial spondyloarthritis are shown in Box 18.33. These criteria encompass the whole spectrum of disease, with evidence of sacroiliitis being based on radiographic or MRI evidence of disease. Spinal stiffness can be measured by Schober's test; the skin over the midline of the spine is marked 5 cm below and 10 cm above the dimples of Venus and the increase in distance between those marks during flexion is recorded. An increase of <5 cm implies spinal stiffness.
**Box 18.33**

**Back pain criteria for diagnosing axial/ankylosing spondylitis**

- **Age of onset** <45 years
- **Insidious onset**
- **Improvement of back pain with exercise**
- **No improvement of back pain with rest**
- **Pain at night** with improvement on getting up

The presence of **four of the five criteria suggests ankylosing spondylitis with 80% sensitivity**. All criteria have high sensitivity.

**Non-spinal complications** (uveitis or costochondritis) suggest the diagnosis of spondyloarthritis *(Box 18.34)*:

- **Costochondral junction inflammation** causes anterior chest pain. Measurable reduction of chest expansion is due to costovertebral joint involvement.
- **Peripheral joint involvement** is asymmetrical and affects a few, predominantly large, joints. Hip involvement leads to fixed flexion deformities of the hips and further deterioration of posture. Young teenage boys occasionally present with a lower-limb monoarthritis (see p. 704), which later develops into AS.
- **Acute anterior uveitis** occurs in approximately 30% of patients with axial spondyloarthritis and related diseases, and is occasionally the presenting complaint. Severe eye pain, photophobia and blurred vision are an emergency (see pp. 1332–1333).
- **Other extra-articular features** include:
  - cardiovascular disease – aortic incompetence occurs in up to 1% of patients with established AS and cardiac conduction abnormalities in around 5%
  - respiratory disease – rarely, chest wall rigidity is associated with interstitial lung disease
  - renal impairment – reported in 10–35% of patients with AS and most commonly linked to chronic NSAID use
  - axial osteoporosis – occurs in approximately 25%. with vertebral fracture in 10%.

**Box 18.34**

**Non-articular problems in spondyloarthritis**

- Uveitis, in all types
- Cutaneous lesions in reactive arthritis (keratoderma blennorrhagica), histologically identical to pustular psoriasis
- Nail dystrophy, in psoriasis and reactive arthritis
- Aortitis, occasionally in ankylosing spondylitis and reactive arthritis

Overall clinical assessment of disease activity is based on a 1–10 score for levels of fatigue, spinal pain, arthralgia, swelling, localized tenderness, inflammation of tendons/enthesis, and duration and severity of morning stiffness. This can be measured using the Bath Ankylosing Spondylitis Disease Activity Index (see Further reading).

### Investigations

- **Blood.** ESR and CRP are usually raised.

- **HLA testing.** This is rarely of value because of the high frequency of HLA-B27 in the population, but may give supporting evidence in a difficult case.

- **X-rays.** The medial and lateral cortical margins of both sacroiliac joints lose definition owing to erosions and eventually become sclerotic (Fig. 18.27). Radiological appearances in the spine of blurring of the upper or lower vertebral rims at the thoracolumbar junction are caused by an enthesitis at the insertion of the intervertebral ligaments and may eventually affect the whole spine. Persistent inflammatory enthesitis causes bony spurs (syndesmophytes), which lead to bony ankylosis and permanent stiffening. The sacroiliac joints eventually fuse, as may the costovertebral joints, reducing chest expansion. Calcification of the intervertebral ligaments and fusion of the spinal facet joints and syndesmophytes leads to what is often called a ‘bamboo’ spine (Fig. 18.28).
FIGURE 18.27 X-ray of ankylosing spondylitis. The sacroiliac joints are eroded and show marginal sclerosis (white arrows). There is bridging syndesmophyte formation at the thoracolumbar junction (black arrows).
FIGURE 18.28 X-ray of bamboo spine in ankylosing spondylitis. In advanced disease, there is calcification of the interspinous ligaments and fusion of the facet joints, as well as syndesmophytes at all levels. The sacroiliac joints fuse.

- **MRI.** MRI with gadolinium demonstrates sacroiliitis before it is seen on X-rays, as well as persistent enthesitis.

### Management

- The key to effective management of AS is early diagnosis so that a regimen of preventative exercises is started before syndesmophytes have formed. Morning exercises aim to maintain spinal mobility, posture and chest expansion; regular NSAIDs to improve symptoms and signs of spondyloarthritis are often required to achieve this goal.
- Failure to control pain and to encourage regular spinal and chest exercises leads to an irreversible dorsal kyphosis and wasted paraspinal muscles, which, along with stiffening of the cervical spine, makes forward vision difficult.
- When the inflammation is active and the morning pain and stiffness are too severe to permit effective exercise, an evening dose of a long-acting or slow-release NSAID or an NSAID suppository improves sleep, pain control and exercise compliance.
- Sulfasalazine, methotrexate and leflunomide may help peripheral arthritis but not spinal disease.
- When NSAIDs have failed, the TNF-α-blocking drugs adalimumab, etanercept, golimumab, certolizumab and infliximab (see **Box 18.30**) have all been shown to reduce symptoms of
spinal and peripheral joint inflammation substantially and to improve function, as well as quality of life. Evidence of reduction of bony progression, however, has not been found. Relapse occurs on stopping therapy but may be delayed by several months making intermittent treatment feasible. Other biologics do not help spondyloarthritis.

- Early clinical studies have shown apremilast, a phosphodiesterase type 4 (PDE4) inhibitor, and secukinumab, an anti-IL-17, to be effective in spondyloarthritis.

### Prognosis

With exercise and pain relief, the prognosis is excellent and over 80% of patients are fully employed. Anti-TNF therapies are likely to reduce the morbidity of severe disease, lowering the risk of permanent spinal stiffness and progressive peripheral joint disease.

### Psoriatic arthritis

The prevalence of psoriasis is 2–3% worldwide; in this population, around 10% have arthritis, which precedes skin disease in around 15% of cases. A family history of psoriasis may be a clue to the diagnosis. The aetiology and pathogenesis are described on page 1353.

### Clinical features

Patterns of psoriatic arthritis include:

- **Mono- or oligoarthritis.**
- **Polyarthritis:** often begins with an asymmetrical pattern and progresses to be virtually indistinguishable from RA.
- **Spondylitis:** unilateral or bilateral sacroiliitis and early cervical spine involvement; only 50% are HLA-B27-positive.
- **Distal interphalangeal arthritis:** the most typical pattern of joint involvement in psoriasis, often with adjacent nail dystrophy (see p. 1355) reflecting enthesis extending into the nail root. Dactylitis, in which an entire finger or toe is swollen, with joint and tendon sheath involvement, is characteristic of this condition.
- **Arthritis mutilans:** affects about 5% of patients who have psoriatic arthritis and causes marked periarticular osteolysis and bone shortening (‘telescopic' fingers) (**Fig. 18.29**).
Radiologically, psoriatic arthritis is erosive but the erosions are central in the joint, not juxta-articular, and produce a ‘pencil in cup’ appearance (Fig. 18.30). The skin and nail disease can be mild and may develop after the arthritis.

Management and prognosis

NSAIDs and/or analgesics help the pain but can occasionally worsen the skin lesions. Local synovitis responds to intra-articular corticosteroid injections. Sulfasalazine, methotrexate and
leflunomide are commonly used in patients with persistent peripheral joint synovitis, although none has a proven effect on slowing the development of joint damage. Ciclosporin may also be considered in severe disease. Hydroxychloroquine is best avoided because it may rarely cause acute psoriatic skin reactions. Similarly, oral corticosteroids may destabilize skin disease; they are best avoided but are valuable when injected into a single inflamed joint.

Anti-TNF-α agents, such as etanercept and golimumab (see pp. 680–682), and ustekinumab (an anti-IL-12/23 inhibitor), are highly effective and safe for severe skin and joint disease. They should be used when methotrexate has failed. An anti-IL-17 inhibitor has shown promise in late-phase clinical trials, and apremilast, a PDE4 inhibitor given orally, has been approved by the FDA for psoriatic arthritis. Rituximab has no role in treating psoriatic arthritis.

The prognosis for the joint involvement is generally better than in RA.

### Reactive arthritis

Reactive arthritis is a sterile synovitis, which occurs following an infection.

Spondyloarthritis develops in 1–2% of patients after an acute attack of dysentery, or after a sexually acquired infection – non-specific urethritis (NSU) in the male, non-specific cervicitis in the female. In males, positivity for HLA-B27 increases the risk of developing reactive arthritis after such an infection by 30–50-fold but not all patients are HLA-B27-positive. Women are less commonly affected.

### Aetiology

A variety of organisms can be the trigger, including strains of *Salmonella* or *Shigella* spp. in bacillary dysentery. *Yersinia enterocolitica* causes diarrhoea and a reactive arthritis. In NSU, the organisms are *Chlamydia trachomatis* or *Ureaplasma urealyticum*.

People with reactive arthritis are not more susceptible to infection but appear to respond differently. Bacterial antigens or bacterial DNA have been found in the inflamed synovium of affected joints, suggesting that this persistent antigenic material is driving the inflammatory process. The methods by which HLA-B27 increases susceptibility to reactive arthritis include:

- T-cell receptor repertoire selection
- molecular mimicry causing autoimmunity against HLA-B27 and/or other self antigens
- mode of presentation of bacteria-derived peptides to T lymphocytes.

There are other organisms that also trigger reactive arthritis but have a different genetic basis; see post-streptococcal arthritis (pp. 703–704), gonococcal arthritis (pp. 690–691) and brucellosis (p. 691). In these conditions, the borderline between reactive arthritis and septic arthritis is more indistinct and they can cause both.

### Clinical features

The arthritis is typically an acute, asymmetrical, lower-limb arthritis, occurring a few days to a
couple of weeks after the infection. The arthritis may be the presenting complaint if the infection is mild or asymptomatic. Enthesitis is common, causing plantar fasciitis or Achilles tendon enthesitis (see p. 662), and dactylitis may also occur (Fig. 18.31). Seventy per cent of patients recover fully within 6 months but many have a relapse.

![Clinical features of reactive arthritis. MTP, metatarsophalangeal.](image)

In susceptible individuals with reactive arthritis, sacroiliitis and spondylitis may also develop. Sterile conjunctivitis occurs in 30%. Acute anterior uveitis complicates more severe or relapsing disease but is not synchronous with the arthritis.

The skin lesions resemble psoriasis:

- **Circinate balanitis** in the uncircumcised male causes painless superficial ulceration of the glans penis. In the circumcised male, the lesion is raised, red and scaly. Both heal without scarring.
- **Keratoderma blennorrhagica** involves the skin of the feet and hands, which develops painless, red and often confluent raised plaques and pustules that are histologically similar to pustular psoriasis.
- **Nail dystrophy** occurs.

### Management

Treating persisting infection with antibiotics alters the course of the arthritis, once it has developed. Cultures should be taken and any infection treated. Sexual partners must be
Pain responds well to NSAIDs and locally injected or oral corticosteroids. The majority of individuals with reactive arthritis have a single attack that settles, but a few develop a disabling relapsing and remitting arthritis. Relapsing cases are sometimes treated with sulfasalazine or methotrexate (see Box 18.30). TNF-α-blocking agents remain the drugs of next choice in severe and persistent disease but are rarely necessary.

**Enteropathic arthritis associated with inflammatory bowel disease**

Enteropathic synovitis occurs in up to 10–15% of patients who have ulcerative colitis or Crohn's disease (see pp. 408–411). The link between the bowel disease and the inflammatory arthritis is not clear. Selective mucosal leakiness may expose the individual to antigens that trigger synovitis.

The arthritis is asymmetrical and predominantly affects lower-limb joints. An HLA-B27-associated sacroiliitis or spondylitis also occurs. The joint symptoms may predate the development of bowel disease and lead to its diagnosis.

Remission of ulcerative colitis or total colectomy usually leads to remission of the joint disease, but arthritis can persist even in well-controlled Crohn's disease.

**Management**

The inflammatory bowel disease should be treated (see pp. 409–411). In all cases of enteropathic arthritis, the symptoms are helped by NSAIDs, although they may make diarrhoea worse. A monoarthritis is best treated by intra-articular corticosteroids. Sulfasalazine is more frequently prescribed than mesalazine, as it may help both bowel and joint disease. The TNF-α-blocking drugs infliximab, adalimumab and certolizumab are used in inflammatory bowel disease and can help the arthritis.

**Crystal arthritis**

**Aetiology**

The two main types of crystal-induced arthritis are caused by sodium urate and calcium pyrophosphate crystals, which are distinguished by their different shapes and refringence properties under polarized light with a red filter (Fig. 18.32). Rarely, crystals of calcium apatite (see p. 670) or cholesterol cause acute synovitis.
Gout and hyperuricaemia

Gout is an inflammatory arthritis associated with hyperuricaemia and intra-articular sodium urate crystals.

Epidemiology

The prevalence of gout has increased substantially in the last two decades to 2.5% in the UK and 3.9% in the USA. Asian populations are also increasingly at risk as their diet becomes more Western. This rising prevalence is due to changing diets with purine-rich foods, high saturated fats and fructose-containing drinks; alcohol misuse; increasing co-morbidities that promote hyperuricaemia; and suboptimal management. Gout is more common in men than women (5:1); it rarely occurs before young adulthood (when it suggests a specific genetic defect), and seldom in pre-menopausal females. Some 85–90% of cases are idiopathic. Hyperuricaemia is common in certain ethnic groups (e.g. Maoris).

The last two steps of purine metabolism in humans are the conversion of hypoxanthine to xanthine, and of xanthine to uric acid, catalysed by the enzyme xanthine oxidase. Primates lost the gene for uricase, which degrades uric acid, during evolution 10–20 million years ago, so hyperuricaemia possibly offered an evolutionary advantage.

Serum uric acid (SUA) levels are higher in men than in women. Hyperuricaemia is defined as a serum uric acid level greater than two standard deviations from the mean, of 420 µmol/L in males and 360 µmol/L in females. The limit of solubility when crystal formation may occur is 360 µmol/L at 35°C and 300 µmol/L at 30°C. Hyperuricaemia is mostly asymptomatic, although OA joints are more prone to attacks of gout. The range of SUA for individuals with gout is higher than in healthy controls. SUA levels increase with age, obesity, a ‘Western’ diet (see above) and combined hyperlipidaemia, diabetes mellitus, ischaemic heart disease and
hypertension (metabolic syndrome; see p. 209). Gout is often familial.

### Pathogenesis of hyperuricaemia and gout

Uric acid is the final product of endogenous and dietary purine metabolism in humans, and SUA depends on the balance between purine synthesis, ingestion of dietary purines and the elimination of urate by the kidney (66%) and intestine (33%).

Some 90% of people with gout have impaired excretion of uric acid (10% have increased production due to high cell turnover and <1% due to an inborn error of metabolism). Renal excretion is coordinated by a group of renal tubular urate transport molecules and a complex process of glomerular filtration, proximal tubule reabsorption via the urate transporter-1 (URAT1) and active re-secretion (Fig. 18.33). GLUT9 (a product of the SLC2A9 gene) transports uric acid, along with glucose and fructose, into the cell from the tubule and back into the circulation. Genetic variations in both URAT1 and SLC2A9 have been linked to the development of hyperuricaemia in humans. Both the entry of uric acid via the URAT1 mechanism and the exit into circulation by SLC2A9 can be blocked by uricosuric drugs, such as probenecid. The body pool is about 1000 mg and 60% is turned over daily. Low-dose aspirin blocks uric acid secretion. Insulin resistance enhances uric acid resorption. Causes of hyperuricaemia are shown in Box 18.35.

![Urate renal transport.](image)

**FIGURE 18.33** Urate renal transport. The net result is that about 5–10% of the glomerular load is excreted in the urine under normal circumstances.

### Box 18.35

**Causes of hyperuricaemia**

**Impaired excretion of uric acid**

- Chronic renal disease (clinical gout unusual)
- Drug therapy, e.g. thiazide diuretics, low-dose aspirin
- Hypertension
• Lead toxicity
• Primary hyperparathyroidism or hypothyroidism
• Increased lactic acid production from alcohol, exercise, starvation
• Glucose-6-phosphatase deficiency (interferes with renal excretion)

**Increased production of uric acid**

**Increased purine synthesis de novo due to:**
• Hypoxanthine–guanine–phosphoribosyl transferase (HGPRT) reduction (an X-linked inborn error causing the Lesch–Nyhan syndrome)
• Phosphoribosyl-pyrophosphate synthase overactivity
• Glucose-6-phosphatase deficiency with glycogen storage disease type 1

**Increased turnover of purines due to:**
• Myeloproliferative disorders, e.g. polycythaemia vera
• Lymphoproliferative disorders, e.g. leukaemia
• Others, e.g. carcinoma, severe psoriasis

**Gout as an autoinflammatory disease**

The involvement of the innate immune system and inflammasomes indicates that gout is an autoinflammatory disease, similar to the hereditary periodic fevers (see pp. 705–706). A series of receptors recognize bacteria and viruses as ‘foreign’ and eliminate them by activating the cytokine cascade. One such receptor (NLRP3) has been implicated in crystal-triggered inflammation. Activation of the inflammasome (see p. 126) activates IL-1β, leading to cellular activation, which triggers an IL-8-mediated influx of neutrophils. Ingestion by polymorphonuclear leucocytes of sodium urate crystals causes the release of pro-inflammatory cytokines, particularly IL-1β and complement. Colchicine inhibits the microtubule formation that is necessary for this process to occur.

**Clinical features**

Hyperuricaemia may be asymptomatic or may cause:
• **Acute gout**, followed by an asymptomatic intercritical phase; a second acute attack is likely within 2 years.
• **Chronic interval gout**, with acute attacks superimposed on low-grade inflammation and potential joint damage.
• **Chronic polyarticular gout**, which is rare, except in elderly people on longstanding diuretic treatment, in renal failure, or when allopurinol is started too soon after an acute attack.
• **Tophaceous gout**.
• **Urate renal stone** formation (see pp. 754–757).
Acute gout presents typically in a middle-aged male with a sudden onset of agonizing pain, swelling and redness of the first MTP joint. The attack may be precipitated by excess food, alcohol, dehydration or diuretic therapy. Untreated attacks last about 7 days. Recovery is typically associated with desquamation of the overlying skin. In 25% of attacks, a joint other than the great toe is affected.

In severe attacks, overlying crystal cellulitis makes gout difficult to distinguish clinically from infective cellulitis. A family or personal history of gout and the finding of a raised SUA suggest the diagnosis but, if in doubt, blood and joint fluid cultures should be taken to exclude sepsis.

Chronic tophaceous gout is described below.

### Investigations

The clinical picture is often diagnostic, as is the rapid response to NSAIDs or colchicine.

- **Joint fluid microscopy** is the most specific and diagnostic test but is technically difficult.
- **Serum uric acid** is usually raised (>600 µmol/L). If it is not, it should be rechecked several weeks after the attack, as levels fall immediately after an acute episode. Acute gout rarely occurs with a serum uric acid in the lower half of the normal range below the saturation point of 360 µmol/L.
- **Serum urea, creatinine** and estimated glomerular filtration rate (eGFR) are monitored for signs of renal impairment.

### Management

The use of NSAIDs or coxibs in high doses rapidly reduces the pain and swelling. The first dose should be taken at the first indication of an attack:

- **naproxen**: 750 mg immediately, then 500 mg every 8–12 h
- **diclofenac**: 75–100 mg immediately, then 50 mg every 6–8 h

After 24–48 hours, reduced doses are given for a further week. Caution: NSAIDs may cause renal impairment. In individuals with renal impairment or a history of peptic ulceration, alternative treatments include:

- **Colchicine**: loading doses will cause diarrhoea or colicky abdominal pain, so 500 µg 2–3 times per day is usually sufficient to terminate attacks without side-effects.
- **Corticosteroids**: oral prednisolone or intramuscular or intra-articular depot methylprednisolone is used.

### Dietary advice

The first attacks may be separated by up to 2 years and are managed symptomatically. Recognition and prompt treatment, including lifestyle modifications, are paramount. Advice to reduce alcohol intake, especially beer, which is high in purines and fructose, and consumption
of non-diet carbonated soft drinks, which are also high in fructose, is essential; other dietary change include reduction of total calorie and cholesterol intake, and avoidance of purine-rich foods, such as offal, red meat, shellfish and spinach. These modifications can reduce serum urate by 15% and delay the need for drugs that reduce serum urate levels. Dietary advice is readily available on the Internet.

**Treatment with agents that reduce serum uric acid levels**

The aim of treatment is to reduce the uric acid level below the 360 µmol/L level; some guidelines recommend a level below 300 µmol/L.

**Allopurinol**

Allopurinol should only be used when the attacks are frequent and severe (despite dietary changes), or associated with renal impairment or tophi, or when the patient finds NSAIDs or colchicine difficult to tolerate. Allopurinol is a xanthine oxidase inhibitor, which reduces serum uric acid levels rapidly; it is relatively non-toxic but should be used at low doses (50–100 mg) in renal impairment. It should never be started within a month of an acute attack and always under cover of NSAIDs or colchicine for the first 2–4 weeks before and 4 weeks after starting allopurinol, as it may induce acute gout. The dose can be increased gradually from 100 mg every few weeks until the uric acid level is below the 360 µmol/L level. Skin rashes and gastrointestinal intolerance are the most common side-effects. A hypersensitivity reaction is the most serious but rare adverse event, as is bone marrow suppression.

**Febuxostat**

Febuxostat (80–120 mg) is a non-purine analogue inhibitor of xanthine oxidase that is well tolerated and as effective as allopurinol. It is safer in renal impairment, as it undergoes hepatic metabolism rather than renal excretion, and is helpful in patients who cannot tolerate allopurinol; however, there is evidence that it may increase cardiovascular risks, and this is being monitored in ongoing observational studies. Allopurinol remains the drug of first choice, unless there are strong contraindications to its use.

**Pegloticase**

Pegloticase, a pegylated recombinant uricase given intravenously, lowers urate levels dramatically but its place in therapy is unclear.

**Uricosuric agents**

These also lower the serum uric acid but their use is restricted throughout Europe by the very rare occurrence of serious hepatotoxicity. *Benzbromarone* acts on the URAT1 transporter and is well tolerated. *Sulfinpyrazone* and *probenecid* are best avoided in renal impairment. Availability of these drugs varies between countries – in the UK, benzbromarone and probenecid can be obtained for treating named patients.
Losartan
Losartan is an angiotensin I receptor antagonist and is uricosuric in hypertensive patients with gout. It may reduce the risk of gout in patients with the metabolic syndrome.

Anakinra and canakinumab
Anakinra blocks IL-1β and canakinumab is a human monoclonal antibody with specific cross-reactivity for IL-1β but not for other members of the IL-1 family. Their cost-effectiveness in managing gout resistant to conventional agents is still subject to trials. Increased knowledge of the mechanisms of urate transport and the inflammatory response it induces is likely to provide new therapeutic targets in the future.

Chronic tophaceous gout
Individuals with persistently high levels of uric acid can present with chronic tophaceous gout, as sodium urate forms smooth white deposits (tophi) in skin and around joints, on the ear, fingers (Fig. 18.34) or the Achilles tendon. Large deposits are unsightly and ulcerate. There is chronic joint pain and sometimes superimposed acute gouty attacks.

Periarticular deposits lead to a halo of radio-opacity and clearly defined (‘punched out’) bone cysts on X-ray.

Tophaceous gout is often associated with renal impairment and/or the long-term use of diuretics. There may be acute or chronic urate nephropathy or renal stone formation. Whenever possible, diuretics should be stopped or changed to less urate-retaining ones, such as bumetanide. Treat with allopurinol and/or uricosuric agents (see above). Pegloticase is used preventatively in people undergoing chemotherapy for malignancies (tumour lysis syndrome), and in those rare individuals who have refractory tophaceous gout.

Calcium pyrophosphate dihydrate deposition arthropathy (DPPD)
There has been a complex evolution of descriptive terminology for this condition over time and previous terms, including pseudogout, have been unified into calcium pyrophosphate
dihydrate deposition (CPPD) arthropathy. This condition occurs in hyaline and fibrocartilage, and is the most common cause of cartilage calcification. CPPD-associated arthritis is the third most common inflammatory arthritis, which increases with age, OA, joint trauma/injury and metabolic disease (hyperparathyroidism, haemochromatosis, hypomagnesaemia), and has a familial predisposition. Shedding of crystals into a joint precipitates acute synovitis that resembles gout, except that it is more common in elderly women and usually affects the knee or wrist.

**Diagnosis**

The diagnosis is made by detecting rhomboidal, weakly positively bi-refringent crystals in joint fluid (see Fig. 18.32), or deduced from the presence of cartilage calcification on X-ray. Joint fluid looks purulent so should be sent for culture to exclude septic arthritis, as the attacks may also be associated with fever and a raised white blood cell count.

**Management**

Unlike in gout, there is no specific treatment to eliminate calcium pyrophosphate crystals. Therefore, management is focused on symptom control and treatments overlap with those for gout and OA. An evidence base is lacking in this condition, however, and there have been no randomized controlled clinical trials of acute management. Aspiration of the joint reduces the pain dramatically but it is usually necessary to use an NSAID or colchicine, as for gout. If infection can be excluded, an intra-articular injection of a corticosteroid helps. Studies of blockade of the NLRP3 inflammasome-IL-1 pathway (see p. 688) are under way.

**Basic calcium phosphate deposition disease**

Basic calcium phosphate (BCP) crystals, including hydroxyapatite, tricalcium phosphate and octacalcium phosphate, can be deposited in any tissues, particularly at intra-articular and periarticular locations. Crystal formation is thought to be partly regulated by the effects of extracellular inorganic phosphate on chondrocytes and is linked with the development of OA. BCP crystals cause joint damage through induction of fibroblast proliferation, inflammatory cytokines (IL-1β and TNF-α), nitric oxide and metalloproteinases.

BCP crystal deposits in periarticular soft tissue may be asymptomatic or can cause acute calcific periarthritus (particularly in the supraspinatus tendon), tendonitis, bursitis and enthesitis. Less frequently, they can cause arthritis. In acute attacks, periarticular tissues or joints can be swollen, tender and hot. This presentation may mimic cellulitis, gout, CPPD disease and septic arthritis. Periarticular or articular BCP crystal deposits are also found in an extremely destructive chronic arthropathy of the elderly that occurs most often in shoulders (Milwaukee shoulder) or other large joints, such as the hips and knees, and in erosive OA of the fingers.
**Diagnosis**

The diagnosis is made clinically and septic arthritis should be excluded. A neutrophilia with elevation of ESR and CRP may occur during an acute attack. Intra- and/or periarticular calcifications, with or without erosive, destructive or hypertrophic changes, may be seen on X-ray. Alizarin red S staining is not specific for BCP crystals in synovial fluid and other calcium-containing particulates are also stained by this method.

**Management**

Management of acute attacks is similar to that of CPPD disease with NSAIDs, oral colchicine, aspiration of effusions and/or intra-/periarticular injection of steroids to try to shorten the duration of symptoms. In patients with underlying progressive articular changes, the response to medical therapy is usually less rewarding. Total joint replacement may be required for patients with severe destructive arthropathy in large joints.

**Further reading**

**Infections of Joints**

Joints become infected by direct injury or by blood-borne infection from an infected skin lesion or other site. The incidence of definite and probable septic arthritis in Western Europe is 4–10 per 100,000 patient-years per year. The rising global incidence of this condition has been linked with an ageing population, increased immunosuppressive use, musculoskeletal prostheses and surgical procedures. It is a medical emergency that requires prompt treatment to prevent irreversible joint destruction and has a significant mortality of up to 11%, reaching
50% in polyarticular sepsis.

Chronically inflamed joints (e.g. in RA) are more prone to infection than are normal joints. Individuals who are immunosuppressed, by AIDS or by immunosuppressive agents, are particularly at risk, as are infants, the elderly and those who use excess alcohol. Artificial joints are also potential sites for infection.

**Septic arthritis**

The organism that most commonly causes septic arthritis is *Staphylococcus aureus*. Other organisms include streptococci, other species of staphylococcus, *Neisseria gonorrhoeae*, *Haemophilus influenzae* in children, and these and other Gram-negative organisms in the elderly or complicating RA.

---

**Clinical features**

Suspected septic arthritis is a medical emergency. In young and previously fit people, the joint is hot, red, swollen and agonizingly painful; it is held immobile by muscle spasm. In contrast, the onset may be insidious with a lack of systemic symptoms; in the elderly, immunosuppressed and patients with RA, a high index of suspicion is needed.

In 20% of patients, the sepsis affects more than one joint. Chronic destructive arthritis due to tuberculosis is rare.

---

**Investigations**

- **Aspirate** the joint and send the fluid for urgent Gram-staining and culture. The fluid is usually frankly purulent. The culture techniques should include those for gonococci and anaerobes.
- **Blood cultures** are often positive.
- **Leucocytosis** is usual, unless the person is severely immunosuppressed.
- **X-rays** are of no value in diagnosis in acute septic arthritis.
- **Skin wound swabs, sputum and throat swab or urine** may be positive and indicate the source of infection.

---

**Management**

There are no RCTs to guide management in adults. The prognosis is similar for patients with a proven microbiological diagnosis to those with a suspected but not proven diagnosis; therefore it is vital to treat on the basis of clinical suspicion, probability (with subsequent confirmed identity) of organism, local pattern of antibiotic sensitivity and microbiological advice.

Therapy should be started immediately before culture results are available because joint destruction may occur within weeks.

- The joint should be immobilized initially, followed by early physiotherapy to prevent
stiffness and muscle wasting.

• Intravenous antibiotics should be given for 1–2 weeks. It is usual to give two antibiotics to which the organism is sensitive for 6 weeks, then one for a further 6 weeks, orally. Response is monitored clinically and with ESR and CRP.

Empirical treatment in septic arthritis

Empirical regimens include intravenous flucloxacillin 2 g given 6-hourly, plus sodium fusidate 500 mg orally 8-hourly. If the patient is allergic to penicillin, replace flucloxacillin with erythromycin 1 g i.v. 6-hourly or clindamycin 600 mg i.v. 8-hourly. In immunosuppressed patients, flucloxacillin 1–2 g i.v. 6-hourly plus gentamicin (to cover Gram-negative organisms) should be used. Teicoplanin i.v. should replace flucloxacillin if meticillin-resistant Staphylococcus aureus (MRSA) is likely. Change the antibiotics if the organism is not sensitive. Drainage of the joint and arthroscopic joint washouts are helpful in relieving pain.
Management of infected prostheses

If chronically infected, the prosthesis is removed and the joint space filled with an antibiotic-impregnated spacer for 3–6 weeks before a new prosthesis is inserted. The whole process is covered by antibiotics, such as teicoplanin i.v. and oral sodium fusidate.

Specific types of bacterial arthritis

Gonococcal arthritis

This is the most common cause of a septic arthritis in previously fit young adults, more commonly affecting women, and men who have sex with men.

Patients present with a fever and characteristic pustules on the distal limbs, often in association with polyarthralgia and tenosynovitis, when about 40% have a gonococcaemia. This phase settles and blood cultures usually become negative. Nucleic acid amplification tests may be positive even when cultures are negative. Later, large-joint mono- or pauciarticular arthritis may follow. Culture is usually positive from the genital tract, although the joint fluid may be sterile. It is not clear whether this joint inflammation is simply a septic arthritis (which responds rapidly to antibiotics), or whether there is also a reactive element to bacterial lipopolysaccharide.

Management consists of oral penicillin, ciprofloxacin or doxycycline for 2 weeks, and joint rest. Resistance to antibiotics is increasing (see pp. 234–235).

Tuberculous arthritis

Around 1% of people with tuberculosis develop joint and/or bone involvement. It occurs as the primary disease in children. In adults, it is usually due to haematogenous spread from secondary pulmonary or renal lesions. The onset is insidious and diagnosis often delayed.

The organism invades the synovium or intervertebral disc. There are caseating granulomas and rapid destruction of cartilage and adjacent bone. Some patients develop a reactive polyarthritis (Poncet's disease).

The hip or knee (30%) is quite commonly affected but around 50% develop spinal disease. Patients become febrile with night sweats, anorexia and weight loss. The usual risk factors for tuberculosis apply – debility, excess alcohol use or immunosuppression. HIV-positive/AIDS patients are at particular risk.

Investigations should include culture of fluid, and culture and biopsy of the synovium. Mycobacterium tuberculosis is the usual organism but atypical mycobacteria are occasionally implicated. A chest X-ray should be performed. Initially, joint or spinal X-rays may be normal but joint-space reduction and bone destruction develop rapidly if treatment is delayed. MRI shows the abnormality earlier in the spine and CT-guided biopsy from the affected disc is often necessary to obtain cultures.
Management is as for pulmonary tuberculosis with therapy for 9 months. The joint should be rested and the spine immobilized in the acute phase.

**Meningococcal arthritis**

Joint inflammation may complicate meningococcal septicaemia, presenting as a migratory polyarthritis. Organisms are rarely cultured from the joint and most cases are due to immune complex deposition. Treatment is urgent with immediate penicillin therapy.

**Infective endocarditis**

This condition may present with arthralgia, polymyalgia rheumatica-like symptoms or an infective arthritis. It is discussed on pages 1017–1021.

**Lyme arthritis**

About 25% of people with Lyme disease develop arthralgia, less commonly an acute pauciarticular arthritis (see p. 284); this usually resolves but 10% of untreated cases go on to develop a chronic arthritis. There are no positive markers in these patients of an ongoing infection (see p. 284).

**Diagnosis** is by the detection of IgM antibodies against the spirochaete *Borrelia burgdorferi*.

**Treatment** with antibiotics (amoxicillin or doxycycline) is highly effective in early disease. The response of chronic arthritis to antibiotic treatment is discussed below.

**Brucellosis**

Brucellosis (see p. 283) has a worldwide distribution. The most common cause of chronic brucellosis and of arthritis is *Brucella melitensis*. There is usually a migratory large joint mono- or oligoarticular arthritis, which is septic or reactive. Arthritis is more common in chronic infections of more than 6 months.

**Syphilitic arthritis**

Congenital syphilis (see p. 329) can cause an acute painful epiphysitis or osteochondritis sometimes associated with para-articular swelling in the first few weeks of life. Later, at age 8–16 years, painless effusion of the knees may occur (Clutton's joints).

In acquired syphilis, arthralgia and arthritis occur in the secondary stage. Charcot's (neuropathic) joints usually involve the knees in tabes dorsalis (see p. 866).

**Leprosy**
Acute or chronic symmetrical polyarthritis resembling RA, swollen hands and feet due to lepra reactions, tenosynovitis and thickened nerves with or without cutaneous manifestations are seen in leprosy (see pp. 285–286).

**Actinomycetes infection**

Actinomycetes can affect the mandible or vertebrae.

**Arthritis in viral disease**

A transient polyarthritis or arthralgia can occur before, during or after many viral illnesses. These include infectious mononucleosis, chickenpox, mumps, adenovirus, rubella, erythrovirus B19, hepatitis B and C, arboviral infections and HIV. In most of these, it is due to a direct toxic effect or immune complex deposition.

**Rubella**

In rubella (see p. 252), the virus can occasionally be isolated from the joint. This arthritis is rare in countries where rubella vaccination is routine. It occurs most commonly in up to 50% of young adult females a few days after rubella infection (6% of men). It is a symmetrical polyarthritis involving the MCP or PIP joints most commonly, but many joints can be affected. It closely resembles RA. IgM rubella antibodies are present. It resolves within a few weeks in most cases. A mild arthritis occurs rarely 2–4 weeks after rubella vaccination.

**Erythrovirus B19**

Erythrovirus B19 (see p. 252) causes an acute, self-limiting arthritis and is associated with erythema infectiosum (‘slapped cheek disease’).

**Hepatitis**

In hepatitis B infection (see pp. 454–457), a sudden, symmetrical polyarticular arthritis of the small joints of the hands occurs in approximately one-third of patients, often in the prodromal phase, and mostly resolves before the onset of jaundice. Hepatitis C infection causes type II mixed cryoglobulinaemia (see p. 748).

**Arbovirus**

Arbovirus infections (see p. 257), which are endemic in many parts of the world, give rise to an arthralgia and/or arthritis. For example, the Ross River virus causes an epidemic polyarthritis in Australia and the South Pacific; it involves the small joints of the hands and clears in 2–4 weeks. Other viral infections causing epidemic arthritis include chikungunya (see
Musculoskeletal aspects of infection with HIV and AIDS

Musculoskeletal manifestations are common in these patients and are often caused by triggers such as opportunistic infections and drug therapy rather than HIV itself. Infective arthritis seen in these immunosuppressed patients often has minimal symptoms and signs. Certain of the antiviral agents cause an acute arthritis, possibly because of crystallization in the joint.

Arthralgia is common in AIDS. There is a seronegative, predominantly lower-limb arthritis, similar to psoriasis or Reiter's disease. Spondylitis also occurs but is not associated with HLA-B27. Avascular necrosis, possibly associated with corticosteroids or alcohol, is seen.

Non-articular diseases, such as Sjögren- and lupus-like syndromes, systemic vasculitis of the necrotizing and hypersensitivity types and myositis, also occur.

Fungal infections

Fungal infections of joints occur rarely. Bone abscesses may be seen. Destructive joint lesions can also occur with blastomycosis. A benign polyarthritis accompanied by erythema nodosum occasionally occurs in coccidioidomycosis and histoplasmosis. Culture of purulent synovial fluid and skin tests for fungi may help the diagnosis.

Autoimmune Rheumatic Diseases

Autoimmunity and autoantibodies

Autoimmune diseases are conditions in which the immune system attacks tissues of the body. The antigens can be present in multiple organs so the clinical manifestations are systemic and diverse. In some diseases, such as Graves' disease, Hashimoto's thyroiditis and type 1 diabetes mellitus, only a single organ is affected. Each individual autoimmune rheumatic disease (ARD) has a characteristic pattern of symptoms and signs, which are used to make the diagnosis. In some ARDs, there are also characteristic autoantibodies (i.e. antibodies that recognize antigens that are normal constituents of the body, such as DNA and phospholipids). Positive blood tests for autoantibodies are useful but not essential in the diagnosis of ARDs (see Box 18.4).

Systemic lupus erythematosus
Systemic lupus erythematosus (SLE) is an inflammatory, multisystem autoimmune disorder with arthralgia and rashes as the most common clinical features, and cerebral and renal disease as the most serious problems.

**Epidemiology**

SLE occurs worldwide and is about nine times as common in women as in men, with a peak age of onset between 20 and 40 years. The prevalence varies between ethnic groups, being highest (at 1 : 250) in African/Caribbean women. In other populations, the prevalence varies between 1 : 1000 and 1 : 10 000.

**Aetiology**

The cause is unknown but there are several predisposing factors:

- **Hereditity.** There is a higher concordance rate in monozygotic twins (up to 25%) compared with dizygotic twins (3%). First-degree relatives have a 3% chance of developing the disease but approximately 20% have autoantibodies.

- **Genetics.** Three whole-genome analyses have led to the identification of approximately 20 genes linked to the development of SLE. These include some HLA genes, as well as genes involved in T- and B-lymphocyte function. Homozygous deficiencies of the complement genes C1q, C2 or C4 are very rare but convey a high risk of developing SLE.

- **Sex hormone status.** Pre-menopausal women are most frequently affected.

- **Drugs.** Drugs such as hydralazine, isoniazid, procainamide and penicillamine can induce a form of SLE that is usually mild, in that the kidneys and central nervous system are not affected.

- **Ultraviolet light.** This can trigger flares of SLE, especially in the skin.

- **Exposure to Epstein–Barr virus.** This has been suggested as a trigger for SLE.

**Pathogenesis**

When cells die by apoptosis, the cellular remnants appear on the cell surface as small blebs that carry self antigens. These antigens include nuclear constituents (e.g. DNA and histones), which are normally hidden from the immune system. In people with SLE, removal of these blebs by phagocytes is inefficient, so that they are transferred to lymphoid tissues, where they can be taken up by antigen-presenting cells. The self antigens from these blebs can then be presented to T cells, which in turn stimulate B cells to produce autoantibodies directed against these antigens (see pp. 144–146). It has been shown that, in some patients, the autoantibodies are present in stored blood samples that were taken years before the patient developed clinical features of SLE. The combination of availability of self antigens and failure of the immune system to inactivate B cells and T cells that recognize these self antigens (i.e. a breakdown of tolerance; see pp. 144–146) leads to the following immunological consequences.
• Development of autoantibodies that either form circulating complexes or deposit by binding directly to tissues.
• Activation of complement and influx of neutrophils, causing inflammation in those tissues.
• Abnormal cytokine production: increased blood levels of IL-10 and interferon-alpha are particularly closely linked to high activity of inflammation in SLE. However, no form of anticytokine biological therapy has yet been adopted routinely in the treatment of SLE.

More recently, other cells have been implicated in the pathogenesis of SLE. These include dendritic cells, which are activated by immune complexes containing nucleic acids to produce interferon, and invariant natural killer T cells (iNKT cells), which are reduced in number and function in patients with SLE.

Pathology
SLE of the skin and kidneys is characterized by deposition of complement and IgG antibodies, and by influx of neutrophils and lymphocytes. Biopsies of other tissues are carried out less frequently but can show vasculitis affecting capillaries, arterioles and venules. The synovium of joints can be oedematous and may contain immune complexes. Haematoxylin bodies (rounded, blue, homogeneous haematoxylin-stained deposits) are seen in inflammatory infiltrates and are thought to result from the interaction of antinuclear antibodies and cell nuclei.

The pathology of lesions in other organs is described in the appropriate chapters.

Clinical features
The manifestations of SLE vary greatly between patients. Most patients suffer fatigue, arthralgia and/or skin problems. Involvement of major organs is less common but more serious (*Fig. 18.35*).
General features
Fever is common in exacerbations. Patients complain of marked malaise and tiredness, and these symptoms do not correlate with disease activity or severity of organ-based complications.

The joints and muscles
Joint involvement is the most common clinical feature (>90%). Patients often present with symptoms resembling RA with symmetrical small joint arthralgia. Joints are painful but characteristically appear clinically normal, although sometimes there is slight soft tissue swelling surrounding the joint. Deformity because of joint capsule and tendon contraction is rare, as are bony erosions. Rarely, major joint deformity resembling RA (known as Jaccoud's arthropathy) is seen. Avascular necrosis affecting the hip or knee is a rare complication of the disease or of treatment with corticosteroids.

Myalgia is present in up to 50% of patients but a true myositis is seen in only <5%. If myositis is prominent, the patient may well have an overlap ARD with both polymyositis and SLE.
The skin

The skin (see p. 1367) is affected in 85% of cases. Erythema, in a ‘butterfly’ distribution on the cheeks of the face and across the bridge of the nose (see Fig. 31.33), is characteristic. Vasculitic lesions on the fingertips and around the nail folds, purpura and urticaria occur. In 40–50% of cases, there is photosensitivity (especially in patients positive for anti-Ro antibodies). Prolonged exposure to sunlight can lead to exacerbations of the disease. Livedo reticularis, palmar and plantar rashes, pigmentation and alopecia are seen. Scarring alopecia can lead to irreversible bald patches, which are especially upsetting for women, who form the majority of people with SLE. Raynaud's phenomenon (see p. 1054) is common and may precede the development of other clinical problems by years.

Discoid lupus is a benign variant of lupus in which only the skin is involved. The rash is characteristic and appears on the face as well-defined erythematous plaques that progress to scarring and pigmentation (see p. 1366). Subacute cutaneous lupus erythematosus, a rare variant, is described on page 1367.

The lungs

Up to 50% of patients will have lung involvement at some time during the course of the disease (see p. 1122). Recurrent pleurisy and pleural effusions (exudates) are the most common manifestations and are often bilateral. Pneumonitis and atelectasis are seen; eventually, a restrictive lung defect develops, with loss of lung volumes and raised hemidiaphragms. This ‘shrinking lung syndrome’ is poorly understood but may have a neuromuscular basis. Rarely, pulmonary fibrosis occurs, more commonly in overlap syndromes (see p. 699). Intrapulmonary haemorrhage associated with vasculitis is a rare but potentially life-threatening complication.

The heart and cardiovascular system

The heart is involved in 25% of cases. Pericarditis, with small pericardial effusions detected by echocardiography, is common. A mild myocarditis also occurs, giving rise to arrhythmias. Aortic valve lesions and a cardiomyopathy can rarely be present. A non-infective endocarditis involving the mitral valve (Libman–Sacks syndrome) is very rare. Raynaud's, vasculitis, and arterial and venous thromboses can occur, especially in association with the antiphospholipid syndrome (see below). There is an increased frequency of ischaemic heart disease and stroke in people with SLE, which is partly due to altered levels of common risk factors such as hypertension and lipid levels, but the presence of chronic inflammation over many years may also be contributory. It is not known whether intensive treatment of cardiovascular risk factors in SLE will alter the risk of developing coronary disease or stroke. The benefit of statin therapy in the absence of significant hypercholesterolaemia remains to be proved.

The kidneys

A classification of types of nephritis is given on pages 733–734. Postmortem studies suggest that histological changes are very frequent, but clinical renal involvement occurs in only approximately 30% of cases. All patients should have regular screening of urine for blood and
protein. An asymptomatic patient with proteinuria may be in the early stages of lupus nephritis, and treatment may prevent progression to renal impairment. Proteinuria should be quantified and haematuria should prompt examination for urinary casts or fragmented red cells that suggest glomerulonephritis. Renal biopsy is important to define the type and severity of nephritis. Renal vein thrombosis can occur in nephrotic syndrome or in association with antiphospholipid antibodies.

The nervous system
Involvement of the nervous system occurs in up to 60% of cases and symptoms often fluctuate. There may be a mild depression, but occasionally, more severe psychiatric disturbances occur. Epilepsy, migraines, cerebellar ataxia, aseptic meningitis, cranial nerve lesions, cerebrovascular disease or a polyneuropathy may be seen. The pathogenic mechanism for cerebral lupus is complex. Lesions may be due to vasculitis or immune-complex deposition, thrombosis or non-inflammatory microvasculopathy. In people with cerebral lupus, infection should be excluded, or treated in parallel with administration of corticosteroids and immunosuppression.

The eyes
Retinal vasculitis can cause infarcts (cytoid bodies), which appear as hard exudates, and haemorrhages. There may be episcleritis, conjunctivitis or optic neuritis, but blindness is uncommon. Secondary Sjögren syndrome is seen in about 15% of cases.

The gastrointestinal system
Mouth ulcers are common and may be a presenting feature. These may be painless or become secondarily infected and painful. Mesenteric vasculitis can produce inflammatory lesions involving the small bowel (infarction or perforation). Liver involvement and pancreatitis are uncommon.

Investigations

Blood

- **A full blood count** may show a leucopenia, lymphopenia and/or thrombocytopenia. Anaemia of chronic disease or autoimmune haemyolytic anaemia also occurs. The ESR is raised in proportion to the disease activity. In contrast, the CRP is usually normal but may be high when the patient has lupus pleuritis, arthritis or a coexistent infection.

- **Urea and creatinine** only rise when renal disease is advanced. Low serum albumin or high urine albumin/creatinine ratio are earlier indicators of lupus nephritis.

- **Autoantibodies** of many different types may be present in SLE but the most significant are ANA, anti-dsDNA, anti-Ro, anti-Sm and anti-La (Box 18.36). Antiphospholipid antibodies are present in 25–40% of cases but not all of these patients develop antiphospholipid
syndrome (see below).

**Box 18.36**

**Antinuclear autoantibodies and disease associations**

• **Serum complement** C3 and C4 levels are often reduced during active disease. The combination of high ESR, high anti-dsDNA and low C3 may herald a flare of disease. All these markers tend to return towards normal as the flare improves, but in some patients, anti-dsDNA levels remain high even during clinical remission.

**Histology**

• Characteristic histological and immunofluorescent abnormalities (deposition of IgG and complement) are seen in biopsies from the kidney and skin.

**Diagnostic imaging**

• CT scans of the brain sometimes show infarcts or haemorrhage with evidence of cerebral atrophy. MRI can detect lesions in white matter that are not seen on CT. However, it can be very difficult to distinguish true vasculitis from small thrombi.

**Management**
General measures
The disease and its management should be discussed with the patient, particularly the effect upon the patient's lifestyle: for example, appearance and debility due to fatigue. Patients are advised to avoid excessive exposure to sunlight and it is also necessary to reduce cardiovascular risk factors.

Symptomatic treatment
Many patients do not need treatment with corticosteroid tablets or immunosuppressive agents. Arthralgia, arthritis, fever and serositis all respond well to standard doses of NSAIDs (see pp. 665–666). Topical corticosteroids are effective and widely used in cutaneous lupus. Antimalarial drugs (chloroquine or hydroxychloroquine) help mild skin disease, fatigue and arthralgias that cannot be controlled with NSAIDs but patients require regular eye checks because of rare retinal toxicity (1 in 2000).

Corticosteroids and immunosuppressive drugs
Single intramuscular injections of long-acting corticosteroids or short courses of oral corticosteroids are useful in treating severe flares of arthritis, pleuritis or pericarditis. In some cases, these symptoms can only be kept under control using long-term oral corticosteroids.

Renal or cerebral disease and severe haemolytic anaemia or thrombocytopenia must be treated with high-dose oral corticosteroids, and the first two of these require immunosuppressive drugs in addition. Cyclophosphamide was most commonly used to achieve remission in these severe forms of lupus but is being replaced by mycophenolate mofetil, which has fewer side-effects. Azathioprine is also used to maintain remission. Newer agents, which specifically target cells or cytokines in the immune system, are coming into use, especially in refractory cases. These include rituximab (anti-CD20) and belimumab, which are both monoclonal antibodies acting against B lymphocytes.

Prognosis
An episodic course is characteristic, with exacerbations and complete remissions that may last for long periods. However, SLE can also be a chronic persistent condition. The mortality rate in SLE has fallen dramatically over the last 50 years; the 10-year survival rate is about 90%, but this is lower if major organ-based complications are present. Deaths early in the course of disease are mainly due to renal or cerebral disease or infection. Later, coronary artery disease and stroke become more prevalent. Chronic progressive destruction of joints, as seen in RA and OA, occurs rarely, but a few patients develop deformities such as ulnar deviation. People with SLE have an increased long-term risk of developing some cancers, especially lymphoma.

Pregnancy and SLE
Fertility is usually normal, except in severe disease, and there is no major contraindication to pregnancy. Recurrent miscarriages can occur, especially in women with antiphospholipid
antibodies. Exacerbations can arise during pregnancy and are frequent postpartum. The patient's medications should be reviewed. Mycophenolate should be stopped, whereas azathioprine, hydroxychloroquine and low-dose oral corticosteroids are safe. Hypertension must be controlled. People with anti-Ro or anti-La antibodies have a 2% risk of giving birth to babies with neonatal lupus syndrome (rash, hepatitis and fetal heart block).

**Antiphospholipid syndrome**

Patients who have thrombosis (arterial or venous) and/or recurrent miscarriages (see p. 1299), and who also have persistently positive blood tests for antiphospholipid antibodies (aPL), have the antiphospholipid syndrome (APS). Antiphospholipid antibodies can be detected by several different tests:

- The **anticardiolipin test**, which detects antibodies (IgG or IgM) that bind the negatively charged phospholipid, cardiolipin.
- The **lupus anticoagulant test**, which detects changes in the ability of blood to clot in a test tube. Despite the name, it is not a test for lupus. It is a test for APS. The anticoagulant effect caused by aPL in the test tube causes an opposite procoagulant effect inside the body because the balance of factors stimulating thrombosis is different there.
- The **anti-β₂-glycoprotein I test**, which detects antibodies that bind β₂-glycoprotein I, a molecule that interacts closely with phospholipids.

A persistently positive test (i.e. positive on at least two occasions ≤12 weeks apart) in one or more of these assays is needed to diagnose APS. However, some people who test positive for aPL will never develop APS: that is, not all aPLs are harmful. APS can present in patients who already have another ARD, especially SLE. APS can also occur on its own (primary APS).

New diagnostic tests for APS are being developed and include anti-prothrombin assays, tests for IgA aPL and tests for antibodies to the N-terminal domain of β₂-glycoprotein I. Although not currently used in clinical practice, these tests may soon be helpful for assessing the overall thrombosis risk of a patient with APS, or for diagnosing patients with ‘seronegative’ APS who have typical clinical features but test negative for anti-cardiolipin, lupus anticoagulant and anti-β₂-glycoprotein I.

**Pathogenesis**

Negatively charged phospholipids and β₂-glycoprotein I are present on the outer surface of apoptotic blebs, and so aPLs are believed to arise by a similar mechanism to the lupus autoantibodies described above. Pathogenic aPLs bind to the N-terminal domain of β₂-glycoprotein I. Changes in the oxidation state of β₂-glycoprotein I in patients with APS enhance the availability of this domain to bind aPLs, and this interaction is facilitated when the protein is bound to phospholipid on the surface of cells such as endothelial cells, platelets, monocytes
and trophoblasts. This change alters the functioning of those cells, leading to thrombosis and/or miscarriage.

Clinical features

Since APS is defined by the presence of thrombosis and/or pregnancy loss, it is not surprising that these are the most common features. Ischaemic strokes occur in about 20% of patients and deep vein thrombosis in about 40%. Unlike most causes of thrombophilia, APS can cause either arterial or venous thrombosis (though rarely both in the same patient). Some 27% of women who have had two or more spontaneous miscarriages have APS.

Large studies, however, show that people with APS can also have many other features, including:

- thrombocytopenia
- chorea, migraine and epilepsy
- valvular heart disease
- cutaneous manifestations (e.g. livedo reticularis)
- positive Coombs test
- renal impairment due to ischaemia in the small renal vessels.

Occasionally, APS is catastrophic. Catastrophic APS is a rare variant (about 1% of cases) in which multiple infarcts in different organs of the body cause failure of multiple organs simultaneously. There is a high mortality from catastrophic APS.

Management

In people with APS who have had one thrombosis or more, the recommended treatment to prevent further thrombosis is long-term anticoagulation with warfarin. The optimal target INR is unclear and many patients are managed with a lower target INR. Pregnant women with APS are given oral aspirin and subcutaneous low-molecular-weight heparin from early in gestation. This therapy reduces the chance of a miscarriage but pre-eclampsia and poor fetal growth remain common. There are no definite guidelines for managing people with aPL who have never had thrombosis. Aspirin or clopidogrel is sometimes given prophylactically, especially in those with high-IgG aPL. Warfarin is given much more rarely in these circumstances, but may be indicated in patients at particularly high risk: for example, those who test positive for all three of anti-cardiolipin, lupus anticoagulant and anti-β2-glycoprotein I. Newer anticoagulants that act against specific clotting factors are replacing warfarin in some clinical situations and may come into use in APS. An example is the factor X inhibitor rivaroxaban, which is currently being assessed in a clinical trial in APS.

Systemic sclerosis (scleroderma)
Systemic sclerosis (SSc, or scleroderma; see p. 1366) is a multisystem disease and is distinct from localized scleroderma syndromes, such as morphea, that do not involve internal organ disease and are rarely associated with vasospasm (Raynaud's phenomenon). SSc has the highest case-specific mortality of any of the autoimmune rheumatic diseases. It occurs worldwide but there may be racial or ethnic differences in clinical features. For example, renal involvement is less frequent in Japanese cases.

The incidence of SSc is 10/million population per year with a 3 : 1 female to male ratio. The peak incidence is between 30 and 50 years of age. It is rare in children.

Environmental risk factors for scleroderma-like disorders include exposure to vinyl chloride, silica dust, adulterated rapeseed oil and trichloroethylene. Drugs such as bleomycin also produce a similar picture. Although unusual, familial cases are reported and twin cohorts suggest higher concordance in monozygotic pairs, consistent with genetic determinants of aetiology.

Pathology and pathogenesis

Vascular features

Widespread vascular damage involving small arteries, arterioles and capillaries is an early lesion. There is initial endothelial cell damage with release of cytokines, including endothelin-1, which causes vasoconstriction. There is continued intimal damage with increasing vascular permeability, leading to cellular activation and activation of adhesion molecules (E-selectin, VCAM, intercellular adhesion molecule 1 (ICAM-1)), with migration of cells into the extracellular matrix. Migrating lymphocytes are IL-2-producing cells, expressing surface antigens such as CD3, CD4 and CD5. All these factors cause release of other mediators (e.g. IL-1, 4, 6 and 8, TGF-β and platelet-derived growth factor) with activation of fibroblasts. Plasma levels of the chemokine CXCL4 are elevated in SSc and correlate with skin and lung fibrosis.

The damage to small blood vessels also produces widespread obliterative arterial lesions and subsequent chronic ischaemia.

Fibrotic features

Fibroblasts synthesize increased quantities of collagen types I and III, as well as fibronectin and glycosaminoglycans, producing fibrosis in the lower dermis of the skin as well as the internal organs. It is possible that antibodies to platelet-derived growth factor receptor, which have been found in blood of people with SSc, stimulate fibroblasts to cause fibrosis.

Clinical features (Fig. 18.36)

Raynaud's phenomenon

Raynaud's phenomenon is seen in almost 100% of cases and can precede the onset of the full-
Limited cutaneous scleroderma (LcSSc): 70% of cases

This condition usually starts with Raynaud's phenomenon many years (up to 15) before any skin changes. The skin involvement is limited to the hands, face, feet and forearms. The skin is tight over the fingers and often produces flexion deformities of the fingers. Involvement of the skin of the face produces a characteristic ‘beak’-like nose and a small mouth (microstomia). Painful digital ulcers and telangiectasia with dilated nail-fold capillary loops are seen. Digital ischaemia may lead to gangrene. Gastrointestinal tract involvement is common. Pulmonary hypertension develops in 21% of people with LcSSc and pulmonary interstitial disease also occurs.

Diffuse cutaneous scleroderma (DcSSc): 30% of cases

Initially oedematous in onset, skin sclerosis rapidly follows. Raynaud's phenomenon usually starts just before or concomitant with the oedema.

Diffuse swelling and stiffness of the fingers is rapidly followed by more extensive skin thickening, which can involve most of the body in the severest cases. Later, the skin becomes
atrophic. Early involvement of other organs occurs with general symptoms of lethargy, anorexia and weight loss.

- **Gastrointestinal involvement** includes heartburn, reflux or dysphagia due to oesophageal involvement (see p. 372), which is almost invariable, and anal incontinence occurs in many patients. Malabsorption from bacterial overgrowth due to dilatation and atony of the small bowel is not infrequent; more rarely, dilatation and atony of the colon occurs. Pseudo-obstruction is a known complication.

- **Renal involvement** is acute or chronic (see pp. 749–750). Acute hypertensive renal crisis used to be the most common cause of death in systemic sclerosis. Angiotensin-converting enzyme (ACE) inhibitors and better care, along with dialysis and renal transplantation, have changed this.

- **Lung disease**, both fibrosis (in 41% of cases) and pulmonary hypertension (17% of cases), contributes significantly to mortality in SSc. Pulmonary hypertension can be isolated or secondary to fibrosis, and high plasma levels of endothelin-1 are seen.

- **Myocardial fibrosis** leads to arrhythmias and conduction defects. Pericarditis is found occasionally.

  Sometimes, these systemic features occur without skin involvement (SSc *sine* scleroderma).

### Investigations

- **Full blood count**. A normochromic, normocytic anaemia occurs and a microangiopathic haemolytic anaemia is seen in some people with renal disease.

- **Urea and electrolytes**. Urea and creatinine rise in acute kidney injury.

- **Autoantibodies** *(Box 18.36)*:

  - In *LcSSc*: speckled, nucleolar or anti-centromere antibodies (ACAs) occur in 70% of cases. Anti-Th/To antibodies target small nuclear ribonucleoproteins and are found in up to 7% of cases of LcSSC.

  - In *DcSSc*: there are anti-topoisomerase-1 antibodies (called anti-Scl-70) in 30% of cases, and anti-RNA polymerase (I, II and III) antibodies in 20–25%. Anti-Scl-70 is highly specific for DcSSC. Anti-RNA polymerase positivity is associated with an increased risk of renal involvement. Anti-U3RNP antibodies bind a small nuclear ribonucleoprotein called fibrillarin and are present in up to 6% of patients with SSc – more commonly in DcSSc than LcSSC.

    - *RF* is positive in 30%.
    - *ANA* is positive in 95%.

- **Urine** microscopy and, if there is proteinuria, the urine albumin/creatinine ratio should be measured.

- **Imaging**:

  - *Chest X-ray*: to exclude other pathology, for changes in cardiac size and established lung
disease.

- **Hands**: deposits of calcium around the fingers (in severe cases, erosion and absorption of the tufts of the distal phalanges, termed ‘acro-osteolysis’).
- **Barium swallow**: generally confirms impaired oesophageal motility. Scintigraphy, manometry, impedance and upper gastrointestinal endoscopy are also valuable.
- **High-resolution CT**: to demonstrate fibrotic lung involvement.

**Other investigations** of gastrointestinal tract (e.g. see *Fig. 13.5*), lung, renal and cardiac as appropriate.

### Management

Treatment should be organ-based in order to try to control the disease. Currently, there is no cure. In contrast to many other ARDs, corticosteroids and immunosuppressants are rarely used in SSc, with the exception of SSc-related pulmonary fibrosis.

- **Education**, counselling and family support are essential.
- **Regular exercises** and skin lubricants may limit contractures but no treatment has proven efficacy in reducing skin fibrosis.
- **Raynaud’s phenomenon** may be improved by hand warmers and oral vasodilators (calcium-channel blockers, ACE inhibitors, angiotensin receptor blockers). In severe cases, parenteral vasodilators (prostacyclin analogues and calcitonin gene-related peptide) are used. Lumbar sympatheticectomy can help foot symptoms. Radical micro-arteriolysis (digital sympathectomy) can be used where individual fingers or toes are severely ischaemic, and thoracic sympathectomy under video-assisted thoracic surgery is now performed.
- **Oesophageal symptoms** can almost always be improved by proton pump inhibitors but prokinetic drugs are rarely helpful.
- **Symptomatic malabsorption** requires nutritional supplements and rotational antibiotics to treat small intestinal bacterial overgrowth.
- **Renal involvement** requires intensive control of hypertension. The first drug of choice is an ACE inhibitor. Vigilance for hypertensive scleroderma renal crisis (SRC) is critical, especially in early-stage dcSSc with rapidly progressive skin and tendon friction rubs. High-dose corticosteroids (above 10 mg prednisolone daily) may increase the risk of SRC.
- **Pulmonary hypertension** is treated with oral vasodilators, oxygen and warfarin. Advanced cases should receive prostacyclin therapy (inhaled, subcutaneous or intravenous) or the oral endothelin-receptor antagonists (bosentan and sitaxentan). Right heart failure is treated conventionally and transplantation (heart–lung or single lung) is used in eligible cases.
- **Pulmonary fibrosis** is currently treated with immunosuppression, most often with cyclophosphamide or azathioprine combined with low-dose oral prednisolone.

### Prognosis
In limited cutaneous scleroderma, the disease is often milder, with much less severe internal organ involvement and a 70% 10-year survival. Pulmonary hypertension is a significant later cause of death. Lung fibrosis and severe gut involvement also determine mortality. In diffuse disease, where organ involvement is often severe at an earlier stage, many patients die of pulmonary, cardiac or renal involvement. Overall, pulmonary involvement (vascular or interstitial) accounts for around 50% of scleroderma-related deaths.

Localized forms of scleroderma occur either in patches (morphea; see p. 1366) or linear forms. These are more commonly seen in children and adolescents, and do not convert into systemic forms, although ANA may occur in localized scleroderma and, very occasionally, localized and systemic forms coexist.

### Polymyositis and dermatomyositis

Polymyositis (PM) is a rare disorder of unknown cause, in which the clinical picture is dominated by inflammation of striated muscle, causing proximal muscle weakness. When the skin is involved, it is called ‘dermatomyositis’ (DM). The incidence is about 2–10/million population per annum and it occurs in all races and at all ages. The aetiology is unknown, although viruses (e.g. Coxsackie, rubella, influenza) have been implicated and persons with HLA-B8/DR3 appear to be genetically predisposed.

### Clinical features

#### Adult polymyositis

Women are affected three times more commonly than men.

The onset can be insidious, over months, or acute. General malaise, weight loss and fever can develop during the acute phase, but the cardinal symptom is proximal muscle weakness. The shoulder and pelvic girdle muscles become wasted but are not usually tender. Face and distal limb muscles are not usually affected. Movements such as squatting and climbing stairs become difficult. As the disease progresses, involvement of pharyngeal, laryngeal and respiratory muscles can lead to dysphonia and respiratory failure. These severe complications are rare if the disease is treated early.

#### Adult dermatomyositis

This condition is also more common in women. Apart from muscle weakness, these patients often suffer from myalgia, polyarthritis and Raynaud's phenomenon, but DM is primarily distinguished from PM by the characteristic rash. This typically affects the eyelids, where heliotrope (purple) discoloration is accompanied by periorbital oedema, and the fingers, where purple–red, raised vasculitic patches are seen. These patches occur over the knuckles (Gottron's papules; Fig. 18.37) in 70% of patients, and this appearance is highly specific for DM. Ulcerative vasculitis and calcinosis of the subcutaneous tissue are seen in 25% of cases. In the long term, muscle fibrosis and contractures of joints occur.
Antisynthetase syndrome

Some 20–30% of people with PM or DM have antibodies to tRNA synthetase enzymes. These people are more likely to develop pulmonary interstitial fibrosis, Raynaud's phenomenon, arthritis, and hardening and fissuring of skin over the pulp surface of the fingers (mechanic's hands). This variant of PM/DM is sometimes called anti-synthetase syndrome and often has a poor outcome. Respiratory muscles are affected in PM/DM and this compounds the effects of interstitial fibrosis. Dysphagia is seen in about 50% of patients owing to oesophageal muscle involvement.

Association with other ARDs

There is an association with other ARDs (e.g. SLE, RA and SSc) and their associated clinical features, such as deforming arthritis, malar rash and skin sclerosis.

Association with malignancies

The relative risk of cancer is 2.4 for male and 3.4 for female patients, and a wide variety of cancers have been reported. The onset and clinical picture do not differ from those of typical DM/PM. The associated cancer may not become apparent for 2–3 years, and recurrent, refractory or ANA-negative DM should prompt a search for occult malignancy.

Malignancy (e.g. lung, ovary, breast, stomach) can also predate the onset of myositis, particularly in males with DM.

Childhood dermatomyositis

This variant most commonly affects children between the ages of 4 and 10 years. The typical rash of DM is usually accompanied by muscle weakness. Muscle atrophy, subcutaneous calcification and contractures may be widespread and severe. Ulcerative skin vasculitis is common and recurrent abdominal pain due to vasculitis is also a feature.
**Investigations**

- **Serum creatine kinase (CK)**, aminotransferases, lactate dehydrogenase (LDH) and aldolase are usually raised and are useful guides to muscle damage, but may not reflect activity.
- **ESR** and **CRP** may be raised.
- **Serum autoantibody studies** include antinuclear antibody testing, which is usually positive in people with DM. RF is present in up to 50%, and many **myositis-specific antibodies** (MSAs) have been recognized and correlate with certain subsets. Anti-synthetase antibodies have been described above.
- **Electromyography (EMG)** shows a typical triad of changes with myositis: spontaneous fibrillation potentials at rest, polyphasic or short-duration potentials on voluntary contraction, and salvos of repetitive potentials on mechanical stimulation of the nerve.
- **MRI** can be used to detect abnormally inflamed muscle.
- **Needle muscle biopsy** shows fibre necrosis and regeneration in association with an inflammatory cell infiltrate with lymphocytes around the blood vessels and between muscle fibres. Open biopsy allows more thorough assessment.
- **Screening for malignancy** is usually limited to relatively non-invasive investigations such as chest X-ray, mammography, pelvic/abdominal ultrasound, urine microscopy and a search for circulating tumour markers.
- **PET** scanning can detect malignancy.

**Management**

Bed rest may be helpful but must be combined with an exercise programme. Prednisolone is the mainstay of treatment: 0.5–1.0 mg/kg body weight as initial therapy, continued until at least 1 month after myositis has become clinically and enzymatically inactive. Tapering of steroids must be slow. Early intervention with steroid-sparing agents, such as methotrexate, azathioprine, ciclosporin, cyclophosphamide and mycophenolate mofetil, is common, especially where there is clinical relapse or a rise in CK as the dose of steroids is reduced. Intravenous immunoglobulin therapy (IVIG) is helpful in some recalcitrant cases. Treatment of childhood DM tends to be more intensive, with earlier use of immunosuppressive agents. Use of biological agents such as rituximab has been described. Rituximab is more likely to be effective in autoantibody-positive cases.

**Inclusion body myositis**

Inclusion body myositis is an idiopathic inflammatory myopathy usually occurring in men over 50 years. Weakness of the pharyngeal muscles causes difficulty in swallowing in over 50%. It is a slowly progressive weakness of mainly distal muscles. In contrast to polymyositis, the CK is only slightly elevated; the EMG shows both myopathic and neuropathic changes. On MRI,
the changes are often more distal but can be similar to those of polymyositis. A muscle biopsy shows inflammation and basophilic rimmed vacuoles with diagnostic filamentous inclusions and vacuoles on electron microscopy. A trial of corticosteroids is worthwhile but generally the response is poor.

### Sjögren syndrome

The syndrome of dry eyes (keratoconjunctivitis sicca) in the absence of RA or any of the autoimmune diseases is known as ‘primary Sjögren syndrome’. There is an association with HLA-B8/DR3. Dryness of the mouth, skin or vagina may also be a problem. Salivary and parotid gland enlargement is seen. In the majority of cases, dryness and fatigue are the only symptoms, and Sjögren syndrome is irritating and inconvenient rather than dangerous. However, in a minority there may be systemic symptoms such as:

- arthralgia and occasional non-progressive polyarthritis, like that seen in SLE (but much less common)
- Raynaud's phenomenon
- dysphagia and abnormal oesophageal motility, as seen in systemic sclerosis (but less common)
- other organ-specific autoimmune disease, including thyroid disease, myasthenia gravis, primary biliary cirrhosis, autoimmune hepatitis and pancreatitis
- renal tubular defects (uncommon) causing nephrogenic diabetes insipidus and renal tubular acidosis
- pulmonary diffusion defects and fibrosis
- polyneuropathy, fits and depression
- vasculitis
- increased incidence of non-Hodgkin's B-cell lymphoma.

### Pathology and investigations

Biopsies of the salivary gland or of the lip show a focal infiltration of lymphocytes and plasma cells.

- **Schirmer tear test.** A standard strip of filter paper is placed on the inside of the lower eyelid; wetting of <10 mm in 5 min indicates defective tear production.
- **Rose Bengal staining.** Staining of the eyes shows punctate or filamentary keratitis.
- **Laboratory abnormalities.** These include raised immunoglobulin levels, circulating immune complexes and autoantibodies. RF is usually positive. Antinuclear antibodies are found in 80% of cases and anti-mitochondrial antibodies in 10%. Anti-Ro (SSA) antibodies are found in 60–90%, compared with 10% of cases of RA and secondary Sjögren syndrome. This antibody is of particular interest because it can cross the placenta and cause congenital heart
Management

Symptomatic treatment is with artificial tears and saliva replacement solutions. Hydroxychloroquine may help fatigue and arthralgia. Corticosteroids are rarely needed but are used to treat persistent salivary gland swelling or neuropathy. A trial of rituximab in Sjögren syndrome is under way but it is not yet standard therapy.

‘Overlap’ syndromes and undifferentiated autoimmune rheumatic disease

An overlap syndrome is one where the patient shows the characteristic clinical features of more than one ARD. Treatment of each ARD is usually the same as when they occur separately.

Undifferentiated ARD is a term used for the condition of patients who have evidence of autoimmunity (e.g. positive autoantibody test) and some clinical features of such diseases (commonly, Raynaud's phenomenon and/or arthralgia) but not enough to make a clear diagnosis of any individual ARD. These patients sometimes develop a clearer ARD over time, but some always remain undifferentiated and tend to have relatively mild disease without major organ problems.

Systemic Inflammatory Vasculitis

Vasculitis is a histological term describing inflammation of the vessel wall. Vasculitis can be seen in many diseases (Boxes 18.37–18.38). The group of diseases described in this section (systemic inflammatory vasculitides) is characterized by widespread vasculitis leading to systemic symptoms and signs, generally requiring treatment with corticosteroids and/or immunosuppressive drugs. Two main features are helpful in classifying these vasculitides: the size of the blood vessels involved and the presence or absence of anti-neutrophil cytoplasmic antibodies (ANCA) in the blood. Revisions in the commonly used terms for various vasculitides have been proposed to reflect increased pathophysiological understanding of these conditions (Fig. 18.38 and Box 18.38).
• **Large-vessel vasculitis** refers to the aorta and its major tributaries.
• **Medium-vessel vasculitis** refers to medium- and small-sized arteries and arterioles.
• **Small-vessel vasculitis** refers to small arteries, arterioles, venules and capillaries.

• Systemic lupus erythematosus
• Scleroderma
• Polymyositis/dermatomyositis
• Drug-induced Behçet's disease
• Goodpasture syndrome
• Hypocomplementaemia
• Serum sickness
Large-vessel vasculitis

Polymyalgia rheumatica and giant cell (temporal) arteritis are systemic illnesses of the elderly. Both are associated with the finding of a giant cell arteritis on temporal artery biopsy.

Polymyalgia rheumatica

Polymyalgia rheumatica (PMR) causes a sudden onset of severe pain and stiffness of the shoulders and neck, and of the hips and lumbar spine: a limb girdle pattern. These symptoms are worse in the morning, lasting from 30 minutes to several hours. The clinical history is usually diagnostic and the patient is always over 50 years old. Up to 25% of patients may have...
some inflammation of peripheral joints.

Approximately one-third of patients develop systemic features of tiredness, fever, weight loss, depression and occasionally nocturnal sweats, especially if PMR is not diagnosed and treated early. A differential diagnosis is shown in Box 18.39.

**Box 18.39**

**Symptom patterns in some muscle disorders**

- **Polymyositis** – proximal muscle ache and weakness
- **Polymyalgia rheumatica** – proximal morning stiffness and pain
- **Myopathy** – weakness, but no pain or stiffness

**Investigation of PMR**

- **A raised ESR and/or CRP** is a hallmark of this condition. It is rare to see PMR without an acute-phase response. If it is absent, the diagnosis should be questioned and the tests repeated a few weeks later before treatment is started.
- **Serum alkaline phosphatase and γ-glutamyl-transpeptidase** may be raised as markers of the acute inflammation.
- **Anaemia** (mild normochromic, normocytic) is often present.
- **Temporal artery biopsy** shows giant cell arteritis in 10–30% of cases, but is rarely performed unless giant cell arteritis is also suspected.

**Giant cell arteritis**

Giant cell arteritis (GCA) is inflammatory granulomatous arteritis of large cerebral arteries, which occurs in association with PMR. The patient may have current PMR or a history of recent PMR, or may be on treatment for PMR. It is extremely rare under 50 years of age. Presenting symptoms of GCA include severe headaches, tenderness of the scalp (combing the hair may be painful) or of the temple, claudication of the jaw when eating, and tenderness and swelling of one or more temporal or occipital arteries. The most feared manifestation is sudden, painless, temporary or permanent loss of vision in one eye due to involvement of the ophthalmic artery (see pp. 845–846). Systemic manifestations of severe malaise, tiredness and fever occur.

**Investigation of GCA**

- **Normochromic, normocytic anaemia.**
- **ESR** is usually raised (in the region of 50–120 mm/h) and the CRP very high.
Liver biochemistry may be abnormal, as in PMR. The albumin may be low.

A temporal artery biopsy from the affected side is the definitive diagnostic test. This should be taken before, or within 7 days of starting, high doses of corticosteroids. The lesions are patchy and the whole length of the biopsy (>1 cm long) must be examined; even so, negative biopsies occur.

The histological features of GCA are:

- Cellular infiltrates of CD4+ T lymphocytes, macrophages and giant cells in the vessel wall. Note that giant cells are not visible in all cases.
- Granulomatous inflammation of the intima and media.
- Breaking up of the internal elastic lamina.
- Giant cells, lymphocytes and plasma cells in the internal elastic lamina.

Management of PMR or GCA

Corticosteroids produce a dramatic reduction of symptoms of PMR within 24–48 hours of starting treatment, provided the dose is adequate. If this improvement does not occur, the diagnosis should be questioned and an alternative cause sought, such as RA, vasculitis, infection or malignancy. This treatment should reduce the risk of patients who have PMR developing GCA. NSAIDs are less effective and should not be used.

In GCA, corticosteroids are obligatory because they significantly reduce the risk of irreversible visual loss and other focal ischaemic lesions, but much higher doses are needed than in PMR. If GCA is suspected, it may not be possible to arrange a temporal artery biopsy rapidly. In these circumstances, treatment should not be delayed, especially if there have already been episodes of visual loss or stroke.

Starting daily doses of prednisolone are:

- **PMR**: 10–15 mg prednisolone as a single dose in the morning
- **GCA**: 60–100 mg prednisolone, usually in divided doses.

The dose should then be reduced gradually in weekly or monthly steps. While the dose is above 20 mg, the step reductions are 5 mg, reducing the evening doses first. Between 20 mg and 10 mg, the reduction can be in 2.5 mg steps, but below 10 mg the rate should be slower and the steps of 1 mg each. Most patients will eventually be able to stop corticosteroids after 12–18 months but up to 25% may need low doses long-term. Steroid-sparing immunosuppressive agents are used in refractory cases where it is hard to reduce the corticosteroid dose without causing a flare of disease or a rise in ESR or CRP.

Calcium and vitamin D supplements, and sometimes bisphosphonates, are necessary to prevent osteoporosis while high-dose steroids are being used (see pp. 713–715).

Takayasu's arteritis

Takayasu's is a granulomatous inflammation of the aorta and its major branches; it is discussed
Medium-sized vessel vasculitis

Polyarteritis nodosa

Classical polyarteritis nodosa (PAN) is a rare condition that usually occurs in middle-aged men. It is accompanied by severe systemic manifestations, and its occasional association with hepatitis B antigaenaemia suggests a vasculitis secondary to the deposition of immune complexes. Pathologically, there is fibrinoid necrosis of vessel walls with microaneurysm formation, thrombosis and infarction.

Clinical features

These include fever, malaise, weight loss and myalgia. These initial symptoms are followed by dramatic acute features that are due to organ infarction.

- **Neurological.** Mononeuritis multiplex is due to arteritis of the vasa nervorum.
- **Abdominal.** Pain is due to arterial involvement of the abdominal viscera, mimicking acute cholecystitis, pancreatitis or appendicitis. Gastrointestinal haemorrhage occurs because of mucosal ulceration.
- **Renal.** Presentation is with haematuria and proteinuria. Hypertension and acute/chronic kidney disease occur.
- **Cardiac.** Coronary arteritis causes myocardial infarction and heart failure. Pericarditis also occurs.
- **Skin.** Subcutaneous haemorrhage and gangrene occur. A persistent livedo reticularis is seen in chronic cases. Cutaneous and subcutaneous palpable nodules occur but are uncommon.
- **Lung.** Involvement is rare.

Investigations and management

- **Blood count.** Anaemia, leucocytosis and a raised ESR occur.
- **Biopsy.** Material from an affected organ shows features listed above.
- **Angiography.** Microaneurysms in hepatic, intestinal or renal vessels can be demonstrated if necessary.
- **Other investigations.** These are performed as appropriate (e.g. electrocardiogram and abdominal ultrasound), depending on the clinical problem. ANCA is positive only rarely in classic PAN.

**Treatment** is with corticosteroids, usually in combination with immunosuppressive drugs such as azathioprine.
Kawasaki's disease

Kawasaki's disease is an acute systemic vasculitis involving medium-sized vessels, affecting mainly children under 5 years of age. It is very frequent in Japan and an infective trigger is suspected. It occurs worldwide and is also seen in adults.

Clinical features and management

The clinical features are:

- fever lasting 5 days or more
- bilateral conjunctival congestion 2–4 days after onset
- dryness and redness of the lips and oral cavity 3 days after onset
- acute cervical lymphadenopathy accompanying the fever
- polymorphic rash involving any part of the body
- redness and oedema of the palms and soles 2–5 days after onset.

The persistent fever plus at least four of the other five features should be present to make the diagnosis, or fewer than four if coronary aneurysms can be seen on two-dimensional echocardiography, MRI or angiography.

Cardiovascular changes in the acute stage include pancarditis and coronary arteritis, leading to aneurysms or dilatation. Other features include diarrhoea, albuminuria, aseptic meningitis and arthralgia; in most, there is a leucocytosis, thrombocytosis and a raised CRP. Anti-endothelial cell autoantibodies are often detectable.

Treatment is with a single dose of high-dose intravenous immunoglobulin (2 g/kg), which prevents the coronary artery disease, followed after the acute phase by aspirin 200–300 mg daily. There is no evidence that steroid treatment improves the outcome.

Small-vessel vasculitis

The two revised categories of small-vessel vasculitis (SVV) are characterized by a paucity of vessel wall immunoglobulin and presence (in many but not all patients) of ANCA in one, and a prominence of vessel wall immunoglobulin in the other (see pp. 1120–1121).

ANCA-associated vasculitis (AAV) includes:

- granulomatosis with polyangiitis (GPA; see p. 1121)
- eosinophilic granulomatosis with polyangiitis (EGPA; see p. 1121)
- microscopic polyangiitis (MPA; see p. 1121).

Immune complex (ANCA-negative) small-vessel vasculitis includes:

- anti-glomerular basement membrane (anti-GBM) disease (see p. 1121)
- IgA vasculitis (IgAV, Henoch–Schönlein) (see p. 748)
- cryoglobulinaemic vasculitis (CV) (see p. 748)
• hypocomplementaemic urticarial vasculitis (HUV, anti-C1q vasculitis)
• cutaneous leucocytoclastic vasculitis (see p. 1377).

**Cutaneous leucocytoclastic vasculitis** is the characteristic acute purpuric lesion that histologically involves the dermal postcapillary venules. This lesion affects only the skin and should be differentiated from similar lesions produced in systemic vasculitis. The purpura may be accompanied by arthralgia and glomerulonephritis. Hepatitis C infection is common and may be an aetiological agent. The condition can also be caused by drugs such as sulphonamides and penicillin.

**Primary central nervous system vasculitis** is a very rare condition (incidence 2–4 cases per million person years) characterized by clinical features confined to the central nervous system and characteristic appearances on angiography or cerebral biopsy. The most common clinical features are headache, altered cognition, focal weakness and stroke. Blood tests, including inflammatory markers and autoantibodies, are usually normal but a normal cerebral MRI essentially excludes the diagnosis.

### Management of small-cell vasculitis

The treatment depends on the organs involved. Vasculitis confined to the skin may not require systemic treatment, whereas involvement of major organs (e.g. lungs or kidneys in GPA) requires high-dose corticosteroids, immunosuppression and, sometimes, plasma exchange. Clinical trials have shown that depletion of B cells with rituximab is as effective as cyclophosphamide in treating AAV and can help reduce the dose of corticosteroids required to maintain remission.

### Behçet's disease

Behçet's disease is an inflammatory disorder of unknown cause. There is a striking geographical distribution, it being most common in Turkey, Iran and Japan. The prevalence per 100 000 is 10–15 in Japan and 80–300 in Turkey. There is a link to the HLA-B51 allele, with a relative risk of 5–10; this association is not seen in patients in the USA and Europe.

### Clinical features

The cardinal clinical feature is recurrent oral ulceration. The **international criteria for diagnosis** require oral ulceration and any two of the following:

• genital ulcers
• defined eye lesions, including an anterior or posterior uveitis or retinal vascular lesions
• defined skin lesions – erythema nodosum, pseudofolliculitis and papulopustular lesions
• positive skin pathergy test (see below)
• oral ulcers – aphthous or herpetiform.
Other manifestations include a self-limiting peripheral mono- or oligoarthritis affecting knees, ankles, wrists and elbows; gastrointestinal symptoms of diarrhoea, abdominal pain and anorexia; pulmonary and renal lesions; thrombophlebitis (especially in the legs); vasculitis; and a brainstem syndrome, organic confusional states and a meningoencephalitis. All the common manifestations are self-limiting except for the ocular attacks. Repeated attacks of uveitis can cause blindness.

The **pathergy reaction** is highly specific to Behçet's disease. Skin injury – by a needle prick, for example – leads to papule or pustule formation within 24–48 hours. Blood tests usually show raised ESR and CRP but not autoantibodies.

### Management

Corticosteroids, immunosuppressive agents and ciclosporin are used for chronic uveitis and the rare neurological complications. Colchicine helps erythema nodosum and joint pain. Thalidomide may be useful in some cases, although side-effects of drowsiness and peripheral neuropathy are common. It should not be used in pregnant women because of phocomelia (limb abnormalities). Anti-TNF agents can be used to control severe uveitis and serious manifestations such as neurological and gastrointestinal Behçet's disease.

### Arthritis in Children

Joint and limb pains are common in children but arthritis is, fortunately, rare. Babies and young children may present with immobility of a joint or a limp, but the diagnosis can be extremely difficult. *Figure 18.39* summarizes the differential diagnosis.
For chronic conditions, the child and family often need a great deal of support from physiotherapists, occupational therapists, psychologists, teachers, social workers and orthopaedic surgeons. These are best obtained in specialist paediatric centres.

**Juvenile idiopathic arthritis**

**Systemic-onset juvenile idiopathic arthritis**

*Still's disease* (which accounts for 10% of cases of juvenile idiopathic arthritis (JIA)) affects boys and girls equally up to 5 years of age; after this, girls are more commonly affected. Adult-onset Still's disease is rare.

Clinical features include a high (>39°) fever with an evanescent pink maculopapular rash and arthralgia, arthritis, myalgia and generalized lymphadenopathy. Hepatosplenomegaly, pericarditis and pleurisy occur. The differential diagnoses include malignancy – in particular, leukaemia and neuroblastoma – and infection. Laboratory tests show a high ESR and CRP, neutrophilia and thrombocytosis. Autoantibodies are negative. Macrophage activation syndrome (an excessive proliferation of T cells and macrophages) is a rare but potentially fatal complication, which can follow infection (often viral) or a change in medication.

**Oligoarthritis (persistent)**

This variant is the most common form of JIA (50–60%) but is still a relatively uncommon condition. It affects, by definition, four or fewer joints, especially knees, ankles and wrists, often in an asymmetrical pattern. It affects mainly girls, with a peak age of 3 years. The prognosis is generally good, with most going into remission. Uveitis (often with a positive
ANA) occurs and requires regular screening by slit-lamp examination. Blindness can occur if it is untreated. Prognosis is generally good, with remission occurring eventually in most patients.

### Oligoarthritis (extended)

In approximately 25% of patients, oligoarthritis extends to affect many more joints after around 6 months. This form of arthritis can be very destructive.

### Polyarthritis JIA

The *RF-positive* form (usually also ACPA-positive) occurs in older girls, usually over 8 years. It is a systemic disease; the arthritis commonly involves the small joints of the hands, wrists, ankles and feet initially, and eventually larger joints. It can be a very destructive arthritis and needs aggressive treatment.

The *RF-negative* form is more common. It usually affects girls under 12 years but can occur at any age. The arthritis is often asymmetrical, with a distribution similar to that seen in the RF-positive form. It may also affect the cervical spine, temporomandibular joints and elbows. Patients may be ANA-positive, with a risk of chronic uveitis. All children must have regular ophthalmological examination.

### Enthesitis-related arthritis

This form affects teenage and younger boys mainly, often those with a family history of HLA-B27 disorders. It produces an asymmetrical arthritis of lower-limb joints and enthesitis. It is associated with HLA-B27 and a risk of iritis. It is the childhood equivalent of adult ankylosing spondylitis but spinal involvement is rare in childhood. Approximately 1 in 3 develops spinal disease in adulthood.

### Psoriatic arthritis

This arthritis occurs in children and is similar in pattern to the adult form. The arthritis can be very destructive. Psoriasis may develop long after the arthritis but is found commonly in a first-degree relative.

### Management of JIA

Early recognition and aggressive treatment prevent joint damage and allow normal growth and development. There is no cure but clinical remission is an achievable goal. JIA should always be referred to a specialist paediatric rheumatology unit with facilities to assess and design treatment plans that aim to prevent long-term disability. These units also need facilities for rehabilitation, education and surgical intervention. NSAIDs reduce pain and stiffness, but
disease-modifying agents such as methotrexate are used to control moderate and severe disease. Corticosteroids are often required in systemic disease: intravenous pulsed methylprednisolone is used, followed by methotrexate (10–15 mg/m²) weekly to control disease and prevent growth suppression.

**Cytokine modulators** (see Box 18.30) are used if methotrexate fails; they are highly effective in all types except systemic-onset JIA, where the results are variable. Etanercept and adalimumab are the most common drugs used but anakinra, tocilizumab and abatacept are being used in systemic-onset JIA. Anakinra (see p. 682), an IL-1β receptor antagonist, helps in methotrexate-resistant systemic-onset disease. Sulfasalazine is used only in enthesitis-related JIA. Aspirin may be a cause of Reye syndrome and should not be used under the age of 12 years.

### Prognosis

Before cytokine modulators, up to 50% of children developed long-term disability; 25% continued to have active arthritis into adult years. Death was due to infection or systemic disease with pericarditis or amyloidosis. The prognosis is much improved but long-term studies, particularly on safety, are awaited.

### Childhood rheumatic diseases other than juvenile idiopathic arthritis

#### IgA vasculitis (Henoch–Schönlein purpura)

This condition is the most common systemic vasculitis seen in children. It is described on page 748.

#### Rheumatic fever

Rheumatic fever still occurs occasionally in developed countries but is more common in developing countries. It is described on page 282.

The arthritis affects large joints and migrates between joints, each being affected for a few days at a time. This pattern is unlike systemic-onset JIA, where arthritis is usually much more persistent in each affected joint. The fever is persistent but rarely as high as in systemic-onset JIA, and the temperature often remains above normal. A child may not volunteer a history of sore throat and the carditis may be silent. Isolated arthritis is the presenting symptom in 14–42%. The disease is easily missed if not included in the differential diagnosis of acute childhood arthritis.

**Treatment** is described on page 282.

#### Hypermobility and hypermobility syndrome
A large proportion of children are hypermobile in at least one joint. Though in most cases it is asymptomatic and causes no problems, a proportion of them will develop various musculoskeletal complaints in early childhood, such as late walking, flat feet or nocturnal leg pains, probably due to hypermobile ankles and knees suffering recurrent sprains and strains after exercise. Joint effusions, subluxation, dislocation and ligamentous injuries may occur throughout childhood. Low back pain may develop in affected adolescents. These symptoms in hypermobile children may lead to a diagnosis of joint hypermobility syndrome (Ehlers–Danlos syndrome type III; see pp. 666–667).

More severe hypermobility is also seen in the other, rarer forms of Ehlers–Danlos syndrome and Marfan syndrome (see pp. 667 and 1028–1029).

**Management** is with exercise directed at improving the strength of muscles that cross affected joints, as well as overall fitness and endurance. It may be necessary to reduce or change sporting and other activities. Cognitive behavioural therapy helps in teenagers.

---

### Idiopathic musculoskeletal pain

This can become chronic in children. Management requires exclusion of the causes shown in Figure 18.39, but without performing unnecessary laboratory investigations. Nocturnal musculoskeletal pains are episodic and may be associated with hypermobility. They are called ‘growing pains’. They often last 15–30 minutes and awaken the child from sleep, and may require physiotherapy and analgesics, together with advice and support for the parents.

**Low back pain** in children may reflect psychosocial problems at home or school as much as any obvious musculoskeletal pathology.

---

### Osteochondritis

Osteochondritis can affect the ossification centre of the ends of bones. A typical condition is *Osgood–Schlatter disease*, which is characterized by localized pain and swelling over the tibial tubercle or at the patellar tendon insertion. It is usually seen in athletic teenagers and responds to local treatment and changes of sporting activities. *Sever's disease* is an osteochondritis of the insertion of the Achilles tendon into the calcaneum.

---

### Perthes' disease

This is an idiopathic, possibly avascular, necrosis of the proximal femoral epiphysis, of unknown aetiology. It presents as a painless limp, usually in boys aged 3–12 years, and is occasionally bilateral. If severe, it may require surgical correction.

---

### Transient synovitis of the hip (irritable hip)

This causes painful limitation of movement, usually of one hip, after an upper respiratory
infection in young children (usually boys). Symptoms usually resolve within a few weeks (2–3% develop Perthes' disease) but other more serious causes of hip pain should be excluded. Management is with rest and analgesia until the pain resolves.

Further reading

Rheumatological Problems Seen in Other Diseases
Gastrointestinal and liver disease

• **Enteropathic synovitis** (see pp. 686–687).

• **Autoimmune hepatitis** (see pp. 463–464) may be accompanied by an arthralgia similar to that seen in SLE. Joint pain occurs in a bilateral, symmetrical distribution, predominantly affecting the small joints of the hands. Joints usually look normal but sometimes there is a slight soft tissue swelling. These patients often have positive tests for antinuclear antibodies.

• **Primary biliary cholangitis** patients occasionally have a symmetrical arthropathy.

• **Hereditary haemochromatosis** is associated with arthritis in 50% of cases, which is often the first sign of the disease and cartilage calcification is common.

• **Whipple's disease** (see p. 400) is accompanied by fever and arthralgia.

Malignant disease

It is not uncommon for malignant diseases to present with musculoskeletal symptoms. Gout occurs in conditions such as chronic myeloid leukaemia. Neoplastic disease of bone is described on pages 718–719.

Hypertrophic pulmonary osteoarthropathy

Hypertrophic pulmonary osteoarthropathy (HPO) is a paraneoplastic, non-metastatic complication, frequently associated with carcinoma of the bronchus. It may be the presenting feature of the disease. It rarely occurs with other conditions that also cause clubbing, presenting most often in middle-aged men with pain and swelling of the wrists and ankles. Other joints are occasionally involved. The mechanism is unclear. One suggestion is the release of VEGF into the circulation. Primary HPO is a hereditary condition involving a mutation in the **HPGD** gene that degrades prostaglandin E₂ (PGE₂). The mutation therefore allows over-production of PGE₂, which may cause clubbing.

The diagnosis is made on the presence of clubbing of the fingers (usually gross in primary)
and periosteal new bone formation along the shafts of the distal ends of the radius, ulna, tibia and fibula on X-ray. A chest X-ray usually shows the malignancy.

**Management** should be directed at the underlying carcinoma; if this can be removed, the arthropathy disappears. NSAIDs relieve the symptoms.

---

**Sarcoidosis**

Sarcoidosis (see pp. 1118–1120) is a multisystem granulomatous disease and is associated with erythema nodosum, which occurs in 20% of cases at or soon after the onset of the disease. The most useful diagnostic test is a chest X-ray, which shows hilar lymphadenopathy in 80% of cases. The serum ACE may be raised.

Other patterns of arthritis occur later in the disease. These include a transient rheumatoid-like polyarthritis and an acute monoarthritis that can be mistaken for gout. Bone cysts can also develop.

**Treatment** is with NSAIDs; if these fail to control the symptoms, corticosteroids are usually very effective.

---

**Paraneoplastic polyarthritis**

This condition is seen with carcinoma of the breast in women and of the lung in men, and also with renal cell carcinoma. The neoplasm may be occult at onset and the diagnosis is then difficult to make.

---

**Skin disease**

**Psoriatic arthritis**

This disease is discussed on pages 685–686.

**Erythema nodosum**

Erythema nodosum (see p. 1363) is accompanied by arthritis in over 50% of cases. The knees and ankles are particularly affected, being swollen, red and tender. The arthritis subsides, along with the skin lesions, within a few months. Treatment is with NSAIDs or occasionally steroids.

---

**Neurological disease**

**Neuropathic (Charcot's) joints**

These are damaged by trauma as a result of the loss of the protective pain sensation. They were first described by Charcot in relation to tabes dorsalis. They also occur in syringomyelia,
diabetes mellitus and leprosy. The site of the neuropathic joint depends on the localization of the pain loss:

• In tabes dorsalis, the knees and ankles are most often affected.
• In diabetes mellitus, the joints of the tarsus are involved.
• In syringomyelia, the shoulder is involved.

Neuropathic joints are not painful, although there may be painful episodes associated with crystal deposition. Presentation is usually with swelling and instability. Eventually, severe deformities develop.

The characteristic finding is a swollen joint with abnormal but painless movement, in association with neurological findings that depend on the underlying disease (e.g. dissociated sensory loss in syringomyelia or polyneuropathy in diabetes). X-ray changes are characteristic, with gross joint disorganization and bony distortion.

**Treatment** is symptomatic. Surgery may be required in advanced cases.

### Blood disease

Arthritis due to haemarthrosis is a common presenting feature of people with haemophilia (see pp. 571–573). Attacks begin in early childhood in most cases and are recurrent. The knee is the most commonly affected joint but the elbows and ankles are sometimes involved. The arthritis can lead to bone destruction and disorganization of joints. Apart from replacement of factor VIII, affected joints require initial immobilization followed by physiotherapy to restore movement and measures to prevent and correct deformities.

**Sickle cell crises** (see p. 539) are often accompanied by joint pain that particularly affects the hands and feet in a bilateral, symmetrical distribution. Affected joints usually look normal but are occasionally swollen. This condition may also be complicated by avascular necrosis (see p. 715) and by osteomyelitis.

Arthritis can also occur in **acute leukaemia** (see pp. 608–612); it may be the presenting feature in childhood. The knee is particularly affected and is very painful, warm and swollen. Treatment is directed at the underlying leukaemia. Arthritis may also occur in chronic leukaemia, with leukaemic deposits in and around the joints.

Individuals with **thalassaemia major** (see pp. 536–537) are living longer and are presenting with back pain due to premature disc degeneration, secondary spondylosis and crush fractures caused by osteoporosis. There is marked discal calcification.

### Endocrine and metabolic disorders

**Hypothyroid** patients may complain of pain and stiffness of proximal muscles, resembling polymyalgia rheumatica. They may also have carpal tunnel syndrome. Less often, there is an arthritis accompanied by joint effusions, particularly in the knees, wrist and small joints of the hands and feet. These problems respond rapidly to thyroxine.

**Hyperparathyroidism** may be complicated by cartilage calcification and acute CPPD.
In acromegaly, arthralgia occurs in about 50% of patients. It particularly affects the small joints of the hands and knees. There may be a carpal tunnel syndrome.

In Cushing’s disease, back pain is common.

Joint disorders related to diabetes mellitus are described on page 1273. Familial hypercholesterolaemia is associated with oligo- or polyarthritis, usually with tendon xanthomata. Arthritis also occurs in combined hyperlipidaemia.

Miscellaneous Arthropathies

Familial Mediterranean fever

Systemic autoinflammatory syndromes (SAIDs) are rare genetic and acquired disorders which present with recurrent attacks of fever in childhood and adult life.

Familial Mediterranean fever (FMF) is inherited as an autosomal recessive condition and occurs in certain ethnic groups, particularly Arabs, Turks, Armenians and Sephardic Jews. The gene, called MEFV, has been localized to chromosome 16. It encodes for pyrin (or marenosmin), a suppressor of the activation of caspase 1, which stimulates the biosynthesis of IL-1β, which drives inflammation. Failure of suppression leads to FMF attacks.

These are characterized by recurrent episodes of fever, arthritis and serositis. Abdominal or chest pain due to peritonitis or pleurisy occurs. The arthritis is usually monoarticular and episodes last up to 1 week. The CRP is markedly raised during the attacks. The condition may be mistaken for palindromic rheumatism (see p. 675), but such attacks are not usually accompanied by fever.

The diagnosis can be made by PCR, if available, but is based on the clinical picture and exclusion of other conditions.

Treatment involves regular colchicine 1000–1500 µg daily, which can usually prevent the attacks. In resistant patients, thalidomide (see p. 601) and anakinra can be tried. In general, the disorder is benign, but in 25% of cases, renal amyloidosis develops.

Other systemic autoinflammatory syndromes (SAIDs) are being increasingly recognized. These include tumour necrosis factor receptor-associated periodic syndrome (TRAPS), mevalonate kinase deficiency (MKD), cryopyrin-associated periodic syndrome (CAPS), and periodic fever, aphthous stomatitis, pharyngitis and adenitis (PFAPA).

SAPHO (synovitis, acne, palmoplantar pustulosis, hyperostosis, osteitis)

This rare syndrome appears to be a reaction to chronic Propionibacterium acnes infection. It produces chronic multifocal osteitis with anterior chest wall pain and peripheral synovitis. There is inflammatory cytokine release and global neutrophil activation. Etanercept (see p. 680) may help.
**Osteochondromatosis**

In this condition, foci of cartilage form within the synovial membrane. These foci become calcified and then ossified (osteochondromas). They may give rise to loose bodies within the joint. The condition occurs in a single joint of a young adult and X-rays are usually diagnostic.  

*Management* involves removal of loose bodies and synovectomy.

**Pigmented villonodular synovitis**

This is characterized by exuberant synovial proliferation that occurs either in joints or in tendon sheaths. The main manifestation in joints is recurrent haemarthrosis. It may produce progressive local bone destruction. A malignant form is seen occasionally.  

*Management* is synovectomy or radiotherapy. In tendon sheaths, the condition gives rise to a nodular mass that requires excision.

**Relapsing polychondritis**

Relapsing polychondritis is a rare inflammatory condition of cartilage. It occurs equally in males and females, usually the elderly. Tenderness, inflammation and eventual destruction of cartilage occur, mainly in the ear, nose, larynx or trachea. A seronegative polyarthritis occurs, as well as episcleritis and evidence of a vasculitis (e.g. glomerulonephritis). The diagnosis is clinical with laboratory evidence of acute inflammation.  

*Treatment* involves corticosteroids and immunosuppressive agents.

**Further reading**

Anatomy and Physiology of Bone

Bone is a specialized connective tissue serving three major functions:

- **Mechanical** – supplying structure and muscle attachment for movement
- **Metabolic** – providing the body's primary store of calcium and phosphate
- **Protective** – enclosing the marrow and other vital organs

### Bone structure

Bone is comprised of cells and a matrix of organic protein and inorganic mineral. Long bones (femur, tibia, humerus) and flat bones (skull, scapula) have different embryological templates, with varying proportions of cortical and trabecular bone.
• **Cortical (compact or lamellar) bone** forms the shaft of long bones and the outer shell of flat bones. Formed of concentric rings of bone, it is particularly adapted to withstand bending strain.

• **Trabecular (cancellous) bone** is found at the ends of long bones and inside flat bones. Comprised of a network of interconnecting rods and plates of bone, it offers resistance to compressive loads. It is also the main site of bone turnover for mineral homeostasis.

• **Woven bone** lacks an organized structure. It appears in the first few years of life, at sites of fracture repair and in high-turnover bone disorders such as Paget's disease.

**Matrix components**

• **Type I collagen** is the main protein, forming parallel lamellae of differing density (which impairs spreading of cracks). In cortical bone, concentric lamellae form around a central blood supply (Haversian system), which communicates via transverse (Volkmann's) canals.

• **Non-collagen proteins** include osteopontin, osteocalcin and fibronectin.

• **Bone mineral** largely consists of calcium and phosphate in the form of hydroxyapatite.

**Bone cells**

**Osteoblasts**

Derived from local mesenchymal stem cells, these cells synthesize matrix (osteoid) and regulate its mineralization. After bone formation, the majority of osteoblasts are removed by apoptosis (see p. 105), others remaining at the bone/marrow interface as lining cells or within the bone as osteocytes. Osteoblasts regulate bone resorption through the balance in expression of the stimulatory receptor activator of nuclear factor kappa B ligand (RANKL) and its antagonist, osteoprotegerin (OPG). Osteoblasts are rich in alkaline phosphatase and express receptors for parathyroid hormone (PTH), oestrogen, glucocorticoids, vitamin D, inflammatory cytokines and the transforming growth factor-beta (TGF-β) family, all of which may therefore influence bone remodelling.

**Osteocytes**

These small cells, derived from osteoblasts, are embedded in bone and interconnected with each other and with bone lining cells through cytoplasmic processes. They respond to mechanical strain by undergoing apoptosis or through altered cell signalling, which in turn activates bone formation with or without prior resorption. As osteocytes also express RANKL and OPG, the relative importance of osteocytes and osteoblasts in bone resorption function continues to be explored.

**Osteoclasts**

These cells have the unique capacity to resorb bone and are derived from haemopoietic precursors of the macrophage lineage. In response to RANKL, macrophage colony stimulating
factor (M-CSF) and local adhesion factors (integrins), osteoclasts attach to bone, creating a ruffled border that forms a number of extracellular lysosomal compartments. Hydrogen ions are actively secreted into these spaces and the acid environment removes the mineral phase before specialized cysteine proteases (e.g. cathepsin K) resorb the collagen matrix.

**Bone growth and remodelling**

Longitudinal growth occurs at the epiphyseal growth plate, a cartilage structure between the epiphysis and metaphysis *(Fig. 19.1)*. Cartilage production is tightly regulated, with subsequent mineralization and growth finally arrested at 18–21 years, when the epiphysis and metaphysis fuse.

![A longitudinal section of a growing long bone.](http://www.nice.org.uk/Guidance/TA160 (23 July 2012).)

In adults, bone is regularly remodelled to ensure repair of microdamage and turnover of calcium and phosphate for homeostasis. This remodelling cycle is carried out by the basic multicellular unit (BMU; *Fig. 19.2*). Signals initiating resorption include osteocyte apoptosis and altered signalling (sclerostin, prostaglandins, RANKL and other molecules), resulting in
localized retraction of bone-lining cells and binding of multinucleate osteoclasts to the bone surface, followed by bone resorption. Bone formation involves reciprocal effects of \textit{wnt} versus \textit{dickkopf (Dkk)} and sclerostin on the LRP5/6-β-catenin pathway. The switch from resorption to formation may rely on osteocyte signalling or on release of signals from the bone matrix, such as TGF-β. Bone remodelling is said to be coupled when formation follows resorption, but may be unbalanced when the amount of bone removed is not replaced with an equal amount.

**FIGURE 19.2** Bone is remodelled in response to alterations in two reciprocal systems. (a) Quiescent bone (centre) may experience reduced load in response, the osteocyte increases expression of sclerostin (SOST+), inhibiting the response to \textit{wnt} via the LRP5/frizzled co-receptor complex (orange). (b) Microdamage causes osteocyte apoptosis, with direct osteoclast-generating effects via receptor activator of nuclear factor kappa B ligand (RANKL), and loss of the inhibitory effect of SOST on later bone formation (dashed line, SOST−). The osteoblastic lining cells retract from an area of bone, forming a bone remodelling unit, while increased expression of RANKL and reduced osteoprotegerin (OPG) activates the formation of bone-resorbing multinucleate osteoclasts from circulating precursors; the resorbed area is then replaced by new osteoid, formed by cuboidal osteoblasts. As new osteocytes are formed, SOST levels rise and the osteoblasts cease formation, the majority undergoing apoptosis. (c) If bone experiences loading without damage, sclerostin expression is reduced (SOST−), increasing signal response to \textit{wnt}, activation of osteoblast bone formation, and increased OPG expression.

Examples of bone remodelling include:

- Myeloma cells have dual lytic effects, with enhanced expression of RANKL and expression of \textit{Dkk}
- In rheumatioid arthritis, RANKL and \textit{Dkk} are increased
- In spondyloarthritis (characterized by new bone formation alongside erosion) \textit{Dkk} is inhibited, with the increased \textit{wnt} activity also increasing OPG relative to RANKL
- Corticosteroids may increase osteocyte SOST expression, and stimulate expression of \textit{Dkk}. 
**Calcium homeostasis and its regulation**

Calcium homeostasis is regulated by the effects of PTH and 1,25-dihydroxyvitamin D \((1,25(OH)_2D_3)\) on gut, kidney and bone. Calcium-sensing receptors are present in the parathyroid glands, kidney and brain.

**Calcium absorption and distribution**

Daily calcium consumption (*Fig. 19.3*), primarily from dairy foods, is 20–25 mmol (800–1000 mg). The combined effect of calcium and vitamin D deficiency contributes to the bone fragility seen in some older persons. Intestinal absorption of calcium is reduced by vitamin D deficiency and in malabsorption states (see p. 204).

![Calcium exchange in the normal human. The amounts are shown in mmol per day.](image)

**Vitamin D metabolism**

The primary source of vitamin D (*Fig. 19.4*) in humans is photoactivation in the skin of 7-dehydrocholesterol to cholecalciferol, which is then converted first in the liver to 25-hydroxyvitamin D \((25(OH)D_3)\) and subsequently in the kidney (by the enzyme 1α-hydroxylase) to 1,25(OH)_2D_3. (This step can occur in lymphomatous and sarcoid tissue, resulting in hypercalcaemia.) Regulation of the latter step is by PTH, phosphate and feedback inhibition by 1,25(OH)_2D_3.
Parathyroid hormone

Parathyroid hormone (PTH), an 84-amino-acid hormone, is secreted from the chief cells of the parathyroid gland, which have calcium-sensing and vitamin D receptors. PTH increases renal phosphate excretion and increases plasma calcium by:

- increasing osteoclastic activity in bone (a rapid response)
- increasing intestinal absorption of calcium (a slower response)
- increasing 1α-hydroxylation of vitamin D (the rate-limiting step)
- increasing renal tubular reabsorption of calcium.

Hypomagnesaemia can suppress the normal PTH response to hypocalcaemia.

Calcitonin

Calcitonin is produced by thyroid C cells. Although calcitonin inhibits osteoclastic bone
resorption and increases the renal excretion of calcium and phosphate, neither excess calcitonin (seen in medullary carcinoma of the thyroid) nor its deficiency following thyroidectomy has significant skeletal effects in humans.

ALP, alkaline phosphatase; Ca, calcium; DXA, dual energy X-ray absorptiometry; MBD-CKD, metabolic bone disorder of chronic kidney disease; PTH, parathyroid hormone.

**Total plasma calcium**

*Normal range 2.2–2.6 mmol/L.* About 40% is ionized and physiologically active; the remainder is complexed or protein-bound. As ionized calcium is difficult to measure, normal practice is to measure total calcium, correcting the value to allow for protein binding.
according to the following formula: add or subtract 0.02 mmol/L for each gram per litre of a simultaneous albumin level below or above 40 g/L. For critical measurements, samples should be taken in the fasting state and without a tourniquet (the latter may increase local plasma calcium concentration).

**Plasma phosphate**

*Normal range 0.8–1.4 mmol/L.* Phosphate is essential to most biological systems. High levels are found in chronic kidney disease (CKD) and hypoparathyroidism, while low levels are associated with primary hyperparathyroidism, hypophosphataemic rickets and osteomalacia, and other disorders associated with reduced renal tubular phosphate reabsorption.

**Plasma PTH**

*Normal range 10–65 ng/mL.* The PTH assay measures the intact hormone. In hypercalcaemia not due to hyperparathyroidism, serum PTH levels are suppressed. Lithium toxicity may be associated with raised PTH levels; in familial hypocalciuric hypercalcaemia (FHH), serum PTH may be normal or marginally elevated.

**Serum 25-hydroxyvitamin D**

Vitamin D status is best assessed using serum 25-(OH)D₃, as 1,25(OH)₂D₃ has a short half-life and does not accurately reflect true vitamin D status. **Vitamin D deficiency** is defined as <25 nmol/L (10 ng/mL) and **vitamin D insufficiency** as <75 nmol/L (30 ng/mL). Rickets and osteomalacia occur with prolonged vitamin D deficiency.

The significance of vitamin D insufficiency is uncertain but it has been linked to a wide range of conditions, including ischaemic heart disease, multiple sclerosis and a variety of cancers. Recent evidence suggests that racial differences are present in the assessment of vitamin D status. Black Americans have consistently lower levels of 25-(OH)D₃ than white Americans but also lower levels of vitamin D-binding protein, resulting in equivalent bioavailable 25-(OH)D₃.

**24-hour urinary calcium**

*Normal range 2.5–6.25 (female) and 7.5 (male) mmol/24 h.* This is increased where renal tubular reabsorption of calcium is decreased, and in hypercalcaemia. One exception is FHH, where the genetic defect leads to inappropriately reduced calcium excretion. Measurement of 24-hour urinary calcium excretion should be performed in the assessment of hypercalcaemic patients.

**Biochemical markers of bone formation and resorption**

The clinical use of these biochemical markers is limited by large biovariability and measurement variance. Serial measurements at the same time of day in individual patients are useful in assessing response to treatment of metabolic bone diseases.
• **Bone-specific alkaline phosphatase.** Circulating alkaline phosphatase is derived from bone, liver and placenta. The bone-specific isoenzyme can be measured as a marker of formation, although there is some overlap with the liver isoenzyme. Elevated serum levels occur during bone growth: for example, in adolescents, fracture repair, and high-bone-turnover states.

• **Type 1 collagen pro-peptides.** These are by-products of collagen synthesis. Serum levels of both the carboxyterminal (P1CP) and aminoterminal (P1NP) pro-peptides reflect bone formation.

• **Serum osteocalcin.** This is another bone formation marker.

• **Serum or urine levels of N-terminal (NTX) and C-terminal (CTX) cross-linked telopeptides.** These reflect bone resorption. They may change rapidly in response to anti-resorptive drugs or in disease states, and have been used to assess fracture risk.

### Diagnostic imaging

• **Plain radiographs.** These identify fractures, tumours and infections. Other specific features may be seen (see following sections).

• **Radionucleotide imaging.** The uptake of a $^{99m}$technetium-labelled bisphosphonate in bone reflects bone turnover and blood flow. Increased uptake is therefore seen in fractures, tumour and metastatic deposits, infection and Paget's disease of bone.

• **Magnetic resonance imaging (MRI).** This is the most sensitive and specific test for the diagnosis of osteomyelitis. It is also useful in the detection of stress fractures, which may not be demonstrated on plain radiographs. A technique to suppress the high signal associated with bone marrow (such as STIR sequences; see p. 651) allows highly sensitive recognition of ‘bone marrow oedema’, a non-specific feature of a number of bone disorders, including osteonecrosis.

• **Bone biopsy (Fig. 19.5).** A core of bone is removed, including both cortices of the iliac crest, using a trephine. The non-decalcified specimen is examined for static and dynamic (bone turnover) indices. An oral tetracycline is given to the patient prior to the biopsy, for 2 days on two occasions 10 days apart, allowing assessment of the rate of bone turnover and mineralization. Biopsy is most commonly used in the assessment of suspected renal bone disease and osteomalacia.
Osteoporosis

Osteoporosis is defined as ‘a disease characterized by low bone mass and micro-architectural deterioration of bone tissue, leading to enhanced bone fragility and an increase in fracture risk’.

Using bone densitometry at the hip or spine measured by dual X-ray absorptiometry (DXA), the World Health Organization (WHO) also defines osteoporosis as a bone density of 2.5 standard deviations (SDs) below the young healthy adult mean value (T-score ≤−2.5) or lower. Values between −1 and −2.5 SDs below the young adult mean are termed ‘osteopenia’. The rationale for this definition is the inverse relationship between bone mineral density (BMD) and fracture risk in postmenopausal women and older men. However, this definition should not
be applied to younger populations.

Fractures due to osteoporosis are a major cause of morbidity and mortality in elderly populations, with osteoporotic fractures of the spine causing acute pain or deformity and postural back pain. One in two women and one in five men aged 50 years will have an osteoporotic fracture during their remaining lifetime. Caucasian and Asian races are particularly at risk. As the risk of fracture increases exponentially with age, changing population demographics will increase the burden of disease.

### Pathogenesis

Osteoporosis results from increased bone breakdown by osteoclasts and decreased bone formation by osteoblasts, leading to loss of bone mass.

Bone mass decreases with age (Fig. 19.6) but will depend on the ‘peak’ mass attained in adult life and on the rate of loss in later life. Genetic factors are the single most significant influence on peak bone mass. Multiple genes are involved, including collagen type 1A1, vitamin D receptor and oestrogen receptor genes. Nutritional factors, sex hormone status and physical activity also affect peak mass. Not all causes of osteoporosis affect bone remodelling and architecture in the same way.

**Oestrogen deficiency** results in increased numbers of remodelling units, premature arrest of osteoblastic synthetic activity and perforation of trabeculae, with a loss of resistance to fracture that is not fully reflected in the bone density measurement.

**Glucocorticoids** induce a high-turnover state initially, with increased fracture risk evident within 3 months of starting therapy. More prolonged use leads to a reduced-turnover state but with a net loss due to reduced synthesis (through increased inhibition of the wnt-LRP5/6 axis).

**Ageing** results in increased turnover at the bone/vascular interface within cortical bone, resulting in a weak structure for the stresses occurring in this area of long bones.
Risk factors for fracture may exert their effect through reducing BMD, or they may increase risk over that attributable to BMD, meaning that they are BMD-independent (Box 19.2). Oestrogen deficiency is a major factor in the pathogenesis of accelerated bone loss due to a normal or premature menopause or amenorrhoea in anorexia and in athletes. In the elderly, vitamin D insufficiency and consequent hyperparathyroidism reduce BMD. However, previous fracture, increasing age, glucocorticoid therapy, smoking and falls increase the risk of fracture at any given BMD. For instance, 10% of women who are 65 years old and have a T-score of −2 at the hip would be expected to sustain a fracture over the next 10 years; if similar women had a Colles' fracture, smoked and had prolonged exposure to steroids, their risk would be closer to 26% in the same period.

Box 19.2
Risk factors for fragility fractures

BMD-dependent
Female sex
Caucasian/Asian
Gastrointestinal disease
Hypogonadism
Immobilization
Chronic liver disease
Chronic kidney disease
Low dietary calcium intake
Vitamin D insufficiency
Chronic obstructive pulmonary disease
Cushing syndrome
Hyperthyroidism
Hyperparathyroidism
Diabetes mellitus
Mastocytosis
Multiple myeloma
Osteogenesis imperfecta

Drugs
Heparin
Calcineurin inhibitors, e.g. ciclosporin
Anticonvulsants
Thiazolidinediones
Aromatase inhibitors
Anti-androgens
GnRH analogues
Proton pump inhibitors
Selective serotonin reuptake inhibitors

**BMD-independent**

Increasing age
Previous fragility fracture
Family history of hip fracture
Low body mass index
Smoking
Excess alcohol use
Glucocorticoid therapy
High bone turnover
Increased risk of falling
Rheumatoid arthritis

Treatment depends on the type of risk factors: if they are recognized as ‘BMD-dependent’, they respond to bone-directed treatment; if classed as ‘BMD-independent’, they require additional intervention (e.g. reduction of falls risk).

**Clinical features**

Fracture is the only cause of symptoms in osteoporosis. *Vertebral crush fracture* is suggested by the sudden onset of severe pain in the spine, often radiating around to the front. However, only about 1 in 3 vertebral fractures is symptomatic. Pain from mechanical derangement, increasing kyphosis, height loss and abdominal protuberance follow crushed vertebrae. *Colles’ fractures* typically follow a fall on an outstretched arm. *Fractures of the proximal femur* usually occur in older individuals falling on their side or back.

Other causes of low-trauma fractures must not be overlooked, including metastatic disease and myeloma.

**Investigations**

*Plain radiographs (Fig. 19.7)* usually show a fracture and may reveal previously asymptomatic vertebral deformities. Such clinically silent fractures may also be detected during DXA scanning with an additional analysis (called *lateral vertebral assessment*, carried out with a much lower radiation dose than conventional imaging).
Bone density

DXA measures areal bone density (mineral per surface area rather than a true volumetric density), usually of the lumbar spine and proximal femur. It is precise and accurate, uses low doses of radiation and is the ‘gold standard’ in diagnosis of osteoporosis (Fig. 19.8). Because of osteophytes, spinal deformity and vertebral fractures, spinal values may be artefactually elevated and should be interpreted with caution in the elderly.
Associated disease and risk factors

Investigations to exclude other diseases or identify contributory factors associated with osteoporosis should be performed and are particularly necessary in men, in whom secondary causes are more common (Box 19.2).

Selection of individuals for treatment: risk assessment

The purpose of treatment in osteoporosis is to reduce the risk of fractures (Box 19.3). Thus, assessment of absolute fracture risk should be made in every case. All patients with a history of fragility fracture should be reviewed for treatment. In those aged over 75 years, DXA is often not necessary prior to treatment, but in those under 75 years of age, DXA is useful in guiding treatment decisions (Box 19.4 and Fig. 19.9). Although age and BMD measurements in the spine and proximal femur are the most useful data for assessing fracture risk, it is vital to recognize that the majority of fragility fractures occur in women with a T-score better than −2.5. Therefore, factors that are known to increase fracture risk independently of BMD should be taken into account when assessing an individual's risk of fracture, for example, using risk calculators such as FRAX®. The threshold for recommending treatment will be determined by the cost-effectiveness of treatment in a particular healthcare setting and by clinical judgement.

Box 19.3

Management of osteoporosis: summary

*Treatment is guided by risk of fracture, not BMD alone.*

If there is an intermediate risk from clinical factors, request a DXA scan (see [http://www.shef.ac.uk/FRAX](http://www.shef.ac.uk/FRAX) or other risk calculator until familiar with assessments).

Do not under-estimate the risk from steroids or previous fracture.

Many guidelines (e.g. NICE) recommend bisphosphonate as first-line drugs in most cases.
Other options include:

- **denosumab:**
  - in the young (to defer bisphosphonate use)
  - for a new fracture on a bisphosphonate or a fall in BMD or bisphosphonate use for 5–10 years
  - after hip fracture
- **teriparatide** if there are multiple vertebral fractures or a high risk
- **i.v. zoledronate** after hip fracture
- **strontium ranelate** if the patient is at high risk and there is no possible alternative.

**BMD monitoring** is required in:

- selected high-risk cases
- low-risk cases not treated.

BMD, bone mineral density; DXA, dual-energy X-ray absorptiometry; NICE, National Institute for Health and Care Excellence.

---

**Box 19.4**

**Indications for DXA scanning**

- Radiographic osteopenia
- Previous fragility fracture (in those aged <75 years)
- Glucocorticoid therapy (in those aged <65 years)
- Body mass index <19 kg/m²
- Maternal history of hip fracture
- BMD-dependent risk factors (see Box 19.2)

In patients presenting with height loss and/or kyphosis, lateral thoracic spine X-ray should be the initial investigation.

BMD, bone mineral density; DXA, dual-energy X-ray absorptiometry.
Prevention and management

- **Symptomatic management.** New vertebral fractures may require bed rest for 1–2 weeks with strong analgesia, muscle relaxants (e.g. diazepam 2 mg 3 times daily) and gradual physiotherapy to restore confident mobilization (see p. 659). Non-spinal fractures should be treated by conventional orthopaedic means.

- **Calcium and vitamin D.** Daily intakes of 800–1200 mg of calcium and 400–800 IU of vitamin D are recommended throughout life for optimum bone health. Dietary intake of calcium, and vitamin D from sunshine and diet, are preferable. For those not meeting calcium intake targets, or those with low serum 25-\((\text{OH})\)D\(_3\) levels, supplements are recommended, e.g. colecalciferol 20 µg and calcium 2 g daily.

- **Lifestyle measures.** Weight-bearing exercise for 30 min 3 times a week may increase BMD, while gentle exercise in the elderly may reduce the risk of falls and improve the protective responses to falling. Smoking and excess alcohol use should be avoided.

- **Reduction of falls.** Physiotherapy and assessment of home safety are helpful. Hip protectors do reduce fractures in the elderly in residential care when worn correctly, but compliance is poor.

**Pharmacological intervention**
Most interventions (see Fig. 19.5) act by inhibiting bone resorption (anti-resorptives), the exception being PTH peptides, which stimulate bone formation. The impression from bone turnover markers that strontium ranelate may have both anti-resorptive and stimulatory effects remains poorly understood.

The evidence base for the anti-fracture efficacy of interventions varies. Some interventions have been shown to reduce fracture at vertebral and non-vertebral sites, including the hip, whereas others have not been demonstrated to be effective at all sites (Box 19.5). Since a fracture at one site increases the risk of subsequent fracture at any site, treatments with efficacy at all major fracture sites (particularly spine and hip) are preferable. Hence, the bisphosphonates and denosumab are generally regarded as first-line options in the majority of postmenopausal women with osteoporosis.

### Bisphosphonates

Synthetic analogues of bone pyrophosphate, bisphosphonates adhere to hydroxyapatite and inhibit osteoclasts. Alendronate and risedronate are given as once-weekly doses, zoledronate as a once-yearly infusion, and ibandronate usually as a once-monthly oral therapy (a 3-monthly intravenous injection is rarely used).

Oral bisphosphonates should be taken fasting, with a large drink of water, while standing or sitting upright. The patient should then remain upright and avoid food and drink for at least 30 minutes.

Bisphosphonates are generally well tolerated but may be associated with upper gastrointestinal side-effects such as oesophagitis, particularly if the dosing instructions are not closely followed. Bisphosphonates should be used with careful monitoring in patients who have chronic kidney disease (stage 4 or 5). Osteonecrosis of the jaw is rarely seen following
high-dose intravenous bisphosphonates in patients who have malignant disease. It is associated with poor dental hygiene. As prolonged suppression of bone turnover is linked with atypical femoral fractures, it is currently advised to reassess bisphosphonate treatment after 5 years. Only those with vertebral fractures and a T-score at the neck of femur of $<-2.5$ at this 5-year scan appear to have a reduced risk of fracture with continued treatment.

**Denosumab**

Denosumab is a fully human monoclonal antibody to RANKL and is administered as a single subcutaneous injection every 6 months. It is an anti-resorptive agent that increases BMD and reduces fractures at the spine, hip and other non-vertebral sites. Fracture risk reduction at the spine is equivalent to that with most bisphosphonates, and risk reduction at the hip is superior (with the exception of zoledronic acid). Adverse effects are infrequent: most commonly dysuria, rarely cellulitis. Osteonecrosis of the jaw and atypical femoral fractures have also occurred but estimating the true frequency of these rare adverse events is not possible with current data.

**Strontium ranelate**

This is used only when no alternative exists because of its adverse cardiovascular effects. It has weak anti-resorptive activity whilst maintaining bone formation. It reduces the risk of vertebral fractures in postmenopausal women with osteoporosis, and the risk of hip and other non-vertebral fractures in high-risk subgroups (women with previous fracture and T-scores at the hip of $-2.4$ or less). Nausea, diarrhoea and headaches are infrequent side-effects.

**Selective oestrogen-receptor modulators**

Selective oestrogen-receptor modulators (SERMs) include raloxifene and bazedoxifene. They have no stimulatory effect on the endometrium but activate oestrogen receptors in bone. Both prevent BMD loss at the spine and hip in postmenopausal women, but have been found to reduce only vertebral fracture rates. Leg cramps and flushing may occur and the risk of thromboembolic complications is also increased to a degree similar to that seen with hormone replacement therapy (HRT; see pp. 1296–1297 and *Box 29.1*). The use of SERMs is associated with a small increase in the risk of stroke.

**Recombinant human parathyroid hormone**

Recombinant human PTH peptide 1–34 (teriparatide) and recombinant human PTH 1–84 are anabolic agents that stimulate bone formation. Teriparatide reduces vertebral and non-vertebral fractures in postmenopausal women with established osteoporosis, although data on hip fracture are not available. It is given by daily subcutaneous injection for 24 months. Recombinant human PTH 1–84 is also administered by once-daily subcutaneous injection but has been shown to reduce only vertebral fractures. An anti-resorptive drug, such as denosumab, should be given on completion of PTH peptide therapy to maintain the increase in BMD. Non-osteoporotic bone diseases, such as osteomalacia, should be excluded prior to
treatment. PTH peptide therapy is indicated mainly in severe cases of vertebral osteoporosis or in women who fail to respond to other therapies. Teriparatide may cause mild transient hypercalcaemia but routine monitoring is not required. Nausea and headache may occur. Recombinant human PTH 1–84 is associated with a higher incidence of hypercalcaemia and hypercalciuria, and routine monitoring is advised. Neither agent should be used in people with skeletal metastases or osteosarcoma.

**Hormone replacement therapy**

Because of its adverse effects on breast cancer and cardiovascular disease risk, HRT is not indicated for osteoporosis except in early postmenopausal women who also have significant perimenopausal symptoms.

**Calcitriol (1,25-(OH)$_2$D$_3$) and calcitonin**

These may reduce vertebral fracture rate, although the data are inconsistent.

**Combination therapies**

Combination therapies, either with two anti-resorptive agents, or an anti-resorptive and an anabolic agent, often produce larger increases in BMD than monotherapy but have not been shown to result in greater fracture reduction.

**Surgery**

This is required to stabilize vertebral fractures. Percutaneous vertebroplasty and balloon kyphoplasty are discussed on page 659. Hip fractures are dealt with by hip replacements or stabilization with pins.

**Treatment of specific conditions**

**Glucocorticoid-induced osteoporosis**

Individuals requiring continuous oral glucocorticoid therapy for 3 months or more (at any dose) should be assessed for coexisting risk factors (age, previous fracture, hormone status). Postmenopausal women, men aged over 50 years and any individuals who have sustained a fragility fracture should receive treatment without waiting for DXA scanning. DXA results and fracture risk assessment guide treatment for other patients (see Box 19.4). For these individuals, bisphosphonates and teriparatide are the approved agents. Denosumab is likely to be equally effective; though it is not yet formally approved for this indication, its mode of delivery may be advantageous in some settings.

**Osteoporosis in men**

Alendronate, risedronate and denosumab increase BMD and reduce vertebral fractures in men with osteoporosis. Teriparatide is also approved for use in this setting. In men with osteoporosis who have clinical and biochemical evidence of hypogonadism, testosterone
replacement is also used.

---

**Osteonecrosis**

This is also known as aseptic, avascular or ischaemic necrosis of bone. There are a multitude of risk factors but over 80% of cases are attributed to glucocorticoid treatment or alcohol excess. Less frequent causes include sickle cell disease, systemic lupus erythematosus (SLE), deep-sea diving (Caisson's disease), endocrine disorders (e.g. Cushing's, diabetes mellitus), trauma, human immunodeficiency virus (HIV) infection and irradiation.

Osteonecrosis usually presents with joint pain, the shoulder or hip being most commonly affected, but can be asymptomatic, particularly on the opposite side in the same person. It may only be recognized when it results in collapse of the articular bone.

MRI best confirms the diagnosis by showing bone marrow oedema. If advanced, it can be seen on plain X-rays.

**Management** is mainly symptomatic. Surgical options include drilling through the bone cortex (decompression), vascularized bone grafts, or rotation of the affected bone away from the load-bearing area; however, joint replacement is often required. Bisphosphonates may reduce pain, and progression has been reduced with statin therapy in steroid-associated osteonecrosis.

---

**Paget's Disease of Bone**

Paget's disease of bone is a focal disorder of bone remodelling. Increased osteoclastic bone resorption is followed by a compensatory increase in new bone formation, increased local bone blood flow and fibrous tissue in adjacent bone marrow. Ultimately, formation exceeds
resorption but the new woven bone is weaker than normal bone, which leads to deformity and increased fracture risk. Paget's disease does not spread, but can become symptomatic at previously silent sites.

Epidemiological studies are difficult because most affected individuals are asymptomatic. Paget's disease is most often seen in Europe and particularly in northern England. It affects men and women (2:3) over the age of 40 years. The incidence approximately doubles per decade thereafter, with up to 10% of individuals radiologically affected by the age of 90. For unknown reasons, the incidence and severity of Paget's disease have decreased in recent years.

### Aetiology and pathogenesis

Genetic factors are implicated in Paget's disease. A positive family history is noted in about 15%. Mutations in **SQSTM1**, which encodes the osteoclast mediator protein p62, have been reported in up to 10% of cases. Intracellular inclusions in the osteoclasts in pagetic lesions are believed to be paramyxovirus nucleocapsid (e.g. canine distemper virus, measles or respiratory syncytial virus). However, similar inclusions are seen in other bone disorders, and theories of a viral aetiology in Paget's remain contentious. Altered expression of **c-fos** (an oncogene) is one suggested mechanism linking viral infection with the pathogenic changes in osteoclasts, which are more numerous and contain an increased number of nuclei (up to 100).

### Clinical features (see *Fig. 19.10A*)

Between 60% and 80% of people with radiologically identified Paget's disease are asymptomatic. Diagnosis often follows the finding of an asymptomatic elevation of serum alkaline phosphatase, or a plain X-ray performed for other indications. The disease may involve one bone (monostotic, in 15%) or many (polyostotic). The most common sites, in order of frequency, are pelvis, femur, lumbar spine, skull and tibia (see *Fig. 19.10C*). Small bones of the feet and hands are rarely involved.
Symptoms and complications include:

- **bone pain**
- **joint pain** when an involved bone is close to a joint, leading to cartilage damage and osteoarthritis
- **deformities**, in particular bowed tibia and skull changes
- **neurological complications** – nerve compression (deafness from VIIIth cranial nerve involvement; cranial nerves II, V and VII may also be involved); spinal stenosis; hydrocephalus due to blockage of the aqueduct of Sylvius
- **high-output cardiac failure** and myocardial hypertrophy due to increased bone blood flow
- **hypocalcaemia** – rarely seen outside the setting of fracture
- **pathological fractures**
- **osteosarcoma** – occurs in fewer than 1% of cases of Paget's and may be heralded by an increase in bone pain or swelling in a previous pagetic bone area.

### Investigations

- **Increased serum alkaline phosphatase** with normal serum calcium and phosphate reflects increased bone turnover. Levels may be normal with limited or monostotic Paget's disease. Levels are reduced with treatment and increased during relapse.
- **Vitamin D** should be measured, as deficiency is frequent in the age group affected by Paget's disease and should be corrected (see p. 718) to avoid hypocalcaemia following bisphosphonate treatment
- **X-ray** features (Fig. 19.10B) vary from predominantly lytic lesions (osteoporosis...
circumscripta in the skull is characteristic), through a mixed phase, to a mainly sclerotic phase of bone expansion, cortical thickening and coarsening of the trabecular pattern.

- **Isotope bone scans** are useful to determine the extent of skeletal involvement, but are unable to distinguish between Paget's disease and sclerotic metastatic carcinoma (especially breast and prostate).

### Management

Bisphosphonates are the mainstay of treatment. New bone formed after treatment is lamellar, not woven (reflecting normalization of bone turnover rather than a direct effect on osteoblasts). Treatment is interrupted and repeat courses are guided by symptoms and by recurrence in elevation of alkaline phosphatase. In addition to treatment of symptomatic patients, treatment of asymptomatic lesions is appropriate if there is a significant risk of potential complications, such as fracture in weight-bearing long bones or the spine, nerve entrapment or deafness with skull involvement, and before orthopaedic procedures in involved bone (to reduce vascularity).

**Intravenous bisphosphonates**

**Zoledronate** is the most commonly used agent for Paget's disease, administered as a single infusion over 15 min. **Pamidronate** is an alternative but takes longer to infuse and is less potent; some patients develop drug resistance for unknown reasons. Both drugs can be associated with a first-dose reaction characterized by ‘flu-like’ symptoms, including transient pyrexia over 24–48 hours, which can be ameliorated with paracetamol.

**Oral bisphosphonates**

Oral bisphosphonates are used at doses higher than those for osteoporosis (e.g. 30 mg risedronate daily for 2 months, or 40 mg alendronate daily for 6 months) and are less effective than intravenous zoledronic acid.

**Surgery**

Joint replacement or osteotomy is sometimes necessary to correct deformity or pain due to associated degenerative joint disease. Neurosurgery may be needed where there is spinal disease. Osteosarcoma usually requires amputation, though wide excision and limb salvage can be successful at distal sites.

### Further reading

**Rickets and Osteomalacia**

Osteomalacia is defective mineralization of newly formed bone matrix or osteoid. Rickets is
defective mineralization at the epiphyseal growth plate and is found in association with osteomalacia in children.

### Aetiology

Many factors can result in defective mineralization of the osteoid. For normal mineralization, adequate levels of vitamin D, calcium and phosphate, adequate activity of alkaline phosphatase, a normal pH at the osteoid surface and normal osteoid composition are all necessary (Box 19.6).

#### Box 19.6

**Causes of rickets/osteomalacia**

**Deficient intake or absorption of vitamin D**
- Inadequate sun exposure or deficient synthesis in skin
- Low dietary intake
- Malabsorption: coeliac disease, Crohn's disease, gastrectomy, primary biliary cirrhosis

**Defective 1α-hydroxylation**
- Chronic kidney disease
- Vitamin D-dependent rickets type I – due to deficiency of 1α-hydroxylase

**Primary renal phosphate wasting**
- Renal tubular acidosis (also by causing metabolic acidosis)
- Hereditary hypophosphataemic rickets (vitamin D-resistant rickets)
- Dent's disease
- Fanconi syndrome
- Multiple myeloma
- Tumour-induced osteomalacia

**Inhibitors of mineralization**
- Fluoride, aluminium, bisphosphonates
- Metabolic acidosis

**Defective vitamin D receptors**
- Hereditary vitamin D-resistant rickets (previously known as vitamin D-dependent rickets type II)

The most common cause of osteomalacia is hypophosphataemia due to hyperparathyroidism
secondary to vitamin D deficiency. The most common cause of vitamin D deficiency worldwide is dietary deficiency. Bread, milk and cereals in high-income countries are now fortified with vitamin D. This has led to a much-reduced incidence of osteomalacia and rickets.

Vitamin D is produced in the skin through the action of sunlight on 7-dehydrocholesterol (see Fig. 19.4). Lack of sun exposure can lead to vitamin D deficiency, especially in individuals living in temperate regions who keep large parts of the skin covered throughout the year.

Vitamin D is a fat-soluble vitamin, so gastrointestinal disease can result in malabsorption. Gastrectomy, cystic fibrosis, coeliac disease, Crohn's disease and primary biliary cirrhosis are well-recognized causes.

Due to the intimate involvement of the kidney in phosphate balance, a number of causes of osteomalacia are mediated by the kidney (see p. 779). Primary renal phosphate wasting occurs in tumour-induced osteomalacia, multiple myeloma and Fanconi syndrome. Proximal (type 2) renal tubular acidosis can cause osteomalacia due to both renal phosphate wasting and abnormal osteoid pH secondary to metabolic acidosis.

### Clinical features

Osteomalacia may be asymptomatic and identified incidentally on routine investigations following a fragility fracture. When symptomatic, it characteristically causes muscle weakness and widespread bone pain. Muscle weakness is due to a multifactorial proximal myopathy, with low vitamin D, hypophosphataemia and high PTH levels all contributing. It results in a characteristic waddling gait with difficulty climbing stairs and getting out of a chair. Generalized bone pain and tenderness are thought to be caused by hydration of the demineralized matrix, resulting in periosteal distension. The pain is typically a dull ache that is worse on weight-bearing and walking. It can be reproduced by pressure on the sternum or tibia. Insufficiency fractures can occur when the quality of the bone is insufficient to handle the stress of weight-bearing.

At birth, neonatal rickets may present as craniotabes (a thin, deformed skull). In the first few years of life, there may be widened epiphyses at the wrists and beading at the costochondral junctions, producing the ‘rickety rosary’, or a groove in the rib cage (Harrison's sulcus). In older children, lower limb deformities are seen. A myopathy may also occur. Hypocalcaemic tetany may occur in severe cases.

### Investigations

- **Serum alkaline phosphatase** is elevated in 90% of cases.
- **Low serum calcium, low phosphate** and **elevated PTH** are each present in approximately half of the cases.
- **Serum 25-(OH)D₃** is low, usually less than 25 nmol/L (10 ng/mL).
- **Serum FGF-23** is elevated in many people with tumour-induced osteomalacia and in
hypophosphataemic rickets.

- **Plain radiographs** demonstrate decreased bone mineralization. The characteristic finding in osteomalacia is Looser's pseudofractures. These are narrow radiolucent lines with sclerotic borders running perpendicular to the cortex. They can be found at any site but are most commonly seen in the femur and pelvis.

- **Tetracycline-labelled bone biopsy** is the gold standard diagnostic test. This is not practical in most clinical settings and is used mainly in research studies.

## Management

Vitamin D replacement is the cornerstone of treatment. Treatment involves two stages: an initial loading stage to replenish body stores of vitamin D, and a subsequent maintenance phase to avoid repeat deficiency. All patients should also receive supplementary calcium of 1000–1200 mg/day. In nutritional deficiency, recommended initial replacement is with vitamin D 50 000 units per week orally. The initial replacement dose should be continued for 8 weeks. Vitamin D is also available as an intramuscular injection; two doses of 300 000 units are usually enough to replenish body stores. Adequacy of vitamin D replacement should be evaluated by re-assaying vitamin D levels, or PTH levels if initially abnormal. This should be followed by regular supplementation with 800–1000 units of vitamin D per day.

Doses for children are lower and are age-dependent. People with gastrointestinal disease and vitamin D deficiency due to malabsorption need higher doses of 10 000–50 000 units per day of vitamin D.

**Tumour-induced osteomalacia** is best treated by removal of the causative neoplasm, which is usually occult and frequently benign. This leads to rapid resolution of symptoms.

## Bone Infections

### Acute and chronic osteomyelitis

Osteomyelitis predominantly occurs in children and chronicity is common. In children, it commonly arises due to haematogenous spread to the vascular metaphysis. In high-income countries, it occurs in around 8 per 100 000 children per year, but it is considerably more common in low-income countries, with boys affected twice as often as girls. Malnutrition, debilitating disease and decreased immunity play a role in the pathogenesis. Without prompt recognition, it has devastating consequences.
*Staphylococcus* is the organism responsible for 90% of cases of acute osteomyelitis. Other organisms include *Haemophilus influenzae* and *Salmonella*; infection with the latter may occur as a complication of sickle cell anaemia. The classic presentation is with fever and localized bone pain with overlying tenderness and erythema, although it is rare in adults and often hard to diagnose, requiring a bone biopsy.

### Diagnosis

- **Imaging:**
  - Plain X-ray is not sensitive in early infection but osteopenia may be present.
  - MRI is highly sensitive, showing marrow oedema in 3 days.
  - Bone scans are also helpful.
- **Blood cultures** are often positive with staphylococcal infection.
- **Bone biopsy and culture** identifies the organism and sensitivities.

### Management

Treatment of osteomyelitis centres on immobilization and antibiotic therapy with intravenous teicoplanin or intravenous flucloxacillin 1–2 g every 6 hours and oral sodium fusidate. Switch to oral antibiotics after 2 weeks and continue for a further 4 weeks. Surgical drainage and removal of dead bone (sequestrum) may be necessary but recurrence is common.

Delayed treatment leads to chronic osteomyelitis. In chronic osteomyelitis, sinus formation is usual. Subacute osteomyelitis is associated with a chronic abscess within the bone (Brodie's abscess). Symptoms may be limited to local pain.

### Tuberculous osteomyelitis

This is usually due to haematogenous spread from a reactivated primary focus in the lungs or gastrointestinal tract. The disease starts in intra-articular bone. The spine is commonly involved (*Pott's disease*), with damage to the bodies of two neighbouring vertebrae leading to vertebral collapse and acute angulation of the spine (gibbus). Later, an abscess forms (‘cold abscess’). Pus can track along tissue planes and discharge at a point far from the affected vertebrae. Symptoms consist of local pain and later swelling if pus has collected. Systemic symptoms of malaise, fever and night sweats occur.

**Management** is as for pulmonary tuberculosis but extended to 9 months (see pp. 1110–1113), together with initial immobilization.

### Neoplastic Disease Of Bone

Bone pain may be due to multiple myeloma, lymphoma, a primary tumour of bone or secondary deposits. The pain is typically unremitting and worse at night, and there are other clinical clues
such as weight loss or ill-health.

**Malignant tumours** of bone are shown in **Box 19.7**. The most common tumours are metastases from the bronchus, breast and prostate. Metastases from kidney and thyroid are less common. Primary bone tumours are rare and usually seen only in children and young adults.

---

<table>
<thead>
<tr>
<th>Box 19.7</th>
</tr>
</thead>
</table>

**Malignant neoplasms of bone**

- **Metastases (osteolytic):**
  - Bronchus
  - Breast
  - Prostate (often osteosclerotic as well)
  - Thyroid
  - Kidney
- **Multiple myeloma**
- **Primary bone tumours** (rare; seen in the young), e.g.:
  - Osteosarcomas
  - Fibrosarcomas
  - Chondromas
  - Ewing's tumour

Symptoms are usually related to the anatomical position of the tumour, with local bone pain. Systemic symptoms (e.g. malaise and pyrexia) and aches and pains occur and are occasionally related to hypercalcaemia. The diagnosis of metastases can often be made from the history and examination, particularly if the primary tumour has already been diagnosed. Symptoms from bony metastases may, however, be the first presenting feature.

---

**Investigations**

- **Skeletal isotope scans** show bony metastases as ‘hot’ areas before radiological changes occur.
- **X-rays** may show metastases as osteolytic areas with bony destruction. Osteosclerotic metastases are characteristic of prostatic carcinoma.
- **MRI** is used extensively, particularly for vertebral lesions.
- **CT and computed tomography-positron emission tomography (CT-PET)** are useful.
- **Serum alkaline phosphatase** (from bone) is usually raised.
- **Hypercalcaemia** occurs in 10–20% of patients who have metastatic malignancies, or is due to ectopic parathormone or PTH-related protein secretion.
- **Prostate-specific antigen** (PSA) and serum acid phosphatase are raised in the presence of
prostatic metastases.

**Management**

Treatment is usually with analgesics and anti-inflammatory drugs. Local radiotherapy to bone metastases relieves pain and reduces the risk of pathological fracture. Some tumours respond to chemotherapy; others are hormone-dependent and respond to hormonal therapy. Bisphosphonates (see p. 714) can help symptomatically. Occasionally, pathological fractures require internal fixation.

**Other Bone Disorders**

**Osteopetrosis (marble bone disease)**

This condition may be inherited in either an autosomal dominant or a typically severe, autosomal recessive pattern. Another recessive form associated with renal tubular acidosis is due to carbonic anhydrase II deficiency.

The severe form is caused by a mutation in the gene encoding a chloride channel necessary for osteoclast activity. Bone density is increased throughout the skeleton but bones tend to fracture easily. Encroachment on the marrow space leads to a leucoerythroblastic anaemia. There is mental retardation and early death. In the mild form, there may be only X-ray changes, but fractures and infection can occur. The acid phosphatase level may be raised. Stem cell transplantation has been successful.

**Scheuermann's disease**

This disease predominantly occurs in adolescent boys. The main feature is a progressive dorsal kyphosis of the thoracic spine. Pain may or may not be present. The cause is unknown. A genetic predisposition, exacerbated by excessive exercise prior to epiphyseal fusion, is one suggested explanation. Older patients with kyphosis may be referred with suspected osteoporotic fractures but found to have long-standing kyphosis due to Scheuermann's. Management is focused on postural exercises and avoidance of precipitants. Surgery may be undertaken to correct kyphosis in severe cases.

**Anatomy and Physiology of the Kidney and Urinary Tract**

**Functional anatomy**
The kidneys are paired organs, 11–14 cm in length in adults, 5–6 cm in width and 3–4 cm in depth. They lie in the retroperitoneum, on either side of the vertebral column at the level of T12–L3 (the right kidney lies lower than the left, pushed down by the liver). Each kidney is enclosed in a fibrous capsule, and has an outer cortex and an inner medulla (Fig. 20.1). There are about 1 million nephrons in each kidney. Each nephron contains a glomerulus, proximal
tubule, loop of Henle, distal tubule and collecting duct. All glomeruli lie in the cortex, and tubules dip in and out of the medulla, where the collecting ducts merge to form the ducts of Bellini, emptying at a papilla at the apex of renal pyramid into a calyx. Urine then flows through merging calyces into the renal pelvis, ureters and bladder.

The renal arteries branch off the abdominal aorta, dividing into smaller branches until arterial blood reaches the glomerulus. About 25% of people have dual or multiple renal arteries on one or both sides. **Afferent glomerular arterioles** arise from interlobular branch arteries to supply the glomerular capillary tuft, which drains into **efferent glomerular arterioles**. Efferent arterioles from (outer) cortical glomeruli drain into a peritubular capillary network within the renal cortex and then into increasingly large and more proximal branches of the renal vein. By contrast, blood from the (inner) juxtamedullary glomeruli passes via vasa recta in the medulla and returns via the cortex to renal veins that drain into the inferior vena cava.

The renal capsule and ureters are innervated via T10–12 and L1 nerve roots, and renal pain is felt over the corresponding dermatomes.

The nephron
A ball of capillaries makes up the glomerular tuft, enclosed by Bowman's capsule, a chamber lined with specialized **parietal epithelial cells** that marks the origin of the tubule (**Fig. 20.2**). The tuft, held together and regulated by **mesangial cells**, then serves as the filtration barrier, allowing filtrate from plasma to move into the urinary (Bowman's) space. The rate of glomerular filtration is influenced by changes in the contractile tone in either the afferent or the efferent arterioles; for example, efferent vasoconstriction will increase the transglomerular capillary pressure, and increase filtration.

**FIGURE 20.2** The glomerular filtration barrier. A. Blood enters the glomerular capillaries and is filtered across the endothelium and the glomerular basement membrane (GBM), and through the filtration slits between podocyte foot processes to produce the primary urine filtrate. In healthy glomeruli, this barrier restricts the passage of macromolecules. The proteins that form the slit diaphragm (SD) are essential for the normal functioning of the filtration barrier. B. Loss of these proteins, either genetically or by acquired means, leads to foot process effacement, breakdown of the barrier and leakage of albumin. C. Electron micrograph of the normal filtration barrier. rbc, red blood cell. (A, B. Adapted from Quaggin S. Sizing up sialic acid in glomerular disease. *Journal of Clinical Investigation* 2007; 117:1480–1483.)

Glomerular capillaries are lined with **endothelial cells**, fenestrated with 60–80-nm pores, and covered with charged glycocalyx. The glomerular basement membrane (GBM), about 300 nm thick and made of type IV collagen, laminin and heparin sulphate, separates endothelium from podocytes (or visceral epithelial cells). Podocytes anchor on to the GBM by means of an extensive trabecular network of foot processes, and hang into Bowman's space. The interdigitating foot processes of podocytes then form the 40-nm filtration slit, a narrow potential space traversed by a protein ‘zipper’ that may prevent the passage of larger molecules (such as albumin) into the urinary space, and regulates the architecture and function of podocytes.

**Mesangial cells** (thought to be related to macrophages) sit within the tuft, able to contract and relax to control blood flow and the filtration surface area along the glomerular capillaries in response to a host of mediators. They also secrete the **mesangial matrix**, which provides the scaffolding for glomerular capillaries.

The **renal tubules** are lined by epithelial cells, which alter the composition of filtrate to form urine eventually. Proximal tubular cells have a luminal brush border to increase (by 30-fold) the surface area exposed to filtrate, rich in transporters and channels. The loop of Henle is lined with squamous cells, which are more permeable to water than solute, and cuboidal epithelium, when the reverse is true. The distal tubule regulates electrolytes and pH through
cuboidal epithelium, and the cortical portion of the collecting ducts contains two cell types with different functions: principal cells (sodium, potassium and water) and intercalated cells (acid–base; see p. 153). Finally, resident interstitial fibroblast-like cells in the renal cortex produce erythropoietin in response to hypoxia (see p. 728).

The juxtaglomerular apparatus
The juxtaglomerular apparatus regulates flow and filtration in each individual nephron. Columnar epithelium in the macula densa (Fig. 20.3) senses the concentration of tubular fluid sodium (higher filtrate flow means more delivered sodium), triggering adenosine-mediated vasoconstriction of the afferent arteriole to drop glomerular filtration (so-called tubule–glomerular feedback). Juxtaglomerular cells secrete renin, able to induce aldosterone release, allowing the apparatus to monitor flow, and respond when necessary to drop glomerular filtration rate (GFR) and retain salt to maintain fluid balance.
FIGURE 20.3 Functional anatomy of the nephron. A. Principal parts of the nephron. The point where the distal tubule is in close proximity to its own glomerulus is called the juxtaglomerular apparatus. This contains the macula densa. B. The countercurrent system. (i) Vasa recta: these vessels descend from the cortex into the medulla and then turn back towards the cortex. (ii) Cortical nephron: these have short descending limbs extending into the outer medulla. (iii) Juxtamedullary nephron: the descending limb dips deeply into the hypertonic inner medulla. Numbers indicate approximate osmolalities.

**Physiology**

A *hydrostatic pressure gradient* of approximately 10 mmHg (a capillary pressure of 45 mmHg minus 10 mmHg of pressure within Bowman's space and 25 mmHg of plasma oncotic pressure) provides the driving force for ultrafiltration of virtually protein-free and fat-free fluid across the glomerular filter into Bowman's space and so into the renal tubule (*Fig. 20.4*).
Pressures controlling glomerular filtration. (1) Capillary hydrostatic pressure (45 mmHg). (2) Hydrostatic pressure in Bowman's space (10 mmHg). (3) Plasma protein oncotic pressure (25 mmHg). Arrows (1, 2, 3) indicate the direction of a pressure gradient.

The **ultrafiltration rate** (GFR) varies with age and sex but is approximately 120–130 mL/min per 1.73 m² surface area in adults. This means that, each day, ultrafiltration of 170–180 L of water and unbound small-molecular-weight constituents of blood occurs. If these large volumes of ultrafiltrate were excreted unchanged as urine, it would be necessary to drink huge amounts of water and salts to stay in balance.

**Absorption of solutes**

Essential electrolytes and other blood constituents, such as glucose and amino acids, are absorbed from filtrate in transit along the long course of the nephron (see Fig. 20.3).

Sodium filters freely, and 60–80% of filtered sodium (and water) is reabsorbed in the late proximal tubule, where the apical membrane Na⁺/H⁺ exchanger (NHE3) trades hydrogen ions into the lumen for absorbed sodium, with anionic chloride (Cl⁻) accompanying sodium to maintain electric neutrality. Secreted H⁺ allows bicarbonate (HCO₃⁻), formed from water and CO₂ by cellular and luminal carbonic anhydrase, to exit the basolateral membrane with absorbed Na⁺. Around 25% is then absorbed in the thick ascending limb of the loop of Henle, as NaCl by the Na⁺/K⁺/2Cl⁻ co-transporter (NKCC). The remaining 5% is absorbed by the thiazide-sensitive NaCl co-transporter and the epithelial sodium channel (ENaC), in the principal cell of the collecting duct. Of the recommended allowance of <6 g/day of **salt** (equivalent to around 2 g Na⁺), around 5–10% will be excreted in urine, stool and sweat.
Potassium is freely filtered at the glomerulus, largely reabsorbed in the proximal tubule, and secreted in the distal tubule and collecting ducts. A clinical consequence of this is that the ability to eliminate unwanted potassium is less dependent on GFR than is the elimination of urea or creatinine. Virtually all bicarbonate, glucose and amino acids (*Fig. 20.3B*) are absorbed in the proximal tubule, making use of the large surface area of this segment of the nephron.

The proximal tubule has a maximal absorptive capacity for many compounds. For instance, if blood glucose levels are elevated above the normal range, the amount filtered (filtered load $=$ GFR $\times$ plasma concentration) may exceed the maximal absorptive capacity of the proximal tubule and glucose will ‘spill over’ into the urine as glycosuria. Inherited or acquired defects in tubular function may also lead to incomplete absorption of a normal filtered load, and substances such as glucose (renal glycosuria), amino acids, phosphate, sodium, potassium and calcium will appear in the urine, either singly or in combination. Examples include cystinuria (a defect of a specific amino acid transporter) or Fanconi syndrome (see pp. 1286–1287).

Other compounds filtered and reabsorbed or secreted to a variable extent include urate, many organic acids and many drugs or their metabolic breakdown products. The more tubular secretion of a compound that occurs, the less dependent elimination is on the GFR.

**Absorption of water**

Urine is concentrated by the countercurrent multiplier mechanism in the loop of Henle, the medullary interstitium, medullary blood vessels (vasa recta) and, finally, the collecting ducts (see pp. 153–154). Sodium and urea in water flow as filtrate into the descending loop, permeable to water and impermeable to sodium. In the thick ascending limb (impermeable to water), active absorption of sodium by the $\text{Na}^+/$$\text{K}^+$/$2\text{Cl}^-$ co-transporter into the interstitium increases the tissue osmolarity. Because of the hairpin nature of the loop, water from the permeable descending limb enters the interstitium by osmosis, where the vasa recta return fluid to the circulation. Constant active absorption of sodium in the ascending loop multiplies this process over time, and the solute concentration at the tip of the loop is fourfold that of extracellular fluid. By this mechanism, salt and water are returned to the circulation. Filtrate entering the collecting duct is increasingly concentrated by the action of antidiuretic hormone (ADH, or vasopressin), leading to the release of intracellular aquaporin water channels, which insert themselves across the apical membrane. Water then enters the cell along an osmotic gradient. When the effect of ADH wears off, water channels return to the cell cytoplasm (see *Fig. 9.5*). The final urine volume is 1–2 L daily.

**Glomerular filtration rate**

In health, the GFR remains constant owing to intrarenal regulatory mechanisms. In disease (e.g. a reduction in intrarenal blood flow, damage to or loss of glomeruli or obstruction to the free flow of ultrafiltrate along the tubule), the GFR will fall. The ability to eliminate wastes and to regulate the volume and composition of body fluid will decline. This is measured as a rise in
The concentration of urea or creatinine in plasma represents the dynamic equilibrium between production and elimination. In healthy subjects, there is an enormous reserve of renal excretory function, and serum urea and creatinine do not rise above the normal range until there is a reduction of 50–60% in the GFR (Fig. 20.5). Thereafter, the level of urea depends on both the GFR and its production rate (Box 20.1). The latter is heavily influenced by protein intake and tissue catabolism. The level of creatinine is much less dependent on diet but is more related to age, sex and muscle mass. Once it is elevated, serum creatinine is a better guide to GFR than urea and is widely used to monitor further deterioration in the GFR.

**FIGURE 20.5** Creatinine clearance versus serum creatinine. Note that the serum creatinine does not rise above the normal range until there is a reduction of 50–60% in the glomerular filtration rate (creatinine clearance).

### Box 20.1

**Factors influencing serum urea levels**
### Measuring or estimating the GFR

If a substance is filtered, and then unmodified by the tubules as it passes along the nephron, the concentration of that substance per mL will be the same in blood and urine. Accurate calculations of the GFR, particularly in cases where the urea and creatinine may be in the normal range or near normal, can be assessed by cystatin C and creatinine clearance. Alternatives for quantifying the true GFR include measuring iohexol or inulin clearance, or radio-isotope (^{51}\text{Cr-EDTA}) GFR. Neither is practical for daily clinical practice.

### Cystatin C

This is a freely filtered, low-molecular-weight protein that appears to be a more accurate marker of kidney function than creatinine. Blood concentrations are less affected by muscle mass, age and gender, but measurement of cystatin C has not widely entered clinical practice as yet.

### Creatinine clearance

Daily production of creatinine (principally from muscle cells) is fairly constant and little affected by protein intake. Serum creatinine and excreted (urinary) creatinine vary little throughout the day. Small quantities of creatinine are secreted into the tubule but this does not usually affect the assay. Urine is collected over 24 hours for measurement of urinary creatinine. A single plasma level of creatinine is measured some time during the 24-hour period, and a creatinine clearance calculated as \( U \times VP \), where \( U = \) urine concentration of creatinine, \( V = \) rate of urine flow in mL/min, and \( P = \) plasma concentration of creatinine. Normal ranges are 90–140 mL/min in men and 80–125 mL/min in women.

### Estimated or calculated GFR – the eGFR
Measurement of GFR is cumbersome and time-consuming, and may be inaccurate if 24-hour urine collections are incomplete. Several formulae have been developed that predict creatinine clearance or GFR from serum creatinine and patient characteristics, often derived from large trials. Variables might include age, weight, gender and ethnicity. Commonly used equations are displayed in Box 20.2. All have their shortcomings, and are less accurate the closer a GFR is to normal (so patients with seemingly abnormal calculated GFRs may have normal kidney function). Of the equations, the CKD-EPI equation is more accurate than the modification of diet in renal disease (MDRD) study equation overall and is most reliable for predicting eGFR >60 mL/min/1.73 m².

Box 20.2

**Estimation of glomerular filtration rate (GFR)**

*To convert creatinine values in µmol/L to mg/dL, multiply by 0.0113.*

**Cockcroft–Gault equation**

\[
\text{Creatinine clearance} = \frac{(140 - \text{age}) \times \text{weight (kg)} \times \text{constant}}{\text{Serum creatinine (µmol/L)}}
\]

Constant = 1.23 for males and 1.04 for women.

**Modification of diet in renal disease (MDRD) equation**

Calculation of estimated GFR by four variables:

\[
\text{Estimated GFR (mL/min/1.73 m}^2\text{)} = 32788 \times (S_{\text{Cr}})^{-1.154} \times (\text{age})^{-0.203} \\
\times \text{constant (0.742 if female)} \times (1.210 \text{ if black African})
\]

**CKD Epidemiology (CKD-EPI) Collaboration equation**

\[
\text{GFR (mL/min/1.73 m}^2\text{)} = 141 \times \min (\text{serum creatinine}/\kappa, 1)^\alpha \times \max (\text{serum creatinine}/\kappa, 1)^{-1.209} \times 0.993^{\text{Age}} \times 1.018 \text{ [if female]} \times 1.159 \text{ [if black]}
\]

where \(\kappa\) is 0.7 for females and 0.9 for males, \(\alpha\) is \(-0.329\) for females and \(-0.411\) for males, \(\min\) indicates the minimum or serum creatinine/\(\kappa\) or 1, and \(\max\) indicates the maximum of serum creatinine/\(\kappa\) or 1.

All these equations have not, however, been fully validated across all ranges of renal...
impairment, weights or body mass index (BMI), or in all ethnic groups. However, for monitoring patients with acute or chronic kidney disease, the convenience and ease of the eGFR has led to its widespread adoption.

**Drugs, toxins, proteins and the kidney**

A substantial fraction of prescription drugs is handled and eliminated by the kidney. Many of these medications (e.g. penicillins, cephalosporins, diuretics, non-steroidal anti-inflammatory drugs (NSAIDs) and antivirals) circulate in the plasma as small organic anions, and are actively eliminated in the proximal tubule by a specific organic anion transporter (OAT) system.

The kidney is also a major site for the catabolism (and so elimination) of many small-molecular-weight proteins and polypeptides, including many hormones such as insulin, parathyroid hormone (PTH) and calcitonin, by endocytosis carried out by the megalin–cubilin complex in the brush border of proximal tubular cells. In chronic kidney disease (CKD), the metabolic clearance of these substances is reduced and their half-life is prolonged. This accounts, for example, for the reduced insulin requirements of patients with diabetes as their renal function declines.

**Endocrine function**

**Renin–angiotensin system**

(See Fig. 20.6.) The *juxtaglomerular apparatus* (JGA) regulates flow and filtration in each individual nephron. Columnar epithelium in the macula densa (see Fig. 20.3) senses the concentration of tubular fluid sodium (higher filtrate flow means more delivered sodium), triggering adenosine-mediated vasoconstriction of the afferent arteriole to drop glomerular filtration (tubuloglomerular feedback). Juxtaglomerular cells secrete renin, able to induce aldosterone release, allowing the apparatus to monitor flow, and respond when necessary to drop GFR and retain salt to maintain fluid balance.
Pro-renin, synthesized by specialized arteriolar smooth muscle cells in the JGA, is cleaved into the active proteolytic enzyme, renin. Active renin is stored in the JGA, and released in response to triggers related to a falling intravascular volume, pressure or increased fluid losses via the kidney. Specifically, these are:

- pressure changes in the afferent arteriole
- changes in sympathetic tone
- chloride and osmotic concentration in the distal tubule via the macula densa (see Fig. 20.3A) – tubuloglomerular feedback
• local prostaglandin and nitric oxide release.

In the blood, renin converts angiotensinogen, an α2-globulin of hepatic origin, to inactive angiotensin I. Angiotensin I is further cleaved by angiotensin-converting enzyme (ACE, present in lung and vascular endothelium) into active angiotensin II (AII), which has two major actions (mediated by two types of receptor, \( \text{AT}_1 \) and \( \text{AT}_2 \)). When AII binds the \( \text{AT}_1 \) subtype (found in the heart, blood vessels, kidney, adrenal cortex, lung and brain), this binding mediates vasoconstriction. AII binding \( \text{AT}_2 \) is probably involved in vascular growth.

AII:
• causes rapid, powerful vasoconstriction
• stimulates the adrenal zona glomerulosa to increase aldosterone production (over hours or days), leading to sodium (and water) absorption in the collecting duct
• causes vasoconstriction of efferent (but also, to a lesser extent, afferent) renal arterioles, resulting in increase of glomerular capillary pressure to maintain GFR.

The net result is that AII has opposing effects on the regulation of GFR:
• an increase in glomerular pressure and consequent rise in GFR
• reduction in renal blood flow and mesangial cell contraction, reducing filtration (see Fig. 20.44).

In renal artery stenosis with resultant low perfusion pressure, AII maintains GFR.

The renin–angiotensin system can be blocked at several points with renin inhibitors, ACE inhibitors and angiotensin II receptor antagonists (AII-RAs). These are useful agents in the treatment of hypertension and heart failure (see pp. 1047 and 985) but have differences in action: ACE inhibitors also block kinin production while AII-RAs are specific for \( \text{AT}_1 \) receptors.

**Erythropoietin**

Erythropoietin (see also p. 519) is the major stimulus for erythropoiesis, the synthesis of red cells. It is a glycoprotein produced principally by fibroblast-like cells in the renal interstitium.

• Under hypoxic conditions, both the α and β subunits of hypoxia inducible factor 2 (HIF-2) are expressed, forming a heterodimer and causing erythropoietin gene transcription. Erythropoietin, once formed, binds to its receptors on erythroid precursor cells, to maintain normal red cell synthesis.

• Under normal oxygen conditions, only the HIF-2-β subunit is constitutively expressed. The α subunit undergoes proline hydroxylation in the presence of iron and oxygen.

The hydroxylated HIF-2-α subunit binds to von Hippel–Lindau protein, with the activating ubiquitination (see p. 104) and subsequent degradation of HIF-2-α via proteosomes so that no erythropoietin is transcribed.

This and other hydroxylation steps have an absolute requirement for molecular oxygen; this forms the basis of oxygen sensing.
Loss of renal substance, with decreased erythropoietin production, results in a normochromic, normocytic anaemia. Conversely, erythropoietin secretion may be increased, with resultant polycythaemia, in people with polycystic renal disease, benign renal cysts or renal cell carcinoma.

Recombinant human erythropoietin has been biosynthesized and is available for clinical use, particularly in people with CKD (see p. 778).

**Vitamin D metabolism**

Naturally occurring vitamin D (see also p. 708; cholecalciferol) requires hydroxylation in the liver at position 25 and again by a renal 1α-hydroxylase enzyme to produce the metabolically active 1,25-dihydroxycholecalciferol (1,25-(OH)₂D₃).

Activity of 1α-hydroxylase is increased by:
- high plasma levels of PTH
- low serum phosphate
- low 1,25-(OH)₂D₃.

Both 1,25-dihydroxycholecalciferol and 25-hydroxycholecalciferol are degraded in part by being hydroxylated at position 24 by 24-hydroxylase. The activity of this enzyme is reduced by PTH and increased by 1,25-(OH)₂D₃ (which therefore promotes its own inactivation).

Reduced 1α-hydroxylase activity in diseased kidneys leads to relative deficiency of 1,25-(OH)₂D₃. As a result, gastrointestinal calcium and, to a lesser extent, phosphate absorption is reduced and bone mineralization impaired. Reduced gut calcium absorption leads to hypocalcaemia, which is sensed by a specific calcium-sensing receptor (CaSR) on parathyroid glands, and in turn induces release of PTH. Receptors for 1,25-(OH)₂D₃ are also found on parathyroid glands, and reduced receptor binding alters the set-point for release of PTH when plasma calcium falls. This combination contributes to the (common) secondary hyperparathyroidism seen in patients with CKD, even of modest degree.

**Autocrine function**

**Endothelins**

The endothelins (ETs) are a family of potent vasoactive peptides that also influence cell proliferation, tissue fibrosis and epithelial solute transport. They do not circulate but act locally. ETs are produced by most types of cell in the kidney. When binding ET-type A receptor, ET mediates vasoconstriction. When binding to ET-type B receptor, ETs cause vasodilatation. Through vasoconstriction by ETA and salt and water retention via ETB receptors, ETs cause hypertension.

**Prostaglandins**

Prostaglandins are unsaturated, oxygenated fatty acids, derived from the enzymatic metabolism
of arachidonic acid, mainly by constitutively expressed cyclo-oxygenase-1 (COX-1) or inducible COX-2 (see **Fig. 24.30**). COX-1 is highly expressed in the collecting duct, while COX-2 expression is restricted to the macula densa. Both COX isoforms convert arachidonic acid to unstable prostaglandin H$_2$ (PGH$_2$). PGH$_2$ is then converted to:

- PGE$_2$ in the collecting duct, responsible for natriuretic and diuretic effects
- PGD$_2$, which is of undetermined significance, produced in the proximal tubule
- prostacyclin (PGI$_2$), synthesized in the interstitium and vessels
- thromboxane A$_2$, a vasoconstrictor, mainly synthesized in the glomerulus.

They all maintain renal blood flow and GFR in the face of vasoconstrictors such as angiotensin II, catecholamines and α-adrenergic stimulation. Inhibition of prostaglandin synthesis by NSAIDs results in a further reduction in GFR, which is sometimes sufficiently severe as to cause acute kidney injury (AKI), particularly in the elderly, with volume depletion, or where ACE inhibitors or AIIs are used.

### Natriuretic peptides

**Atrial natriuretic peptides** (ANPs) are secreted from granules in the cardiac atria in response to atrial stretch (as might be caused by increased venous return or by volume overload). They produce marked sodium and water excretion and increase GFR rate. ANP is also a direct vasodilator, lowering blood pressure; it reduces renin release and aldosterone secretion, and consequently inhibits AII synthesis. Their effects are to reverse salt and water retention. **Brain natriuretic peptide** (BNP) is found in the ventricle as well as the brain and has sequence homology with ANP. Normally, its circulating level is 25% less than for ANP but may exceed it in congestive cardiac failure (see p. 983).

### Nitric oxide and the kidney

Nitric oxide (see **Fig. 25.20**), a molecular gas, is formed by the action of three isoforms of nitric oxide synthase (NOS), all of which are expressed in the kidney: eNOS is found in vessels, nNOS mainly in the macula densa and inner medullary collecting duct, and iNOS in several tubule segments. Nitric oxide binds soluble guanylate cyclase, enhancing the synthesis of cyclic guanosine monophosphate (cGMP) from guanosine triphosphate (GTP), and mediates the following physiological actions in the kidney:

- regulation of renal perfusion and glomerular pressure
- natriuresis, by inhibiting Na$^+$/K$^+$-ATPase and NHE3
- antagonism of ADH
- modulation of tubule–glomerular feedback (see p. 724).

Clinical Approach to the Patient with Kidney and Urinary Tract Disease

Investigation of kidney and urinary tract disease

Examination of the urine

**Appearance**

Unless urine is visibly bloody (or cola-coloured, in cases of myoglobinuria or haemoglobinuria), inspection of the urine is not helpful. Cloudy, offensive-smelling urine may denote infection, but this should be further tested by dipsticks.

**Volume**

In temperate climates, healthy adults will pass between 800–2500 mL per 24 hours (roughly 1 mL/kg/h). Usually, the minimum urine output capable of maintaining solute excretion for health (without accumulation in the body) is around 650 mL. If the kidney loses concentrating capacity (as occurs in CKD or diabetes insipidus), higher urine volumes are needed for the same daily solute output, and urine outputs may rise well above 2500 mL. **Nocturia** is a symptom of kidney disease, as patients without the ability to concentrate solute into a small urine volume will waken, needing to pass urine during the night. High daily volumes are also seen with glycosuria or increased protein catabolism following surgery, as the solute load requiring excretion is higher.

**Specific gravity and osmolality**

Urine specific gravity (SG, where <1.008 is dilute and >1.020 is concentrated) is a measure of the weight of dissolved particles in urine, whereas urine osmolality reflects the number of such particles. Usually, the relationship between the two is close. Measurement of urine SG or osmolality can be helpful in confirming loss of concentrating ability (as might be seen when tubular function fails in acute tubular necrosis or CKD). It can also be helpful in oliguric patients, when a high SG might suggest pre-renal AKI, as opposed to established acute tubular necrosis (see pp. 771–772).

**Urinary pH**

Measurement of urinary pH (usually 5.5–6.5) is helpful only in the investigation and treatment of renal tubular acidosis (see pp. 177–178).
Dipsticks (chemical testing) and urine microscopy

Dipsticks are cheap and hugely helpful in investigating suspected kidney disease, using reagents fixed on pads that change colour on reacting with specific elements in urine. Microscopy on a mid-stream sample spun at 2000 rpm is essential to understand dipstick findings fully.

Blood

Haematuria may originate from anywhere in the urinary tract. Once found on dipstick, a mid-stream sample should be examined for red cells or casts. Red cells (usually 1–2 per high-power field) are described as dysmorphic if they originate from the early nephron (glomerular bleeding), and may be accompanied by red-cell casts. Casts are cylindrical bodies, moulded in the shape of the distal tubular lumen. Red-cell casts – even if only single – always indicate renal disease. A dipstick that is strongly positive for haematuria with no red cells seen on microscopy might suggest haemoglobinuria or myoglobinuria. Bleeding may come from any site within the urinary tract (Fig. 20.7):

- **Overt bleeding from the urethra** is suggested when blood is seen at the start of voiding and then the urine becomes clear.
- **Blood diffusely present** throughout the urine comes from the bladder or above.
- **Blood only at the end of micturition** suggests bleeding from the prostate or bladder base.
Women will commonly have dipstick-positive haematuria during a period; it is usually worth repeating testing after menstruation.

**Protein**

Proteinuria is one of the most common signs of renal disease. Dipsticks will detect proteinuria from around 50–150 mg/L, and may be designed to test for either albuminuria or proteinuria. They will not detect light chains or immunoglobulins (Bence Jones proteins). Normal individuals excrete less than 20 µg of albumin per minute (30 mg in 24 h). Dipsticks, however, detect albumin only in a concentration above 200 µg/min (300 mg per 24 h if urine volume is normal). If two separate urine samples find proteinuria on dipstick testing, a random urine protein:creatinine ratio (uPCR) should be measured. This convenient test has largely replaced formal (timed) 24-hour urine collections for proteinuria; an alternative is the albumin:creatinine ratio (ACR). As albumin is usually the dominant protein lost in the urine, patients who have albuminuria always have proteinuria (and the urine PCR will be higher than the urine ACR). Confusingly, the terms are often used interchangeably. For people with diabetes, the urine ACR has particular prognostic significance, and is usually the preferred screening test (see p. 1269) for the **microalbuminuria** found in early diabetic kidney disease.

Both tests are expressed as mg (protein)/mmol creatinine. Generally, an ACR of 2.5–20 mg/mmol corresponds to albuminuria of 30–300 mg daily (crudely, multiply the result by a factor of 15 – so an ACR of 50 mg/mmol = 750 mg/day albuminuria). Similarly, a uPCR of 3–30 mg/mmol corresponds to 30–300 mg daily (multiplying by a factor of 10 for this test – so a PCR of 50 mg/mmol = 500 mg proteinuria per day). The uPCR assay is relatively cheap and identifies patients whose proteinuria is of tubular and glomerular origin. ACR or PCR levels independently predict all-cause and cardiovascular mortality in the general population in addition to better risk stratifications of patients with CKD for future renal outcomes. Pyrexia, exercise and adoption of the upright posture (**postural proteinuria**) all increase urinary protein output but are benign. Proteinuria may associate with coarse granular casts seen on urine microscopy.

**Glucose**

Renal glycosuria is uncommon, so that a positive test for glucose might prompt consideration of diabetes mellitus. Dipsticks for glucose are very sensitive, however.

**Bacteria and pus cells**

Dipstick tests for bacteriuria are based on the detection of nitrite produced from the reduction of urinary nitrate by bacteria, and also on the detection of leucocyte esterase, an enzyme specific for neutrophils. Although each test on its own has limitations, a positive reaction with both tests has a high predictive value for urinary tract infection (see pp. 763–764). Where positive, a mid-stream sample should be sent for microscopy, culture and sensitivities (MC&S). White blood (pus) cells (WBCs) may be seen on microscopy, as may bacteria. A measurement of ≥10 WBCs/mL in fresh mid-stream urine samples is abnormal and suggests
urinary tract infection (UTI). Not all pyuria is UTI, though; pus cells are seen with renal stones, tubule-interstitial nephritis, papillary necrosis, tuberculosis and interstitial cystitis. White cell casts may be seen with (and are more characteristic of) acute pyelonephritis.

**Blood and quantitative tests**

The use of serum urea, creatinine and GFR as measures of renal function is discussed on pages 726–727. Other quantitative tests of disturbed renal function are described under the relevant disorders, as are diagnostic tests, such as anti-neutrophil cytoplasmic antibody (ANCA), immunofluorescence and complement.

**Imaging techniques**

**Ultrasonography**

Ultrasound of the kidneys and bladder is safe and non-invasive, avoiding ionizing radiation and intravascular contrast medium. In renal diagnosis, it is the imaging method of choice for:

- Assessing renal size and symmetry (normal-sized kidneys with abnormal function suggest an acute cause, as kidneys scar as they fail, and may shrink in length and volume), and allowing directed renal biopsy.
- Ruling out obstruction, either of the bladder and ureters (with unilateral or bilateral hydronephrosis), or of the kidney itself (where pelvicalyceal dilatation may suggest high ureteric or pelvic disease).
- Characterizing renal masses as cystic (either simple cysts or polycystic kidneys) or complex and solid (benign and malignant renal tumours, or infected collections).
- Guiding intervention aimed at relieving obstruction (percutaneous nephrostomy).
- Confirming renal vein patency, and suggesting (but not proving) renal artery disease, in the case of **Doppler ultrasonography (duplex)**.
- Looking for bladder tumours or stones. A scan obtained after voiding (post-micturition) allows bladder emptying to be assessed.

**Computed tomography**

Unenhanced computed tomography (CT) is the first-line investigation for cases of **ureteric colic** and suspected renal calculi. It has superseded excretion urography (also known as intravenous urography (IVU) or intravenous pyelography (IVP)). Multislice detector CT has both improved image resolution and allowed reconstruction of the imaging data in a variety of planes. CT is also used to:

- characterize renal masses that are indeterminate at ultrasonography
- stage renal and bladder tumours
- evaluate the retroperitoneum for tumours, retroperitoneal fibrosis (peri-aortitis) and other causes of ureteric obstruction
• assess severe renal trauma
• visualize the renal arteries and veins by CT angiography.

**Disadvantages** include radiation and contrast nephrotoxicity (see p. 774).

**Positron emission tomography (PET)**, using 18-F-fluorodeoxyglucose (FDG), is useful for detection of infection (e.g. in a cyst), inflammation or tumours, and is often used with CT (PET/CT).

**Magnetic resonance imaging**
Magnetic resonance imaging (MRI) is used as an alternative to CT with no irradiation:
• To stage prostate (but also renal and bladder) cancer.
• To reconstruct the anatomy of the renal arteries using magnetic resonance **angiography** with gadolinium as contrast medium. In experienced hands, its sensitivity and specificity approach that of renal angiography.

The Food and Drug Administration (FDA) advises not using gadolinium in patients with renal insufficiency because of the development of nephrogenic systemic fibrosis (see pp. 1365 and 781).

**Plain X-ray**
A plain radiograph of the abdomen may be useful to identify renal calcification or radiodense calculi in the kidney, renal pelvis, and the line of the ureters or bladder *(Fig. 20.8)*.
Antegrade pyelography

Antegrade pyelography (Fig. 20.9) involves percutaneous puncture of a pelvicalyceal system with a needle and the injection of contrast medium to outline the pelvicalyceal system and ureter to the level of obstruction. Drains can be sited and stents placed during the procedure. Retrograde pyelography under screening control allows a contrast study of the ureter from the bladder. It is invasive, commonly requires a general anaesthetic, and may result in the introduction of infection.
**Micturating cystourethrography**

After bladder catheterization, contrast is instilled into the bladder. The catheter is then removed and the patient screened during voiding to check for vesicoureteric reflux and to study the urethra and bladder emptying. Micturating cystourethrography (MCUG) is used in children with recurrent infection (see p. 764). It is rarely appropriate in adults, as with bladder wall hypertrophy in adulthood, vesicoureteric reflux tends to disappear.

**Aortography or renal arteriography**

Conventional or digital subtraction angiography (DSA) is used both diagnostically, and in cases of suspected renal artery stenosis, to allow therapeutic renal artery balloon angioplasty and stenting. Complications include cholesterol embolization (see pp. 753–754) and contrast-induced kidney damage (contrast nephropathy).

**Renal scintigraphy**

Isotope studies are helpful for dynamic or static studies of perfusion or excretion. Following venous injection of a bolus of tracer, emissions from the kidney can be recorded by gamma camera. Technetium-labelleled diethylenetriaminepenta-acetic acid (\(^{99m}\)Tc-DTPA) is excreted by
glomerular filtration and can be used to confirm renal perfusion. In patients with unilateral renal artery stenosis, there is, typically, a slowed and reduced uptake of tracer with a delay in reaching a peak. Studies carried out before and after administration of an ACE inhibitor may demonstrate a fall in uptake that is suggestive of functional arterial stenosis. Both false-positive and false-negative results are common, particularly in patients with CKD, and renal arteriography remains the ‘gold standard’ in the diagnosis of renal artery stenosis.

Dimercaptosuccinic acid labelled with technetium ($^{99m}$Tc-DMSA) is filtered by the glomerulus and then binds to proximal tubular cells. Static studies are useful to assess the relative contribution in function of asymmetric kidneys. $^{99m}$Tc-DMSA is also useful in highlighting ‘photon-deficient’ areas (where isotope is not seen), suggestive of scars or infarction, when compared to healthy tissue uptake. Mercapto-acetyltriglycine (MAG3) labelled with technetium ($^{99m}$Tc) is excreted by renal tubular secretion, so resistance to flow in the pelvis or ureter (with obstruction) prolongs the parenchymal transit of tracer with a delay in emptying the pelvis. On whole-kidney renograms, the time–activity curve fails to fall after an initial peak, or continues to rise (Fig. 20.10), confirming hold-up to flow. Furosemide may be given to exaggerate urine output and emphasize the delay, in order to aid diagnosis.

![Dynamic scintigram](image)

**FIGURE 20.10** Dynamic scintigram. Note the progressive rise of the right kidney curve to a plateau (in contrast to the normal left kidney curve), owing to urinary tract obstruction on the right side.

Transcutaneous renal biopsy

Renal biopsy (Box 20.3) is carried out under ultrasound control in specialized centres and requires interpretation by an experienced pathologist. It is helpful in the investigation of the nephritic and nephrotic syndromes, acute and chronic kidney disease, haematuria after urological investigations and renal graft dysfunction. Native renal biopsy material must be
examined by conventional histochemical staining, by electron microscopy, and by immunoperoxidase or immunofluorescence. Techniques like *in situ* hybridization and polymerase chain reaction (PCR) analysis are also widely used in renal biopsy specimens.

### Box 20.3

**Transcutaneous renal biopsy**

**Before biopsy**
1. Perform a coagulation screen; it must be normal.
2. Group and save the serum for cross-matching.
3. Give the patient a full explanation of what is involved and obtain consent.

**During biopsy**
1. Ask the patient to lie prone with a hard pillow under the abdomen.
2. Localize the kidney by ultrasound.
3. Inject local anaesthetic along the biopsy track.
4. Instruct the patient to hold a breath when the biopsy is performed.

**After biopsy**
1. Apply pressure dressing to the biopsy site and ask the patient to rest in bed for 8–24 h.
2. Maximize fluid intake to prevent clot colic.
3. Check the pulse and blood pressure regularly.
4. Advise the patient to avoid heavy lifting or gardening for 2 weeks.

The complications of transcutaneous renal biopsy are shown in *Box 20.4*.

### Box 20.4

**Complications of transcutaneous renal biopsy**

- Macroscopic haematuria – up to 10%
- Pain in the flank, sometimes referred to the shoulder tip
- Perirenal haematoma
- Arteriovenous aneurysm formation – about 20%, almost always of no clinical significance
- Profuse haematuria demanding blood transfusion – 1–3%
- Profuse haematuria demanding occlusion of the bleeding vessel at angiography or nephrectomy – approximately 1 in 400
- Introduction of infection
- Mortality rate of about 0.1%
Glomerular disease is usually described by kidney biopsy findings. Commonly used terms are shown in Box 20.5.

### Box 20.5

**Glomerular disease: commonly used terms**

- **Focal**: some, but not all, glomeruli show the lesion
- **Diffuse** (global): most of the glomeruli (>75%) contain the lesion
- **Segmental**: only a part of the glomerulus is affected (most focal lesions are also segmental, e.g. focal segmental glomerulosclerosis)
- **Global**: all of the glomerulus is symmetrically involved
- **Proliferative**: an increase in cell numbers due to hyperplasia of one or more of the resident glomerular cells with or without inflammation
- **Membrane alterations**: capillary wall thickening due to deposition of immune deposits or alterations in basement membrane
- **Crescent formation**: epithelial cell proliferation with mononuclear cell infiltration in Bowman's space

### The Glomerulus and Glomerular Disease

A glomerulus consists of a collection of capillaries seated within Bowman's capsule in the urinary space. Blood flows in via the afferent arteriole, and exits via the efferent arteriole. Filtrate leaves Bowman's space into the proximal tubule. The capillary tuft is supported by mesangial cells and mesangial matrix. Filtrate moves from the capillary lumen into the urinary space across the glomerular filter (see p. 724). Three elements are involved in allowing or preventing filtration: endothelium, the glomerular basement membrane (GBM) and podocytes (*Fig. 20.11*).
Filtration barrier (slit diaphragm)

The glomerular filtration barrier (see Fig. 20.2) consists of the fenestrated endothelium, the GBM and the terminally differentiated visceral epithelial cells known as podocytes. Podocytes attach to the GBM by foot processes via adhesion molecules, such as $\alpha_3\beta_1$ and dystroglycans. Adjacent podocytes are joined laterally via their foot process by slit diaphragms, which bridge across the filtration slits. The various proteins comprising the slit diaphragm include nephrin, CD2-associated protein (CD2AP), canonical transient receptor potential channel 6 (TRPC6), podocin, P-cadherin, $\alpha$- and $\beta$-catenin, and zonula occludens-1 (ZO-1). These co-localize within the subcellular domain to function as a molecular sieve. These proteins, in addition to providing structural support to the cytoskeletal proteins like filamentous actin, also have signalling functions in order to maintain the normal function of podocytes. Abnormalities in any of these proteins result in the breakdown of the filtration barrier with consequent torrential leak of macromolecules.

Podocyte changes

The podocyte structure (see above) is maintained by actin, which supports the cytoskeleton (see Fig. 20.2). A rearrangement of the fluid actin cytoskeleton leads to foot process effacement (flattening). As the architecture of the filtration slit is now disrupted, albumin leaks into the urine, and recovery of the cytoskeleton reverses proteinuria. The cytoskeleton can be altered by:

- abnormalities of cytoskeletal proteins like $\alpha$-actinin-4, which causes hereditary focal segmental glomerular sclerosis
- injury to or abnormalities of slit diaphragm proteins
- changes in the GBM itself
• direct injury to podocytes by viral infection, drugs, toxins or the local activation of the renin–angiotensin system.

**Glomerular disease**

Glomerular disease is the third most common cause (after diabetes and hypertension) of end-stage kidney disease (ESKD) in Europe and the USA, accounting for some 10–15% of such patients. These are diseases in which:
• there may be an immunologically mediated inflammatory injury to glomeruli, or structural or functional glomerular damage without inflammation
• renal interstitial damage is a regular accompaniment
• the kidneys are involved symmetrically
• secondary mechanisms of glomerular injury may come into play following an initial immune insult, such as fibrin deposition, platelet aggregation, neutrophil infiltration and free radical-induced damage
• haemodynamic consequences of a primary injury may further disturb glomerular function
• renal lesions may be part of a generalized disease (e.g. systemic lupus erythematosus, SLE).

**Describing glomerular disease**

The nomenclature for glomerular disease can be confusing, as descriptive terms (as seen on histology) overlap with clinical syndromes and more recent molecular insights into the pathogenesis of disease. If there is predominant inflammation on histology, glomerular disease may be described as a **glomerulonephritis**. If inflammation is absent, **glomerulopathy** is more correct. There remains much overlap between the two, and the terms are often (wrongly) used interchangeably. It may be better to think about glomerular disease in terms of the predominant compartment involved, where the GBM separates podocytes from mesangial and endothelial cells.

• Podocytes (in the urinary compartment) are principally involved in glomerular diseases (usually glomerulopathies) that present as the nephrotic syndrome, where proteinuria is often heavy.
• Endothelial and mesangial cells (in the endocapillary compartment) are principally involved in glomerular disease presenting as nephritis (glomerulonephritis), where haematuria, proteinuria and often hypertension are equally evident.
• Podocytes, endothelial and mesangial cells may be equally involved where a glomerulonephritis presents with heavy proteinuria and the nephrotic syndrome as well.

Clinical classification of glomerular disease is also often used, although there is no complete correlation between histopathological types and clinical features. Four major glomerular syndromes are often described:

**Nephrotic syndrome**: massive proteinuria (>3.5 g/day), hypoalbuminaemia, oedema, lipiduria and hyperlipidaemia. Podocyte malfunction or injury is often causative.
• **Glomerulonephritis (nephritic syndrome):**
  – **Acute glomerulonephritis:** abrupt onset of glomerular haematuria (red blood cell casts or dysmorphic red blood cells), non-nephrotic-range proteinuria, oedema, hypertension and transient renal impairment, or
  – **Rapidly progressive glomerulonephritis:** features of acute nephritis, focal necrosis with or without crescents, and rapidly progressive renal failure over weeks.
• **Mixed nephritic/nephrotic presentations:** where glomerulonephritis is part of a systemic disease (e.g. lupus nephritis, cryoglobulinaemia and Henoch–Schönlein purpura), a nephritic syndrome is often associated with the nephrotic syndrome.
• **Asymptomatic haematuria, proteinuria** or both.

**Nephrotic syndrome**

Nephrotic syndrome is characterized by:
• hypoalbuminaemia
• >3.5 g proteinuria/day
• dyslipidaemia
• salt and water retention, leading to oedema.

Pathophysiology

Hypoalbuminaemia

Loss of urinary protein (largely albumin) of the order ≥3.5 g daily in an adult may lead to hypoalbuminaemia. Normal dietary protein intake in the UK is around 70 g daily and the normal liver can synthesize albumin at a rate of 10–12 g daily. How, then, does a daily urinary protein loss of 3.5 g result in hypoalbuminaemia? This can be partly explained by increased catabolism of reabsorbed protein, largely albumin, in the proximal tubules, even though the rate of albumin synthesis is increased.

Proteinuria

Proteinuria occurs partly because structural damage to the glomerular barrier (podocytes, basement membrane, fenestrated endothelium and endothelial charge) allows the passage of more and larger molecules. The filtration slit between podocytes and normal podocyte architecture, and interdigitating podocyte foot processes are critical to maintaining a barrier to protein loss into the urinary space, as is a functional GBM and healthy capillary endothelium (and its charge).

Hyperlipidaemia

This is a consequence of increased synthesis of lipoproteins (such as apolipoprotein B, C-III lipoprotein (a)), as a direct consequence of a low plasma albumin. Low-density lipoprotein (LDL) increases, partly due to upregulation of a liver serine protease, pro-protein convertase subtilisin kexin-9 (PCSK9), which causes internalization of LDL receptors. Very-low-density lipoprotein (VLDL) and/or intermediate-density lipoprotein (IDL) fractions increase, with no change (or a decrease) in HDL (the LDL/HDL cholesterol ratio increases). There is also reduced clearance of the principal triglycerides bearing lipoprotein (chylomicrons and VLDL), as high plasma levels of free fatty acid (FFA) trigger release of appropriately sialylated angiopoietin-like 4 (Angptl4) protein from adipose tissue, heart and skeletal muscles, inhibiting lipoprotein lipase and resulting in hypertriglyceridaemia.

Oedema in hypoalbuminaemia

See page 155.

Management

General measures

• Initial management should be with dietary sodium restriction and a thiazide diuretic (e.g. bendroflumethiazide 5 mg daily). Unresponsive patients require furosemide 40–120 mg daily.
with the addition of amiloride (5 mg daily; monitor serum potassium concentration regularly). Nephrotic patients may malabsorb diuretics (as well as other drugs) owing to gut mucosal oedema, and intravenous administration may be needed initially. Patients are sometimes hypovolaemic, and moderate oedema may have to be accepted in order to avoid postural hypotension.

- **Normal protein intake** is advisable. A high-protein diet (80–90 g protein daily) increases proteinuria and can be harmful in the long term.

- **Albumin infusion** produces only a transient effect. It is only given to patients who are diuretic-resistant and those with oliguria and uraemia in the absence of severe glomerular damage: for example, in minimal-change nephropathy. Albumin infusion is combined with diuretic therapy, and diuresis often continues with diuretic treatment alone.

- **Hypercoagulable states** predispose to venous thrombosis. The hypercoagulable state is due to loss of clotting factors (e.g. antithrombin) in the urine and an increase in hepatic production of fibrinogen. Prolonged bed rest should be avoided, as thromboembolism is very common (particularly in membranous nephropathy). Long-term prophylactic anticoagulation may be indicated, and if renal vein thrombosis occurs, permanent anticoagulation is required.

- **Sepsis** is a major cause of death in nephrotic patients. The increased susceptibility to infection is partly due to loss of immunoglobulin in the urine. Pneumococcal infections are particularly common and pneumococcal vaccine should be given. Early detection and aggressive treatment of infections, rather than long-term antibiotic prophylaxis, constitute the best approach.

- **Lipid abnormalities** are responsible for an increase in the risk of cardiovascular disease in patients with proteinuria. Treatment of hypercholesterolaemia starts with an HMG-CoA reductase inhibitor (a statin).

- Lastly, **ACE inhibitors and/or angiotensin II receptor antagonists** (AII-RAs) are indicated for their antiproteinuric properties in all types of glomerulonephropathy, but most especially the nephrotic syndrome. These drugs reduce proteinuria by lowering glomerular capillary filtration pressure (a fall in efferent tone drops the transglomerular capillary pressure, and so protein loss into the urinary space); blood pressure and renal function should be monitored regularly.

**Specific measures**

Treat the underlying cause of any urinary protein leak. **Box 20.7** shows the glomerular lesions commonly associated with the nephrotic syndrome.

---

**Box 20.7**

**Glomerulopathies associated with the nephrotic syndrome**
Causes of nephrotic syndrome

**Minimal-change nephropathy (minimal-change disease)**

In minimal-change nephropathy (MCN; also called minimal-change disease, MCD), glomeruli appear normal on light microscopy (**Fig. 20.12**). On electron microscopy, fusion of the foot processes of podocytes is seen, consistent with a disrupted podocyte actin cytoskeleton (see **Fig. 20.2B**). Neither immune complexes nor anti-GBM antibody can be demonstrated by immunofluorescence on glomerular staining for antibody.

![Normal glomerulus on light microscopy in minimal-change nephropathy.](image)

Immature differentiating CD34 stem cells (rather than mature T lymphocytes) appear to be responsible for the pathogenesis of MCN. Podocyte function is also affected by interleukin 13 (IL-13), the production of vascular endothelial growth factor (VEGF), or the upregulation of vascular hyposialylated-angiopoietin-like 4 (ANGPTL4), secreted by the podocytes.

Many drugs have been implicated in MCN, including NSAIDs, lithium, antibiotics (cephalosporins, rifampicin, ampicillin), bisphosphonates and sulfasalazine. Atopy is present in 30% of cases of MCN, and allergic reactions can trigger the nephrotic syndrome. Infections, such as hepatitis C virus (HCV), the human immunodeficiency virus (HIV) and tuberculosis,
are rarer causes.

Clinical features

MCN is most common in children, particularly boys, and is responsible for the large majority of cases of nephrotic syndrome in childhood. Proteinuria is usually ‘highly selective’, where albumin, but not higher-molecular-weight proteins such as immunoglobulins, is lost in the urine. Oedema is usual and in children this may present predominantly around the face. The condition accounts for 20–25% of cases of adult nephrotic syndrome. It is often regarded as a condition that does not lead to CKD (but see focal segmental glomerulosclerosis below).

Management

• Manage symptoms with general measures (above).
• High-dose corticosteroid therapy with prednisolone 60 mg/m² daily (up to a maximum of 80 mg/day) for a maximum of 4–6 weeks, followed by 40 mg/m² every other day for a further 4–6 weeks, reverses proteinuria in more than 95% of children. Response rates in adults are significantly lower and response may occur only after many months (12 weeks with daily steroid therapy and 12 weeks of maintenance with alternate-day therapy). Spontaneous remission also occurs and steroid therapy should, in general, be withheld if urinary protein loss is insufficient to cause hypoalbuminaemia or oedema. In both children and adults, if remission lasts for 4 years after steroid therapy, further relapse is very rare.
• In children, two-thirds relapse after steroid therapy and further courses of corticosteroids are required. One-third of these children regularly relapse on steroid withdrawal, so that a second-line agent should be added after repeat induction with steroids.
• Cyclophosphamide 1.5–2.0 mg/kg daily is given for 8–12 weeks with prednisolone 7.5–15 mg/day. This increases the likelihood of long-term remission. Steroid-unresponsive patients may also respond to cyclophosphamide. No more than two courses of cyclophosphamide should be prescribed in children because of the risk of side-effects, which include future infertility (azoospermia and premature ovarian failure).
• An alternative to cyclophosphamide is ciclosporin 3–5 mg/kg per day, which is effective but must be continued long-term to prevent relapse on stopping treatment. The antiproteinuric effect of ciclosporin is normally attributed to its immunosuppressive action but may result from the stabilization of the actin cytoskeleton in kidney podocytes. Ciclosporin inhibits the calcineurin-mediated dephosphorylation of synaptopodin (a regulator of actin cytoskeleton) and protects it from cathepsin L-mediated degradation. These results have shed new light on the role of calcineurin signalling in proteinuric kidney diseases. Excretory function and ciclosporin blood levels (recommended trough levels 80–150 ng/mL) must be monitored regularly, as ciclosporin is potentially nephrotoxic.
• Rituximab, a depleting monoclonal antibody directed against CD20, present on B lymphocytes, is showing promise in reducing the number of relapses in frequently relapsing
disease, and also in minimizing the immunosuppressant burden in corticosteroid-dependent disease.

- In corticosteroid-dependent children, the anthelminthic agent levamisole 2.5 mg/kg to a maximum of 150 mg on alternate days is also useful in maintenance of remission but its mode of action is unexplained.

### Congenital nephrotic syndrome

Congenital nephrotic syndrome (Finnish type) is an autosomal recessively inherited disorder due to mutations in the gene coding for a transmembrane protein, nephrin; it occurs at a frequency of 1 per 8200 live births in Finland. Nephrin is a critical element of the filtration slit, and its loss of function results in massive proteinuria shortly after birth. The disorder can be diagnosed *in utero*, as increased α-fetoprotein in amniotic fluid is a common feature. Histologically, some glomeruli are small and infantile, whereas others are enlarged and more mature, and have diffuse mesangial hypercellularity. Because of the massive proteinuria, some tubules develop microcysts and are dilated. On electron microscopy, complete effacement of the foot processes of visceral epithelial cells is observed. This condition is characterized by relentless progression to ESKD.

Other inherited nephrotic syndromes involve mutations in other genes that encode other podocyte proteins, such as podocin, α-actinin 4 and Wilms' tumour suppressor gene.

### Focal segmental glomerulosclerosis

Focal segmental glomerulosclerosis (FSGS) describes a sclerotic glomerular lesion that affects some (but not all) glomeruli, and some (but not all) segments of each tuft.

- **Primary FSGS** is an unusual primary cause of the nephrotic syndrome.
- **Secondary FSGS** looks similar on light microscopy. Although proteinuria may be heavy, hypoalbuminaemia is *unusual*.

### Primary focal segmental glomerulosclerosis

#### Clinical features of primary FSGS

This disease of unknown aetiology usually presents as massive proteinuria (usually non-selective), haematuria, hypertension and renal impairment. The associated nephrotic syndrome is often resistant to steroid therapy. All age groups are affected. It usually recurs in transplanted kidneys, sometimes within days of transplantation, and particularly in patients with aggressive primary renal disease.

#### Aetiology of primary FSGS
A circulating permeability factor causes the increased protein leak; plasma from patients increases membrane permeability in isolated glomeruli. Kidneys transplanted into murine models of FSGS develop the lesion, but kidneys from FSGS-prone mice transplanted to a normal strain are protected. Removal of this factor by plasmapheresis results in transient amelioration of proteinuria. The identity of the permeability factor remains unknown but recent findings suggest that cardiotrophin-like cytokine 1 is likely a candidate in FSGS. Soluble urokinase-like plasminogen activator receptor (SuPAR) was initially thought to be involved but now appears less likely to be causative, based on recent experimental and clinical evidence. Mutations in the MYO1E gene, which encodes for myosin 1E, found in podocytes, has been described in families with FSGS.

Pathology

Segmental glomerulosclerosis is seen on light microscopy, which later progresses to global sclerosis. The deep glomeruli at the corticomedullary junction are affected first. These may be missed on transcutaneous biopsy, leading to a mistaken diagnosis of MCN (pp. 735–736). A pathogenetic link may exist between MCN and FSGS, as a proportion of cases classified as having the former condition develop progressive CKD, which is unusual. Immunofluorescence shows deposits of C3 and immunoglobulin M (IgM) in affected portions of the glomerulus. The other glomeruli are usually enlarged but may be of normal size. Focal tubular atrophy and interstitial fibrosis are invariably present. Electron microscopy demonstrates primarily foot process effacement, occasionally in a patchy distribution. The degree of podocyte foot process effacement on electron microscopy can help distinguish between ‘primary’ and ‘secondary’ FSGS. If severe foot process effacement is present in normal and sclerosed glomeruli on electron microscopy, primary FSGS is more likely (this is not the case if foot process effacement is largely localized to sclerosed glomeruli alone).

Five histological variants of FSGS exist:

- In **classic FSGS (Fig. 20.13A)**, the involved glomeruli show sclerotic segments in any location of the glomerulus.
• The glomerular tip lesion is characterized by segmental sclerosis, at the tubular pole of all the affected glomeruli at a very early stage (tip FSGS; Fig. 20.13B). These patients have a more favourable response to steroids and disease runs a more benign course.

• In collapsing FSGS (Fig. 20.13C), podocytes are usually enlarged and coarsely vacuolated with wrinkled and collapsed capillary walls. Collapsing FSGS is commonly seen in young blacks with HIV infection or disease, and is known as HIV-associated nephropathy (HIVAN; see below).

• The perihilar variant (Fig. 20.13D) consists of perihilar sclerosis and hyalinosis in more than 50% of segmentally sclerotic glomeruli. It is frequently observed with secondary FSGS.
• The cellular variant (Fig. 20.13E) is characterized by at least one glomerulus with segmental hypercellularity (proliferation) that occludes the capillary lumen.

**Management**

• *Prednisolone* 0.5–2 mg/kg per day is used in most patients and continued for 6 months before the patient is considered resistant to therapy, which is common.

• *Ciclosporin* at doses to maintain serum trough levels at 150–300 ng/mL may be effective in reducing or stopping urinary protein excretion (tacrolimus is an alternative). Relapse after reducing or stopping ciclosporin is very common so that long-term use is required.

• *Cyclophosphamide, chlorambucil* or *azathioprine* is used for second-line therapy in adults. In patients with FSGS with mesangial hypercellularity and tip lesion, cyclophosphamide 1–1.5 mg/kg per day with 60 mg of prednisolone for 3–6 months, followed by prednisolone and azathioprine, can be used as maintenance therapy.

About 50% of patients progress to ESKD within 10 years of diagnosis, particularly those who are resistant to therapy. The recurrence of this renal lesion following renal transplantation is very high with a poor renal prognosis. Plasmapheresis or immunoabsorption has been the mainstay of treatment in patients with post-transplant recurrence but has had modest results. Anti-CD80 antibodies (abatacept), used in rheumatology, have been tried with success in this condition.

**Secondary FSGS**

Secondary FSGS with similar glomerular changes is seen as a secondary phenomenon when the number of functioning nephrons is reduced for any reason. Here, FSGS represents the common final glomerular lesion seen in response to subsequent haemodynamic glomerular strain. As nephrons fail, increased flow through the remaining nephrons leads to glomerular hypertrophy and hyperfiltration and hydraulic injury, with the secondary changes of FSGS. It is also described as remnant nephropathy (see p. 776). Associations include:

• *reduced nephron number* (e.g. nephrectomy, hypertension, gross obesity, ischaemia, sickle nephropathy, reflux nephropathy, chronic allograft nephropathy, IgA nephropathy, and scarring following renal vasculitis)

• *mutations* in specific podocyte genes

• *viruses*, e.g. HIV type 1, erythrovirus B19, cytomegalovirus, Epstein–Barr virus and simian virus 40

• *drugs* such as heroin, all interferons, anabolic steroids, lithium, sirolimus, pamidronate and calcineurin inhibitors, e.g. ciclosporin, which can also cause FSGS

• *APOL1 gene mutations* in patients of African ancestry, which makes them susceptible to FSGS in response to insults such as hypertension, SLE and HIV.
**HIV-associated nephropathy**

In HIV-associated nephropathy (HIVAN), glomeruli are characteristically ‘collapsed’ on light microscopy (Fig. 20.13C); podocytes are enlarged, hyperplastic and coarsely vacuolated, containing protein absorption droplets and overlying capillaries with varying degrees of wrinkling and collapse of the walls. Direct podocyte HIV-1 infection is associated with loss of podocyte-specific markers such as Wilms' tumour factor and synaptopodin in HIVAN. HIVAN presents with nephrotic-range proteinuria, oedema and CKD, which can be rapid in progression. Antiretroviral therapy (ART) may reverse the renal lesions seen, and restores renal function if treatment is commenced early.

**Membranous glomerulopathy**

Idiopathic membranous glomerulopathy is an autoimmune disease that occurs mainly in adults, and predominantly in men. It presents with asymptomatic proteinuria or frank nephrotic syndrome. Microscopic haematuria, hypertension and/or renal impairment may accompany the nephrotic syndrome. As in other glomerular disease, hypertension and a greater degree of renal impairment are poor prognostic signs. In membranous glomerulopathy, almost half of the patients undergo spontaneous or therapy-related remission. Eventually, however, about 40% develop CKD, usually in association with persistent nephrotic-range proteinuria. Younger people, females and those with asymptomatic proteinuria of modest degree at the time of presentation do best.

**Pathogenesis**

In the primary or idiopathic form (which comprises 75% of the cases), glomerular histology is identical to that seen when membranous glomerulopathy is secondary to another insult. These include:

- drugs (e.g. penicillamine, gold, NSAIDs, probenecid, mercury, captopril)
- autoimmune disease (e.g. SLE, thyroiditis)
- infections (e.g. hepatitis B, hepatitis C, schistosomiasis, *Plasmodium malariae*)
- cancers (e.g. carcinoma of the lung, colon, stomach, breast and lymphoma)
- other causes (e.g. sarcoidosis, kidney transplantation, sickle cell disease).

A majority of patients (70%) with idiopathic membranous nephropathy have been found to have IgG4-type autoantibodies against phospholipase A₂ receptor (PLA₂R), a glycoprotein constituent of normal glomeruli. PLA₂R is present in normal human podocytes and in immune deposits in patients with idiopathic membranous nephropathy, indicating that it could be a major autoantigen in this disease; it is linked to human leucocyte antigen (HLA)-DQA1. Specific IgG4 autoantibodies to anti-aldose reductase (AR) and anti-manganese superoxide dismutase (SOD2) have also been found in the sera and glomeruli of patients with membranous
nephropathy but not in other renal pathologies or normal kidney. Recently, antibodies against a novel antigen, thrombospondin type 1 domain-containing 7A (THSD7A), have been identified in anti-PLA$_2$R-negative patients with membranous nephropathy. This suggests that AR, THSD7A and SOD2 could be additional renal autoantigens of human membranous nephropathy under certain clinical circumstances.

On light microscopy, capillary loops appear thick. Using a periodic acid–Schiff, or silver, stain (which highlights basement membrane), ‘spikes’ of basement membrane are visible. On electron microscopy, small, electron-dense deposits in the sub-epithelial aspects of the capillary walls are seen, encircled by perpendicular basement membrane spikes. Uniform granular capillary wall deposits of PLA$_2$R antigen and IgG subclasses (IgG4 is predominant in idiopathic membranous nephropathy), as well as complement C3, are seen on immunofluorescence. Late in the disease, deposits are completely surrounded by basement membrane and are undergoing resorption, which appears as uniform thickening of the capillary basement membrane on light microscopy (Fig. 20.14).

![Membranous glomerulopathy](image)

As many as a third or more of patients will undergo spontaneous remission if watched for at least 6–12 months, particularly if kidney function is normal and proteinuria modest. In general, patients with heavier proteinuria, progressive renal dysfunction and a high titre of anti-PLA₂R antibodies are considered for early treatment.

• All patients should receive ACE inhibition at the maximum tolerated dose.
• The alkylating agents, cyclophosphamide (1.5–2.5 mg/kg per day for 6–12 months with 1 mg/kg per day of oral prednisolone on alternate days for the first 2 months) and chlorambucil (0.2 mg/kg per day in months 2, 4 and 6, alternating with oral prednisolone 0.4 mg/kg per day in months 1, 3 and 5), are both effective.
• Ciclosporin or tacrolimus is also of use, though remission is less well sustained and treatment courses are longer.
• Mycophenolate mofetil has demonstrated benefit in smaller studies with short follow-up.
• Anti-CD20 antibodies (rituximab, which ablates B lymphocytes) have been shown to improve renal function, reduce proteinuria and increase the serum albumin; no significant adverse affects have been shown in the short term.
• Oral corticosteroids are of no benefit alone but may be additive. A pilot study has shown promise with subcutaneous administration of adrenocorticotrophic hormone (tetracosactide) twice weekly, demonstrating an improvement in proteinuria. It is believed that it acts directly on podocytes by binding to melanocortin receptors. It is licensed by the FDA for use in nephrotic syndrome of any cause.

Amyloidosis

Amyloidosis (see pp. 1288–1289) is a systemic acquired or inherited disorder of protein folding, in which normally soluble proteins or fragments are deposited extracellularly as abnormal insoluble fibrils, causing progressive organ dysfunction and death.

The abnormal protein may be derived from light chains or immunoglobulin (AL amyloid), or from serum amyloid A protein (AA amyloid). The renal consequences are similar, even if systemic features differ.

Pathology

On light microscopy, widespread eosinophilic deposits are seen in the mesangium, capillary loops and arteriolar walls. Deposits stain pink, with green bi-refringence under polarized light with Congo red (Fig. 20.15). On electron microscopy, the characteristic fibrils of amyloid can be seen. Amyloid consisting of immunoglobulin light chains (AL amyloid) can be identified by immunohistochemistry in only 40% of cases, as compared to almost 100% of patients with protein found in secondary amyloid (AA amyloid).
The diagnosis can often be made clinically when features of amyloidosis are present elsewhere (see p. 1289). On imaging, the kidneys are often large. Scintigraphy with radiolabelled serum amyloid P (SAP), a technique for quantitatively imaging amyloid deposits in vivo, is used to detect the rate of regression or progression of amyloidosis over a period of time (see p. 1289). Renal biopsy is necessary in all suspected cases of renal involvement.

Management
Treatments that reduce production of the amyloidogenic protein can improve organ function and survival in immunoglobulin-light-chain-related (AL) amyloidosis and hereditary transthyretin-associated (ATTR) amyloidosis (see p. 1288). In AA amyloidosis, production of serum amyloid A can sometimes be decreased by treatment of the underlying inflammatory condition but cannot be completely suppressed.

Renoprotective measures should be started (see (Box 20.9)). The success of dialysis and kidney transplantation depends on the extent of amyloid deposition in extrarenal sites, especially the heart.

Diabetic nephropathy
Diabetic renal disease is the leading cause of ESKD in the Western world, arising largely as a complication of type 2 diabetes mellitus. Diabetic kidney disease occurs in about 20–30% of both type 1 and type 2 diabetics (see pp. 1269–1270); the natural history is similar from the onset of proteinuria, and the histological lesion is the same. Risk factors for nephropathy include poor glycaemic control, hypertension, male gender, ethnicity and social deprivation.

Pathology
Glomerular hyperfiltration (the GFR increases to >150 mL/min/m²) and initial enlargement of kidney volume occur as local vasoactive factors increase flow. The GBM thickens and the mesangium expands. Progressive depletion of podocytes (see p. 733) from the filtration barrier
(through apoptosis or detachment) results in podocyturia early in the disease. Proteinuria evolves as filtration pressures rise and the filter is compromised. Later, glomerulosclerosis develops with nodules (Kimmelstiel–Wilson lesion) and hyaline deposits in the glomerular arterioles (Fig. 20.16). Mesangial expansion and hyalinosis are partly due to amylin (β-islet-specific amyloid protein) deposits, with increasingly heavy proteinuria.

The Renal Pathology Society has developed a consensus classification combining type 1 and type 2 diabetic nephropathies (Box 20.8). This discriminates lesions by various degrees of severity for use in international clinical practice.

The pathophysiology is discussed on page 1269.

### Management
Lifestyle changes (cessation of smoking, attention to salt intake, weight loss and increased
exercise) are necessary in preventing progression of any diabetic complication.

- **Aim for good (intensive) glycaemic control.** If achieved for even a limited period, this reduces the incidence of ESKD and other microvascular complications in the long term (the so-called ‘legacy effect’ in both type 1 and type 2 diabetes mellitus).

- **Control dyslipidaemia.**

- **Control blood pressure** to <120/80 mmHg with ACE inhibitors or AII-RA; these should be used once microalbuminuria develops, even if blood pressure control is good. Combined use of ACE inhibitors and AII-RA (dual blockade) does not provide additional benefit but is associated with an increased risk of AKI and hyperkalaemia; it is no longer recommended in recent trials.

  As in other kidney diseases, however, nearly the entire course of renal injury in diabetes is clinically silent. The aim of medical intervention during this silent phase is renoprotection (**Box 20.9**), as judged by a slowed loss of glomerular filtration over time. Despite intensified metabolic control and antihypertension treatment in patients with diabetes, a substantial number still go on to develop ESKD.

---

**Box 20.9**

**Renoprotection**

**Goals of treatment**

- Blood pressure <120/80 mmHg
- Proteinuria <0.3 g/24 h

**Treatment measures**

*Patients with chronic kidney disease and proteinuria >1 g/24 h:*

- Angiotensin-converting enzyme inhibitor increasing to maximum dose
- Angiotensin receptor antagonist if goals are not achieved\(^a\)
- Addition of diuretic to prevent hyperkalaemia and help to control blood pressure
- Addition of calcium-channel blocker (verapamil or diltiazem) if goals are not achieved

**Additional management**

- Statins to lower cholesterol to <4.5 mmol/L
- Smoking cessation (threelfold higher rate of deterioration in chronic kidney disease)
- Treatment of diabetes (HbA\(_{1c}\) <7%, 53 mmol/mol)
- Normal protein diet (0.8–1 g/kg body weight)

---

\(^a\)In type 2 diabetes start with angiotensin receptor antagonist.
Other interventions with a less robust evidence base include:

- **Paricalcitol** (a selective activator of the vitamin D receptor), added to treatment with ACE inhibitors, reduced albuminuria (a surrogate marker of progressive renal disease) in patients with type 2 diabetes in a randomized controlled trial. Paricalcitol worked best in patients with a high sodium intake in their diet, who are known to respond poorly to ACE inhibitor and angiotensin receptor blocker therapy.

- **Bardoxolone methyl** is a nuclear 1 factor (erythroid-derived 2)-related factor 2 (NRF-2) activator, an anti-inflammatory known to reduce oxidative stress. A large study failed to demonstrate benefit in patients with type 2 diabetes mellitus and CKD.

- **Pentoxiphylline** (previously used for peripheral vascular disease) slows the rate of GFR decline and proteinuria (by putatively reducing the production of tumour necrosis factor-alpha, TNF-α). This interesting observation requires external validation.

- **Atrasentan** (a selective endothelin A receptor (ETₐ-R) antagonist when used with renin–angiotensin system inhibitors) is similarly generally safe and effective in reducing residual albuminuria. This could ultimately translate into improved renal outcomes in patients with type 2 diabetic nephropathy, but needs confirmation in long-term follow-up studies.

### Isolated proteinuria without haematuria

In asymptomatic patients, this is often an incidental finding. It is usually found at <1 g/day) with normal renal function. Over 50% of these patients have postural proteinuria. The outcome of isolated proteinuria (postural or non-postural) is excellent in the majority of patients, with a gradual decline in proteinuria over time. Occasionally, it may be an early sign of a serious glomerular lesion such as membranous glomerulopathy, IgA nephropathy, FSGS, diabetic nephropathy or amyloidosis (see above). Mild proteinuria may also accompany a febrile illness, congestive heart failure or infectious diseases with no clinical renal significance.

### Glomerulonephritis (asymptomatic, acute and rapidly progressive)

Glomerulonephritis (GN) is immunologically mediated, with involvement of cellular immunity (T lymphocytes, macrophages/dendritic cells), humoral immunity (antibodies, immune complexes, complement) and other inflammatory mediators (including cytokines, chemokines and the coagulation cascade). The immune response can be directed against known target antigens, particularly when GN complicates infections, cancers or drugs. The underlying antigenic target is more often unknown. Primary GN may occur in genetically susceptible individuals (usually determined by major histocompatibility complex (MHC) genes like HLA-A1, B8, DR2 and DR3), following environmental insults. Circulating autoantibodies and/or abnormalities in serum complement, and glomerular deposition of antibodies, immune complexes, complement and fibrin characterize the condition. Glomerulonephritis may present
as:
• asymptomatic urinary abnormalities
• acute nephritis (nephritic syndrome)
• rapidly progressive glomerulonephritis.

The same underlying histology may often present in any of the above ways, and these should be seen as clinical syndromes on a spectrum rather than as distinct diseases.

Asymptomatic urinary abnormalities

*Haematuria with or without sub-nephrotic-range proteinuria* in an asymptomatic patient may lead to the early discovery of potentially serious glomerular disease such as SLE, Henoch–Schönlein purpura, post-infectious GN or idiopathic hypercalciuria in children. Asymptomatic haematuria is also the primary presenting manifestation of a number of specific glomerular diseases discussed below.

**Acute nephritis (nephritic syndrome)**

This classically presents as:
• haematuria (macroscopic or microscopic) – with red-cell casts on urine microscopy
• proteinuria
• hypertension
• oedema (periorbital, leg or sacral)
• temporary oliguria and uraemia.

Nephritis can present indolently or incidentally, and is usually distinguished from rapidly progressive glomerulonephritis (see below) by the lack of cellular necrosis (and crescent formation) in the glomeruli seen on biopsy, and the rate at which renal decline evolves. These syndromes should be seen as a continuum.

**Rapidly progressive glomerulonephritis**

Rapidly progressive glomerulonephritis (RPGN) is a syndrome with glomerular haematuria (red blood cell casts or dysmorphic red blood cells), rapidly developing acute kidney failure over weeks to months and focal glomerular necrosis (*Fig. 20.17*) with or without glomerular crescent development on renal biopsy. The ‘crescent’ is an aggregate of macrophages and epithelial cells in Bowman's space (*Fig. 20.17*). RPGN can develop with immune deposits (anti-GBM or immune complex type, e.g. SLE) or without immune deposits (pauci-immune, e.g. anti-PR3 and or anti-MPO-ANCA-positive vasculitides). It can also develop as an idiopathic primary glomerular disease, or can be superimposed on secondary glomerular diseases such as IgA nephropathy, membranous GN and post-infective GN. It can be classified
Based on the pattern of immune complex deposition in glomeruli (seen on immunofluorescence): that is, linear, granular and negative immunofluorescent patterns (Box 20.10).

**Figure 20.17** Rapidly progressive glomerulonephritis (RPGN). Arrows show 'crescents' with aggregates of macrophages and epithelial cells in Bowman's space. A. Focal necrotizing glomerulonephritis. B. Crescentic glomerulonephritis.

### Box 20.10

**Types of rapidly progressive glomerulonephritis (RPGN)**

**Linear immunofluorescent pattern (Fig. 20.20A)**

- Idiopathic anti-GBM antibody-mediated RPGN
- Goodpasture syndrome

**Granular immunofluorescent pattern (immune complex-mediated RPGN; see Fig. 20.20B)**

- Idiopathic immune complex-mediated RPGN
- Associated with other primary GN:
  - Mesangiocapillary GN (type II > type I)
  - IgA nephropathy
  - Membranous glomerulopathy
- Associated with secondary GN:
  - Post-infectious GN
  - Systemic lupus erythematosus
  - Henoch–Schönlein syndrome
  - Cryoglobulinaemia
**Negative immunofluorescent pattern (pauci-immune RPGN)**

- ANCA-associated systemic vasculitides
  
  ANCA, anti-neutrophil cytoplasmic antibody; GBM, glomerular basement membrane; IgA, immunoglobulin A.

---

**Post-streptococcal glomerulonephritis**

Post-streptococcal glomerulonephritis (PSGN) occurs in childhood. An acute nephritis follows 1–3 weeks after a streptococcal infection. Streptococcal throat infection, otitis media or cellulitis can all be responsible. The infecting organism is a Lancefield group A β-haemolytic streptococcus of a nephritogenic type. The latent interval between infection and the development of symptoms and signs of renal involvement reflects the time taken for immune complex formation and deposition and glomerular injury to occur. PSGN is now rare in developed countries. Renal biopsy shows diffuse, florid, acute inflammation in the glomerulus (without necrosis but occasionally cellular crescents), with neutrophils and deposition of IgG and complement *(Fig. 20.18)*. Ultrastructural findings are those of electron-dense deposits, characteristically but not solely in the sub-epithelial aspects of the capillary walls. Endothelial cells often are swollen. Similar biopsy findings may be seen in **non-streptococcal post-infectious glomerulonephritis** *(Box 20.11).*
FIGURE 20.18  Post-streptococcal glomerulonephritis. A. Large aggregates of immune material (humps) in the extracapillary area. There is an increase in mesangial matrix and mesangial cells with occlusion of the capillary lumen by endothelial cell cytoplasm, leucocytes and mesangial cell cytoplasm. B. Light microscopy showing acute inflammation of the glomerulus with neutrophils. (After Marsh FP. Postgraduate Nephrology. Oxford: Butterworth Heinemann; 1985.)

Box 20.11  Diseases commonly associated with the acute nephritic syndrome

- Post-streptococcal glomerulonephritis
- Non-streptococcal post-infectious glomerulonephritis, e.g. Staphylococcus, pneumococcus, Legionella, syphilis, mumps, varicella, hepatitis B and C, echovirus, Epstein–Barr virus, toxoplasmosis, malaria, schistosomiasis, trichinosis
- Infective endocarditis
- Shunt nephritis
- Visceral abscess
- Systemic lupus erythematosus (see pp. 692–695)
- Henoch–Schönlein syndrome (see p. 748)
- Cryoglobulinaemia (see p. 748)
Management

The acute phase should be treated with good blood pressure control, diuretics and salt restriction for oedema, and dialysis as necessary. If recovery is slow, corticosteroids may be helpful. The prognosis is usually good in children. A small number of adults develop hypertension and/or CKD later in life. Therefore, in older patients, an annual blood pressure check and measurement of serum creatinine are required. Evidence in support of long-term penicillin prophylaxis after the development of glomerulonephritis is lacking. In non-streptococcal post-infectious glomerulonephritis, prognosis is equally good if the underlying infection is eradicated.

Glomerulonephritis with infective endocarditis

GN occurs rarely in patients with infective endocarditis (usually intravenous drug users), or in patients with infected ventriculoperitoneal shunts (shunt nephritis). Histology appearances resemble post-infectious GN but lesions are usually focal and segmental. Crescentic GN with AKI has been described, particularly with *Staphylococcus aureus* infection. Appropriate antibiotic therapy or surgical eradication of infection in fulminant cases usually results in a return of normal renal function.

GN also occurs associated with *visceral abscesses* (mainly pulmonary) and is indistinguishable from post-infectious GN. Complement levels are normal and immune deposits are absent on biopsy. Antibiotic therapy and surgical drainage of the abscess result in complete recovery of renal function in approximately 50% of patients.

IgA nephropathy

IgA nephropathy (Fig. 20.19) has replaced post-streptococcal glomerulonephritis as the most common form of GN worldwide. Demographic and family studies support the existence of a genetic contribution to the pathogenesis of IgA nephropathy, but results from genetic association studies of candidate genes are inconsistent. A genome-wide analysis study conducted in European patients showed a strong association on chromosome 6p in the region of the MHC/DQ and HLA-B loci, suggesting that the HLA region contains the strongest common susceptibility alleles that predispose to IgA nephropathy.
Histology

There is a focal and segmental proliferative glomerulonephritis with mesangial deposits of polymeric IgA1. In some cases, IgG, IgM and C3 are also seen in the glomerular mesangium. Superimposed crescent formation is frequent, particularly following macroscopic haematuria associated with upper respiratory tract infection.

An Oxford histological classification for IgA nephropathy is shown in Box 20.12. The features have prognostic significance and it is recommended that they be taken into account for predicting outcome independent of the clinical features, both at the time of presentation and during follow-up.

*Mesangial hypercellularity is scored 0 for glomeruli with <4 mesangial cells per mesangial area; 1 for those with 4–5 cells; 2 for 6–7 cells; and 3 for ≥8 cells. Scores obtained for all glomeruli are then averaged.

Pathogenesis
The disease may be a result of a number of events, including:

- exaggerated bone marrow and tonsillar IgA1 immune response to viral or other antigens
- an association with an abnormality in O-linked galactosylation in the hinge region of the IgA1 molecule
- functional abnormalities of two IgA receptors – CD89 expressed on blood myeloid cells and the transferring receptor (CD71) on mesangial cells
- circulating immune complexes composed of a glycan-specific IgG and a galactose-deficient IgA1 antibody.

IgA-rich immune complexes deposit in the glomerular mesangium, inducing mesangial cell activation and proliferation, and matrix synthesis and deposition. Removal of these complexes by bacterial proteases attenuates injury, and it is thought that glycan-specific autoantibodies, rather than IgA1 itself, play a key role in the pathogenesis. Up to 50% of patients exhibit elevated serum IgA (polyclonal).

Several diseases are associated with IgA deposits, including Henoch–Schönlein purpura, chronic liver disease, malignancies (especially carcinoma of bronchus), seronegative spondyloarthritis, coeliac disease, mycosis fungoides and psoriasis.

### Clinical features

IgA nephropathy tends to occur in children and young males, presenting with asymptomatic microscopic haematuria or recurrent macroscopic haematuria following an upper respiratory or gastrointestinal viral infection. Proteinuria occurs and 5% of cases can be nephrotic. The prognosis is usually good, especially in those with normal blood pressure, normal renal function and absence of proteinuria at presentation. Surprisingly, recurrent macroscopic haematuria is a good prognostic sign, although this may be due to ‘lead-time bias’ (see p. 591), as patients with overt haematuria come to medical attention at an earlier stage of their illness. The risk of eventual development of ESKD is about 25% in those with proteinuria of more than 1 g per day, elevated serum creatinine, hypertension, ACE gene polymorphism (DD isoform) and tubulointerstitial fibrosis on renal biopsy.

### Management

- All patients, with or without hypertension and proteinuria, should receive an ACE inhibitor or an AII-RA, to reduce proteinuria and preserve renal function.
- Patients with proteinuria of over 1–3 g/day, mild glomerular changes only and preserved renal function should be treated with steroids. Steroids reduce proteinuria and stabilize renal function.
- Addition of azathioprine to steroids does not confer additional benefits. The combination of cyclophosphamide, dipyridamole and warfarin should not be used; nor should ciclosporin.
- In patients with progressive disease (falling to eGFR <60 mL/min), fish oils or prednisolone
with cyclophosphamide for 3 months, followed by maintenance with prednisolone and azathioprine, may be tried.

- A tonsillectomy can reduce proteinuria and haematuria in those patients with recurrent tonsillitis.
- Mesangial IgA deposits are commonly found in the allografts of transplanted patients but loss of graft function as a result is uncommon.

## Alport syndrome

Alport syndrome is a rare hereditary nephritis with haematuria, proteinuria (<1–2 g/day), progressive kidney disease and high-frequency nerve deafness. Approximately 15% of cases may have ocular abnormalities, such as bilateral anterior lenticonus, and macular and perimacular retinal flecks. In about 85% of patients with Alport syndrome there is an X-linked inherited mutation in the COL4α5 gene encoding the COL4α5 collagen chain, a critical component of the glomerular basement membrane. In female carriers, penetrance is variable and depends on the type of mutation or degree of mosaicism following hybridization of the X chromosome. Patients with autosomal recessive or dominant modes of inheritance have also been described with mutations in COL4α3 or COL4α4 gene. In families with stromal cell tumours, there is an additional mutation in the COL4α6 gene.

These mutations present as post-translational defects in α3, α4 and α5 chains, and result in incorrect assembly or folding of monomers; defective monomers are rapidly degraded. Over time, the basement membrane undergoes selective proteolysis, and glomerular membranes thicken unevenly, split and ultimately deteriorate.

Although the basement membrane is abnormal, podocyte function and the slit diaphragm are unaffected. Proteinuria in Alport syndrome is often mild and is the result of glomerular sclerosis, rather than primary loss of slit pores.

In some patients with Alport syndrome and carriers, a thin basement membrane, as seen in benign familial haematuria, is the only abnormality detected on histology. For this reason, the boundary between Alport's and benign familial haematuria has become increasingly vague.

## Management

The disease is progressive and accounts for some 5% of cases of ESKD in childhood or adolescence. Patients with mild CKD can be treated with ACE inhibitors to attenuate proteinuria. Exciting experimental evidence suggests that mesenchymal stem cells can transdifferentiate into podocytes and repair basement abnormalities and slow the rate of progression. Anti-GBM antibody does not adhere normally to the glomerular basement membrane of affected individuals but development of crescentic glomerulonephritis in the transplanted kidney due to anti-GBM alloantibody is a well-recognized complication.
**Thin glomerular basement membrane disease**

This condition is inherited as an autosomal dominant and typically presents with persistent microscopic glomerular haematuria (red blood cell casts or dysmorphic red blood cells). The diagnosis is made on renal biopsy, which shows thinning of the glomerular capillary basement membrane on electron microscopy. The condition was under-diagnosed and is much more common than previously believed. The prognosis for renal function is usually very good but some patients develop renal insufficiency over decades. The cause of renal impairment in this condition is not known but may be due to secondary FSGS or concomitant IgA nephropathy. Misdiagnosis occurs with Alport syndrome, which shares similar histological features. No treatment is of known benefit.

**Anti-GBM glomerulonephritis**

Anti-GBM glomerulonephritis *(Fig. 20.20A)*, characterized by linear capillary loop staining with IgG and C3 and extensive crescent formation, accounts for 15–20% of all cases of RPGN, although overall represents less than 5% of all forms of glomerulonephritis. This condition is rare, with an incidence of 1 per 2 million in the general population. About two-thirds of these patients have Goodpasture syndrome with associated lung haemorrhage (see p. 1121). The remainder have a renal restricted anti-GBM RPGN, which is seen in patients over 50 years and affects both genders equally.

![Immunofluorescence](image.png)

**FIGURE 20.20** Immunofluorescence. A. Anti-glomerular basement membrane antibody (anti-GBM) deposition in a linear pattern typical of Goodpasture syndrome. B. Showing immune complex deposition in a diffuse granular pattern.

Anti-GBM antibodies (detected by enzyme-linked immunosorbent assay, or ELISA) are present in serum and are directed against the **non-collagenous (NCI) component** of α3 (IV) collagen of the basement membrane. This target antigen must be present as a component of the native α3, α4, α5 (IV) network of selected basement membrane in order for pulmonary and renal disease to develop. Anti-GBM glomerulonephritis never occurs in patients with Alport syndrome; although it can develop after patients with Alport's receive a kidney transplant, anti-GBM alloantibodies evolve in response to the ‘foreign’ α3, α4, α5 (IV) collagen network.
absent in a patient's own kidneys.

Anti-GBM RPGN is restricted by the major histocompatibility complex; HLA-DRB1*1501 and HLA-DRB1*1502 alleles increase susceptibility, whereas HLA-DR7 and HLA-DR1 are protective. The thymus expresses α3 (IV) NCl peptides that can eliminate autoreactive CD4+ helper T cells, but a few such cells escape deletion and are kept in check by circulating regulatory cells (Treg). Breakdown of this peripheral tolerance (the mechanism of which is unknown) results in these autoreactive CD4+ cells producing anti-GBM antibodies. These antibodies are very specific: antibodies against α1, α2 and α3 NCl domains do not cause RPGN. Since the α3 (IV) NCl epitope is hidden within the α3, α4 and α5 (IV) promoter, it is presumed that an environmental factor, such as exposure to hydrocarbons or tobacco smoke, is required in order to reveal cryptic epitopes to the immune system.

The mechanism of renal injury is complex. When anti-GBM antibody binds basement membrane, it activates complement and proteases, and results in disruption of the filtration barrier and Bowman's capsule, causing proteinuria and the formation of crescents. Crescent formation is facilitated by IL-12 and γ-interferon, which are produced by resident and infiltrating inflammatory cells.

**Management** involves:

- **plasma exchange** to remove circulating anti-GBM antibodies
- **steroids** to suppress inflammation from antibody already deposited in the tissue
- **cyclophosphamide** to suppress further antibody synthesis.

The **prognosis** is directly related to the extent of glomerular damage (measured by percentage of glomeruli containing crescents, serum creatinine and need for dialysis) at the initiation of treatment. When oliguria occurs or serum creatinine rises above 600–700 µmol/L, renal failure is usually irreversible. Once the active disease is treated, this condition, unlike other autoimmune diseases, does not follow a remitting/relapsing course. If left untreated, autoantibodies diminish spontaneously within 3 years and autoreactive T cells cannot be detected in the convalescent patients. This is suggestive of re-establishment of peripheral tolerance, which coincides with re-emergence of regulatory CD25+ cells in the peripheral blood; these play a key role in inhibiting the autoimmune response. The emergence and persistence of these regulatory cells may underlie the ‘single hit’ nature of this condition.

### ANCA-positive small-vessel vasculitis

(See also p. 702.) Inflammation and necrosis of the blood vessel wall occurs in many primary vasculitic disorders. The small-vessel vasculitides affecting the kidney include:

- granulomatosis with polyangiitis (GPA)
- microscopic polyangiitis (MPA)
- renal-limited vasculitis (without systemic features)
- eosinophilic granulomatosis with polyangiitis (which is frequently ANCA-negative).
The anti-neutrophil cytoplasmic antibody (ANCA)-associated small-vessel vasculitides are GPA, MPA and renal-limited vasculitis. GPA and MPA share a common pathology with focal necrotizing lesions, which affect many different vessels and organs:

- in the lungs, a capillaritis may cause lung haemorrhage
- within the glomerulus of the kidney, crescentic GN and/or focal necrotizing lesions (FNGN) may cause AKI (see Fig. 20.17)
- in the dermis, a purpuric rash or vasculitic (Fig. 20.21) ulceration.

Renal histology is regarded as a ‘gold standard’ for the diagnosis and prognostication of ANCA-associated GN. A consensus group proposed a new classification around four general categories of lesions:

- **focal** (≥50% normal glomeruli that are not affected by the disease process)
- **crescentic** (≥50% of glomeruli with cellular crescents)
- **mixed** (a heterogeneous glomerular phenotype in which no glomerular feature predominates)
- **sclerotic** (≥50% of glomeruli with global sclerosis).

This system has been shown to have a prognostic value for 1- and 5-year renal outcomes, and may guide therapy.

### Pathogenesis

There are two forms of ANCA (see p. 650; Fig. 20.22):

- PR3-ANCA (cANCA)
- MPO-ANCA (pANCA).
If ELISA and indirect immunofluorescence techniques are combined, diagnostic specificity is 99%. ANCA and anti-GBM antibodies do occur together; such patients tend to follow the natural history of Goodpasture syndrome.

- **PR3-ANCA positivity** is found in the large majority (>90%) of patients with active GPA and in up to 50% of patients with MPA.

- **Anti-MPO positivity** is present in the majority of patients with renal-limited vasculitis and in a variable number of cases of MPA. There is some evidence to suggest that ANCA are pathogenic and not just markers of disease; for example, development of drug-induced ANCA is associated with vasculitic lesions in humans. Eosinophilic GPA may have either anti-MPO or anti-PR3 ANCA.

- **Positivity for both types of ANCA** antibodies occurs in up to 10% of patients, who have a variable clinical course but a worse renal outcome.

- **Drugs** (e.g. propylthiouracil, hydralazine, minocycline, penicillamine) may induce vasculitis associated (most commonly) with MPO-ANCA, often in very high titres. Many cases of drug-induced ANCA-associated vasculitis present with constitutional symptoms, arthralgias/arthritis and cutaneous vasculitis. Crescentic GN and lung haemorrhage can also occur.

Both ANCA autoantigens are present in immature neutrophil granules. In contrast to the normally silenced state of these two genes in mature neutrophils of healthy subjects, **PR3** and **MPO** are aberrantly expressed in mature neutrophils of patients with ANCA vasculitis due to unsilencing of both antigens because of epigenetic modifications.

- It is unclear how and why **autoimmunity** causes the formation of ANCA antibodies. Patients with anti-PR3 also have autoantibodies to a peptide translated from the antisense DNA strand of PR3 (complementary PR3; cPR3) or to a mimetic of this peptide. This suggests that
autoimmunity can be initiated through an immune response against a peptide that is antisense or complementary to the autoantigen, which then induces anti-idiotypic antibodies (autoantibodies) that cross-react with the autoantigen.

- A recent study has shown that infection by fimbriated bacteria (Gram-negative pathogens such as *Escherichia coli*, *Klebsiella pneumoniae* and *Proteus mirabilis*) can trigger, due to molecular mimicry, a cross-reactive autoimmunity to lysosomal membrane protein 2 (LAMP-2), a glycosylated membrane protein that is co-localized with PR3 and MPO in the intracellular vesicles of neutrophils.

Other factors that contribute to the initiation of an ANCA autoimmune response and the induction of injury by ANCA include genetic predisposition (α1-antitrypsin deficiency, Pi-Z allele) and environmental factors (e.g. silica exposure, viral infection, *Staph. aureus* infection).

### Management

The sooner treatment is instituted, the greater chance there is of recovery of renal function.

- **High-dose oral corticosteroids** and **intravenous pulsed cyclophosphamide** are of benefit in inducing remission. The best indicators of prognosis are pulmonary haemorrhage and severity of renal failure at presentation.

- **Rituximab** has been shown in two studies to be equally effective as cyclophosphamide for inducing remission in ANCA-associated vasculitides in the short term (6–12 months), with similar adverse event rates. Rituximab may be a therapeutic option in patients who cannot tolerate cyclophosphamide, and in those whose disease is poorly controlled and who relapse while on cyclophosphamide.

- **Fulminant disease** requires intensification of immunosuppression with adjuvant plasma exchanges or intravenous pulsed methylprednisolone (1 g/day for 3 consecutive days). Plasma exchange appeared to have a better outcome than pulsed methylprednisolone in one study.

- Once remission has been achieved, mycophenolate mofetil or azathioprine should be substituted for cyclophosphamide. Use of rituximab every 3 months in fixed dose has recently been shown to be superior to azathioprine in the maintenance of remission.

- Colonization of the upper respiratory tract with *Staph. aureus* increases the risk of relapse, and treatment with sulfamethoxazole/trimethoprim reduces the relapse rate.

- Relapse after complete cessation of immunosuppressive therapy has been observed relatively frequently, and therefore long-term, albeit relatively low-dose, immunosuppression is necessary.

- Intravenous immunoglobulin (anti-thymocyte globulin (ATG) directed against activated T lymphocytes causes lymphopenia), lymphocyte-depleting anti-CD52 (campath-IH) antibodies and anti-TNF therapy have shown promise in the treatment of severe and drug-resistant cases as induction therapy. However, an anti-TNF agent, etanercept, has been ineffective as a sole
agent for maintenance.

- Up to 25% of patients with PR3-ANCA harbour antibodies against human plasminogen and/or tissue plasminogen activator. Their presence has been correlated with venous thromboembolic events and fibrinoid necrotic glomerular lesions, suggesting functional interference with fibrinolysis. However, a formal role for anticoagulation in patients with ANCA-associated GN remains uncertain.

**Mixed nephritic and nephrotic syndrome**

Injury involves mesangial cells, endothelium, the basement membrane and podocytes in this heterogenous group of conditions.

**Mesangiocapillary (membranoproliferative) glomerulonephritis**

Mesangiocapillary (membranoproliferative) glomerulonephritis (MCGN) is an uncommon descriptive lesion that has three subtypes with similar clinical presentations: the nephrotic syndrome, haematuria, hypertension and renal impairment. They also produce similar microscopic findings, although the pathogenesis may be different. Electron microscopy defines:

- **Type 1 MCGN** involves mesangial cell proliferation, with mainly sub-endothelial immune deposition and apparent splitting of the capillary basement membrane, giving a ‘tramline’ effect. It can be associated with persistently reduced plasma levels of C3 and normal levels of C4, and activation of the classical complement cascade. It is often idiopathic but occurs with chronic infection (abscesses, infective endocarditis, infected ventriculoperitoneal shunt) or cryoglobulinaemia secondary to hepatitis C infections (Fig. 20.23A).

- **Type 2 MCGN** demonstrates mesangial cell proliferation with electron-dense, linear (ribbon-
like) intramembranous deposits that usually stain for C3 only (Fig. 20.23B). This dense deposit disease may be idiopathic or may be associated with factor H deficiency and partial lipodystrophy (loss of subcutaneous fat on the face and upper trunk). Alternatively, C3 nephropathy presents with low C3 levels (as in type 1 MCGN), due in this case to activation of the alternative pathway of the complement cascade, where loss-of-function mutations in complement factor H allow uncontrolled alternative pathway activation. Autoantibodies to the C3 convertase enzyme (C3 nephritic factor) are present. In patients of Cypriot origin, an autosomal dominant inherited heterozygous duplication in the CFHR5 gene (CFHR5 nephropathy) leads to a similar presentation.

• **Type 3 MCGN** has features of both type 1 and type 2 disease. Complement activation appears to be via the final common pathway of the cascade.

  Most patients eventually go on to develop ESKD over several years. Type 2 MCGN recurs in virtually 100% of renal transplant patients but recurrence is less common in type 1 (25%).

**Management**

In idiopathic MCGN (all age groups) with normal renal function and non-nephrotic-range proteinuria, no specific therapy is required. Good blood pressure control, ideally with an ACE inhibitor, is of benefit.

In children with the nephritic syndrome and/or impaired renal function, a trial of steroids is warranted (alternate-day prednisolone 40 mg/m$^2$ for a period of 6–12 months). If no benefit is seen, this treatment is discontinued. Regular follow-up, with control of blood pressure, use of agents to reduce proteinuria and correction of lipid abnormalities, is necessary.

In adults with the nephritic syndrome and/or renal impairment, aspirin (325 mg) or dipyridamole (75–100 mg) daily, or a combination of the two, should be given for 6–12 months. Again, if no benefits are seen, the treatment should be stopped. Treatment to slow the rate of progression of CKD is instituted (see p. 782). In C3 nephropathy due to loss-of-function mutation in complement factor H, anti-C5 antibody (eculizumab) has been used successfully in several patients.

**IgM nephropathy**

This disorder is characterized by increased mesangial cellularity in most of the glomeruli, associated with granular immune deposits of IgM and complement. People present with episodic or persistent haematuria and the nephrotic syndrome. Unlike in minimal-change disease, the prognosis is not uniformly good, as steroid response is only 50%. Between 10% and 30% develop progressive renal insufficiency with evidence of secondary FSGS (see p. 737) on repeat biopsy. A trial of cyclophosphamide with prednisolone is used with persistent nephrotic syndrome, particularly when there is a rising plasma creatinine concentration.

**C1q nephropathy**
C1q nephropathy is very similar to IgM nephropathy in presenting features and microscopic appearance, with the exception of C1q deposits in the mesangium. Sometimes it is misdiagnosed as lupus nephritis, particularly in people with negative serology (so-called ‘seronegative lupus’). The distinguishing features are intense C1q staining and absence of tubuloreticular inclusions (attributable to high circulating α-interferon) on electron microscopy. Only some people are steroid-dependent. Progression to CKD is, as in most glomerular diseases, most likely to occur in people with heavy proteinuria and renal insufficiency.

### Idiopathic fibrillary glomerulopathy

In this rare condition, microfibrillary structures are seen in the mesangium and glomerular capillary wall on electron microscopy that are clearly different from those seen in amyloidosis; the fibrils are larger than in amyloidosis (20–30 nm versus 10 nm in diameter) and do not stain with Congo red. The median age at presentation is approximately 45 years (range 10–80 years). People present with proteinuria, mostly in the nephrotic range (60%), and microscopic haematuria (70%), hypertension and CKD (50%) that may progress rapidly; 40–50% of patients develop ESKD within 2–6 years. No treatment is known to be of benefit.

### Immunotactoid glomerulopathy

In this disorder, microtubules that are much larger (30–40 nm in diameter) than the fibrils in fibrillary glomerulopathy are seen on electron microscopy. The majority of patients have circulating paraproteins, or monoclonal immunoglobulin deposition is seen in the glomeruli on immunofluorescence microscopy. A lymphoproliferative disease is the underlying cause in over 50% of cases. The clinical presentation and course are similar to those of fibrillary glomerulopathy. Complete or partial remission of the nephrotic syndrome can be achieved with chemotherapy in 80% of patients.

### Fibronectin glomerulopathy

This is also a form of glomerulonephritis due to fibrillar deposits, which, unlike amyloidosis but like fibrillary glomerulonephritis and immunotactoid glomerulopathy, is negative for Congo red staining. It is inherited as an autosomal dominant disorder and is associated with the massive deposition of fibronectin, a large dimeric glycoprotein consisting of two similar subunits (approximately 250 kDa in weight). The possible genetic abnormality in this disorder is a loss-of-function mutation in uteroglobin.

Fibronectin glomerulopathy is extremely rare and was originally described only in Caucasians of European descent. An Asian family with this disease has since been reported. There are as yet no known cases in black or Hispanic people. It presents with varying degrees of proteinuria seen first between the ages of 20 and 40, followed by hypertension, microscopic haematuria, and slow progression to ESKD in most patients.
Systemic lupus erythematosus (lupus nephritis)

Overt renal disease occurs in at least one-third of systemic lupus erythematosus (SLE) patients and, of these, 25% reach end-stage CKD within 10 years (see also pp. 693–694). Histologically, almost all patients will have changes. **Box 20.13** shows the progression of the histological findings and the clinical picture from classes I to VI.

### Box 20.13

**Classification of lupus nephritis**

- **Class I** – *Minimal mesangial lupus nephritis (LN)*, with immune deposits but normal on light microscopy. Asymptomatic.
- **Class II** – *Mesangial proliferative LN* with mesangial hypercellularity and matrix expansion. Clinically, there is mild renal disease.
- **Class III** – *Focal LN* (involving <50% of glomeruli) with subdivisions for active or chronic lesions. Subepithelial deposits seen. Clinically, there is haematuria and proteinuria; 10–20% of all LN.
- **Class IV** – *Diffuse LN* (involving >50% of glomeruli; **Fig. 20.24**) classified by the presence of segmental and global lesions as well as active and chronic lesions. Subendothelial deposits are present. Clinically, there is progression to the nephrotic syndrome, hypertension and renal insufficiency. Most common and most severe form of LN.
- **Class V** – *Membranous LN* affects 10–20% of patients. Can occur in combination with class III or IV. Good prognosis.
- **Class VI** – *Advanced sclerosing LN* (≥90% globally sclerosed glomeruli without residual activity). This represents the advanced stages of the above, as well as healing. Immunosuppressive therapy is unlikely to help, as it is ‘inactive’. Progressive CKD.

**Figure 20.24** Lupus nephritis type IV – a diffuse proliferative nephritis. There is proliferation of endothelial and mesangial cells.
Serial renal biopsies show that in approximately 25% of patients, histological appearances change from one class to another during the inter-biopsy interval. Immune deposits in the glomeruli and mesangium are characteristic of SLE (tubuloreticular structure in glomerular endothelial cells) and stain positive for IgG, IgM, IgA and the complement components C3, C1q and C4 on immunofluorescence.

**Pathophysiology**

SLE is known to be a multifactorial autoantigen-driven, T-cell-dependent and B-cell-mediated autoimmune disorder (see pp. 692–695).

- Lupus nephritis typically associates with multiple circulating autoantibodies to cellular antigens (particularly anti-dsDNA, anti-Ro), and with complement activation, which leads to reduced serum levels of C3, C4 and (particularly) C1q.

- C1q is the first component of the classical pathway of the complement cascade (see p. 124) and is involved in the activation of complement and clearance of self-antigens generated during apoptosis.

- Although self DNA was thought to be the inciting autoantigen, nucleosomes (structures comprising DNA and histone, generated during apoptosis) are more likely to be antigenic.

- Nucleosome-specific T cells, antinucleosome antibodies and nephritogenic immune complexes are generated.

- T-helper 2 (Th2) cells, with basophils and B-cell survival factors (such as BLyS), enhance B-cell differentiation and survival, and stimulated nucleic acid-binding receptors promote the production of autoreactive antibodies.

- Positively charged histone components of the nucleosome bind to the negatively charged heparan sulphate of the GBM, targeting an inflammatory reaction to the kidney.

- Inflammation stimulates complement activation, mesangial cell proliferation, mesangial matrix expansion and recruitment of inflammatory leucocytes.

The extraglomerular renal features of lupus nephritis include tubulointerstitial nephritis (75% of patients), renal vein thrombosis and renal artery stenosis. Thrombotic manifestations are associated with autoantibodies to phospholipids (anticardiolipin or lupus anticoagulant) (see p. 695), and may present as infarction of glomerular segments, thrombotic microangiopathy or vasculitis.

**Management**

Initial treatment depends on the clinical presentation but hypertension and oedema should always be treated. Disease activity, kidney biopsy and histology, as well as the presence or
absence of extrarenal manifestations of lupus, guide therapy. **Type I lupus nephritis** requires no specific treatment. **Type II** usually runs a benign course but some patients are treated with hydroxychloroquine and/or steroids alone.

- There have been a number of clinical trials with immunosuppressive agents in **types III, IV and V** lupus nephritis. Outcomes are affected by ethnicity, clinical characteristics, irreversible damage (on renal biopsy), initial response to treatment and the future frequency of renal flares.
- Steroids and high-dose intravenous cyclophosphamide or mycophenolate mofetil (MMF) are usually used for induction. In white populations, low-dose cyclophosphamide is a good alternative to high-dose cyclophosphamide, as it is similarly effective and associated with less toxicity.
- MMF is as effective as high-dose intravenous cyclophosphamide in the induction phase with a similar safety profile, but cyclophosphamide may be inferior to MMF in black and Hispanic people.
- Most patients respond to induction therapy. Remission is maintained with MMF (superior to azathioprine) or azathioprine, which is similar in effectiveness to ciclosporin in reducing the risk of relapse.
- B-cell depletion with rituximab (anti-CD20) has been used in some patients, with favourable results over the short term. However, controlled trials have not shown consistent results. It might be useful in severe, refractory lupus nephritis.

### Prognosis

Treatment leading to the normalization of proteinuria, hypertension and renal dysfunction indicates a good prognosis. The prognosis is better in patients with types I, II and V disease. Glomerulosclerosis (type VI) usually predicts ESKD.

### Cryoglobulinaemic renal disease

Cryoglobulins (CGs) are individual or mixed immunoglobulins and complement components, which precipitate reversibly in the cold. Three types are recognized:

- **Type I** is characterized by a cryoprecipitable immunoglobulin of a single monoclonal type, as is found in multiple myeloma and lymphoproliferative disorders.
- **Types II and III** cryoglobulinaemias are mixed types. In each, an antiglobulin is bound to the Fc portion of polyclonal IgG. In type II, the antiglobulin is usually monoclonal IgM with rheumatoid factor activity, often associated with hepatitis C virus infection, but also with other causes listed below. In type III, the antiglobulin is polyclonal IgM. Type II CGs account for 40–60% cases, while 40–50% of all CG cases are of type III.

  Glomerular disease is more common in type II than in type III cryoglobulinaemia. In approximately 30% of these ‘mixed’ cryoglobulinaemias, no underlying or associated disease
is found (essential cryoglobulinaemia). Recognized associations include viral infections (hepatitis B and C, HIV, cytomegalovirus, Epstein–Barr infection), fungal and spirochaetal infections, malaria and infective endocarditis, and autoimmune rheumatic diseases (SLE, rheumatoid arthritis and Sjögren syndrome). Glomerular pathological changes resemble those of MCGN (see Fig. 20.23).

**Presentation** is usually in the fourth or fifth decades of life, and women are more frequently affected than men. Systemic features include purpura, arthralgia, leg ulcers, Raynaud's phenomenon, evidence of systemic vasculitis, a polyneuropathy and hepatic involvement. The glomerular disease presents typically as asymptomatic proteinuria, microscopic haematuria or both, but presentation with an acute nephritic and nephrotic syndrome (the most common presentation) or features of CKD also occurs.

Complement is consumed, cryoglobulins can be detected, and protein electrophoresis, rheumatoid factor, autoantibodies and antiviral antibodies or mRNA of hepatitis C, depending on the associated disorder, should be sought.

The underlying cause should be treated; as hepatitis C virus infection is the most common cause, antivirals, such as proteases, are highly efficacious. Intensive plasma exchange or cryofiltration has been used in selected cases where vasculitis is limb-, organ- or life-threatening to achieve rapid removal of cryoglobulins. Uncontrolled studies of the anti-CD20 chimeric monoclonal antibody rituximab, which depletes B cells, appear promising.

**Henoch–Schönlein syndrome (purpura)**

This clinical syndrome comprises a characteristic skin rash, abdominal colic, joint pain and glomerulonephritis. Approximately 30–70% have clinical evidence of renal disease with haematuria and/or proteinuria. The renal disease is usually mild but the nephrotic syndrome and AKI can occur. The renal lesion is a focal segmental proliferative glomerulonephritis, sometimes with mesangial hypercellularity. In the more severe cases, epithelial crescents may be present. Immunoglobulin deposition is mainly IgA in the glomerular mesangium distribution, similar to IgA nephropathy. There is no treatment of proven benefit; steroid therapy is ineffective. Treatment is usually supportive; in crescentic GN, aggressive immunosuppression has been tried but with variable outcome.

**Other glomerular disorders**

**Fabry's disease**

This is an X-linked lysosomal storage disease resulting from a deficiency of the enzyme α-galactosidase. Glycosphingolipids accumulate in many cells; in the kidney, podocytes are affected. Systemic features include angiookeratomas in the skin, cardiovascular disease, neuropathies and proteinuric progressive CKD. Enzyme replacement with agalsidase (α-galactosidase) slows progression and injury to the heart, kidney and skin (see pp. 1287–1288).
**Sickle nephropathy**

Sickle disease or trait is complicated relatively commonly by papillary sclerosis or necrosis, nephrogenic diabetes insipidus and incomplete renal tubular acidosis. Glomerular lesions are rare and can sometimes be traced to hepatitis B or C infection acquired through repeated blood transfusions. Occasionally, proteinuria or nephrotic syndrome with progressive renal insufficiency is seen without prior infection. Rarely, membranous GN or mesangiocapillary GN with IgG deposits occurs in association. No form of effective therapy is known.

**Glomerulopathy associated with pre-eclampsia**

Patients with pre-eclampsia present with hypertension and proteinuria, often of rapid onset, which usually disappears after delivery. The glomerular lesion is characterized by marked endothelial swelling and obliteration of capillary lumina. Fibrinogen–fibrin deposits may be found in the mesangium. The renal lesion may not be reversible and 30% of patients have changes for ≥6 months. In severe cases, associated with cortical necrosis, there may be a microangiopathic haemolytic anaemia. Normal placental development, regulated by angiogenic factors like vascular endothelial growth factor (VEGF) and by placental growth factors, does not occur in pre-eclampsia. Implantation is abnormal, in part due to a soluble fms-like tyrosine kinase (sFlt1) receptor, an antagonist of placental growth factor and specifically of VEGF, which is upregulated in the placenta of patients with pre-eclampsia. High circulating levels of these receptors antagonize angiopoietic factors and cause endothelial dysfunction. Excessive free radical generation in the placenta of pre-eclamptic patients is due to upregulation of NADPH oxidase activity, caused by generation of an angiotensin II receptor agonist antibody in some patients.

**Paraneoplastic glomerulonephritis**

A rare complication of malignancy, paraneoplastic glomerulonephritis is usually misdiagnosed as idiopathic glomerulonephritis. A number of cancers involve the kidney:

- **Thymoma or Hodgkin’s lymphoma**: polarization of the immune response towards a Th2 profile and possibly excessive production of IL-13 leads to the development of minimal change disease, mesangiocapillary glomerulonephritis or membranous nephropathy.

- **B-cell lymphoma and leukaemia**: these may induce injury through the presence of monoclonal immunoglobulin, cryoglobulin, and possibly hepatitis C virus infection.

- **Polycythaemia vera, essential thrombocythaemia or primary myelofibrosis**: severe thrombocytosis may induce focal segmental glomerulosclerosis, possibly due to elevated levels of platelet-derived growth factor.

- **Myelodysplastic syndromes**: autoimmunity causes a variety of glomerulonephritides.

- **Epithelial carcinoma**: glomerular inflammatory cells and sub-epithelial immune IgG1- and
IgG2-containing complexes are usually present and may aid in the diagnosis of paraneoplastic membranous nephropathy.

Kidney Involvement in Other Diseases

Polyarteritis nodosa

Classical polyarteritis nodosa (PAN) is a multisystem disorder (see also p. 701). Aneurysmal dilatation of medium-sized arteries presents as hypertension, polyneuropathy and ischaemic infarction of a number of organs (including skin, gut, heart and brain). Aneurysms may be seen on renal arteriography. The condition is more common in men and in the elderly; typically, patients are ANCA-negative. It may be associated with drug use and hepatitis B infection. This form of polyangiitis is linked with slowly progressive CKD, often accompanied by severe hypertension. Rapidly progressive kidney failure is rare. Treatment with immunosuppression is less effective than it is for microscopic polyangiitis.

Systemic sclerosis (scleroderma)

Systemic sclerosis (scleroderma, SSc; see pp. 695–697) is a chronic, multisystem disease characterized by fibrosis and vasculopathy of the skin and visceral organs. Plasmacytoid dendritic cells appear to produce high plasma levels of CXCL4, which associate with both skin and lung fibrosis, as well as with pulmonary arterial hypertension in patients with SSc.

Some 10% of SSc patients develop scleroderma renal crisis, characterized by accelerated hypertension, rapidly progressive kidney failure and proteinuria. On kidney biopsy, ‘onion skinning’ in arcuate and interlobular arteries results from vessel intimal proliferation, fibrin thrombi and fibrinoid necrosis. The treatment of choice is ACE inhibitors, which have led to a remarkable improvement in outcomes in scleroderma renal crisis. Death is now rarely due to renal failure, though <30% of patients progress to ESKD.

Haemolytic uraemic syndrome

Haemolytic uraemic syndrome (HUS) is characterized by intravascular haemolysis with red cell fragmentation (microangiopathic haemolysis), thrombocytopenia and AKI due to thrombosis in small arteries and arterioles (Fig. 20.25). These features are also seen in disseminated intravascular coagulation, but coagulation tests are typically normal in HUS.
Diarrhoea-associated HUS

Diarrhoea-associated HUS (D+ HUS) often follows a febrile illness, particularly gastroenteritis associated with *Escherichia coli*, notably strain O157. This strain of *E. coli* produces verocytotoxin (or shiga toxin), with a pathogenic A unit that inhibits protein synthesis and initiates endothelial damage. B units facilitate entry of the A unit into the endothelial cells by binding to a receptor (Gb3) on the endothelial cell. Toxins are transported to and into endothelial cells from the gut on neutrophils. Most patients with D+ HUS recover renal function but supportive care, including fluid and electrolyte balance, antihypertensives, nutritional support and dialysis, is commonly required. Plasmapheresis is not beneficial. About 5% die during the acute episode, 5% develop ESKD and 30% exhibit evidence of long-term damage with persistent proteinuria. Antibiotic and antimotility agents for diarrhoea increase the risk of HUS and its complications.

In 2011, an outbreak caused by shiga toxin-producing *E. coli* O104:H4 was reported in Germany and other European countries. In this outbreak, HUS occurred far more than might usually be expected, and was associated with significant morbidity and mortality (see p. 276). Severe neurological complications were seen; immunoabsorption was successful in many cases.

**Recurrent episodes of HUS** have been described in the same individual, and familial forms of the disease (with both recessive and dominant inheritance) exist.

Atypical HUS

Atypical HUS (aHUS) is a complement-driven illness, often related to a deficiency of complement factor H (CFH) or complement factor I (CFI). Factor H is a soluble protein produced by the liver, which regulates the activity of the alternative complement activation pathway; in particular, it protects host cell surfaces from complement-mediated damage. In some families with aHUS, a mutation has been traced to another complement regulatory protein, CD46 (previously known as membrane co-factor protein, MCP). This protein is highly expressed in the kidney and normally prevents glomerular C3 activation. A loss-of-function mutation in CD46 results in unopposed complement activation and development of HUS.
Functional deficiency of these factors can be acquired due to autoantibody formation, either as an isolated phenomenon or as part of an autoimmune disease such as SLE. A loss-of-function mutation in thrombomodulin (a membrane-bound anticoagulant glycoprotein) has been identified as an alternative complement pathway. Rarely, gain-of-function mutations can affect genes encoding the alternative pathway C3 convertase components, CFB and C3. CFB mutations, which lead to chronic alternative pathway activation, occur in only 1–2% of patients with D+ HUS. About 4–10% of patients have heterozygous mutations in C3, usually with low C3 levels. Most mutations reduce C3b binding to CFH and CD46, which severely impairs degradation of mutant C3b.

**Management of atypical HUS**

Treatment is often difficult, and severe hypertension and recurrence are frequent. The course of the disease is often indolent and progressive.

- Plasmapheresis or plasma infusion is used at initiation of therapy in the majority of patients, often until diagnosis is clear.
- C5 activation is one of the critical steps in the activation of complement cascade.  
  
  *Eculizumab*, a monoclonal humanized anti-C5 antibody, has transformed outcomes, both at acute presentation and in prevention of recurrence (in native kidneys and in transplants).
- Liver transplantation is a potentially curative treatment in patients harbouring CFH and CFI mutations.

**Sporadic cases of aHUS**

These can be associated with pregnancy, SLE, scleroderma, malignant hypertension, metastatic cancer, HIV infection and various drugs, including oral contraceptives, ciclosporin, tacrolimus, chemotherapeutic agents (e.g. cisplatin, mitomycin C, bleomycin) and heparin. Treatment is supportive, with removal of the offending agent or specific treatment of the underlying cause. There is no evidence in favour of plasma infusion or plasmapheresis in these sporadic cases but it is tried, usually as a last resort.

*Streptococcus pneumoniae* produces an enzyme (possibly neuroaminidase) that can expose an antigen (Thomsen antigen) present on red blood cells, platelets and glomeruli. Antibodies to the Thomsen antigen result in an antigen–antibody reaction and can lead to HUS and anaemia. The improved outcome is due to increasing awareness of this complication, judicious use of blood products (washed blood products) and avoidance of plasma infusion or plasmapheresis.

**Metabolism-associated HUS**

Cobalamin C disease is a hereditary disorder of vitamin B$_{12}$ metabolism that may cause HUS and multiple organ damage in infants and, rarely, adults. It is caused by mutations in a gene encoding the methylmalonic aciduria and homocystinuria type C protein (*MMACHC*). The resulting deficiency in methylcobalamin causes hyperhomocysteinaemia, decreased plasma methionine levels, and methylmalonic aciduria.
Abnormal cobalamin C metabolism is associated with platelet activation, generation of reactive oxygen species, endothelial dysfunction, increased tissue factor expression, coagulation activation and HUS.

Parenteral hydroxocobalamin is the principal treatment for infants.

### Thrombotic thrombocytopenic purpura

Thrombotic thrombocytopenic purpura (TTP; see pp. 570–571) is characterized by microangiopathic haemolysis, renal failure and evidence of neurological disturbance. Young adults are most commonly affected.

### Antiphospholipid syndrome

In the antiphospholipid syndrome (APS; see p. 695), the binding of antiphospholipid antibodies (aPL) to beta 2 glycoprotein I (β2GPI) induces endothelial cell–leucocyte adhesion and thrombus formation through the inhibition of endothelial nitric oxide synthase (eNOS).

The central feature of APS is recurrent thrombosis (both venous and arterial) and early pregnancy loss in the presence of antiphospholipid antibodies. Antibodies may be primary or secondary to infections (HIV, hepatitis C) or autoimmune disease (SLE). Some 50% have renal involvement with proteinuria. Thrombotic microangiopathy is a rare but well-recognized presentation. In some cases, a lupus nephritis-like (usually mesangiocapillary GN) lesion is seen. The only proven treatment for APS is systemic anticoagulation. Use of steroids or plasmapheresis is reserved for patients with APS and life-threatening renal involvement with thrombotic microangiopathy. Treatment is variably successful (30–70%).

### Multiple myeloma

AKI is relatively common in myeloma, occurring in 20–30% of affected individuals at the time of diagnosis, and is mainly due to the nephrotoxic effects of the abnormal immunoglobulins. It is often irreversible and may present as:

- **light chain cast nephropathy** – intratubular deposition of light chains, particularly kappa chains, which characteristically appear on renal histology as fractured casts with a giant cell reaction (*Fig. 20.26*)
CAST nephropathy in a patient with multiple myeloma. Light microscopy showing a characteristic fractured cast and giant cell reaction (arrows).

- **AL amyloidosis** – deposition of amyloid fibrils of light chains (Congo red-positive)
- **light chain deposition disease** – nodular glomerulosclerosis with granular deposits of usually lambda light chains (Congo red-negative)
- **plasma cell infiltration** – often an incidental finding at postmortem
- **Fanconi syndrome** – tubular toxicity due to light chains
- **hypercalcaemic nephropathy** – bone resorption causing hypercalcaemia
- **hyperuricaemic nephropathy** – tumour lysis causing tubular crystallization of uric acid
- **radiocontrast nephropathy** – interaction between light chains and radiocontrast.

Treatment of the underlying myeloma is key to recovery (see pp. 628–629). If a patient with cast nephropathy and severe AKI remains dialysis-dependent, the prognosis is poor. Commencement of effective bortezomib-based chemotherapy, which decreases light chain production, and a high-cut-off haemodialysis have shown some promise in relapsed myeloma.

**Further reading**

**Hypertension and the Kidney**

Hypertension can be the cause or the result of renal disease. It is often difficult to differentiate between the two on clinical grounds. Routine tests (as described on p. 1046) should be performed on all hypertensive patients, though renal imaging is usually unnecessary.

The **mechanisms** responsible for the normal regulation of arterial blood pressure and the development of essential primary hypertension are unclear (see pp. 1046–1049). One basic concept is that the long-term regulation of arterial pressure is closely linked to the ability of the kidneys to excrete sufficient salt to maintain normal sodium balance, extracellular fluid volume...
and normal blood volume at normotensive arterial pressures. Cross-transplantation experiments suggest that hypertension travels with the kidney, as hypertension develops in the normotensive recipient of a kidney genetically programmed for hypertension. Similarly, patients with ESKD due to hypertension become normotensive after receiving a kidney transplant from normotensive donors, provided the new kidney functions well.

One renal factor contributing to future hypertension is the total number of nephrons per kidney (‘nephron dose’). People with hypertension and normal renal function have a significantly reduced number of nephrons in each kidney, and individual nephrons are enlarged as a result of glomerular hyperfiltration (see p. 739). Where hypertension is more common (as it is in black or Hispanic men and women), increased glomerular volume is found (a surrogate marker for reduced nephron number).

Whether reduced nephron number is genetic or environmental in origin is unclear. Changes in the intrauterine environment may lead to poor renal growth (and reduced renal volume suggesting lower nephron number) before birth, low birth weight, and hypertension in adult life.

Excess renal sympathetic activity may also contribute. Strategies to achieve bilateral renal sympathetic denervation were hugely effective in patients with refractory hypertension in uncontrolled studies; to date, this benefit has not been borne out by a recent well-controlled trial.

**Essential hypertension**

In essential hypertension, arteriosclerosis of major renal arteries and changes in the intrarenal vasculature (nephrosclerosis) occur. Arterial pressure is a product of cardiac output and systemic vascular resistance (SVR). The compliance of systemic arteries is, then, a critical component; ‘stiff’ (sclerotic) arteries cannot modulate pressure surges in systole, and systolic pressures rise. Over time, vessels (and the kidney) remodel:

- In small vessels and arterioles, intimal thickening with reduplication of the internal elastic lamina occurs and the vessel wall becomes hyalinized.
- In large vessels, concentric reduplication of the internal elastic lamina and endothelial proliferation produce an ‘onion skin’ appearance.
- Reduction in size of both kidneys occurs; this may be asymmetrical if one major renal artery is more affected than the other.
- The proportion of sclerotic (scarred) glomeruli is increased compared with age-matched controls.

Renal function does deteriorate with these changes but severe CKD is unusual in whites (1 in 10 000). In black Africans, by contrast, hypertension much more often results in the development of CKD, with a fourfold higher incidence of ESKD in blacks compared to whites. This difference in incidence of hypertensive renal disease may be due to overestimation of diagnosis on clinical grounds, a higher incidence of hypertension (usually salt-sensitive),
reduced nephron number and a higher frequency of susceptibility alleles for ESKD in the (West) African than the European gene pool.

A genome-wide study found statistically stronger associations between two independent sequence variants in the apolipoprotein L1 gene (APOL1) and non-diabetic nephropathy in African–Americans, in hypertension-attributed ESKD. These kidney disease risk variants most likely arose due to the positive selection for evolutionary advantage that these variants in APOL1 conferred against trypanosomal infection and protection from African sleeping sickness. These observations provide some evidence, similar to findings with sickle cell anaemia, that natural selection might protect from one disease but allow another one to develop.

In accelerated or malignant-phase hypertension:

• Arteriolar fibrinoid necrosis occurs, probably as a result of plasma entering the media of the vessel through splits in the intima. It is prominent in afferent glomerular arterioles.

• Fibrin deposition within small vessels is often associated with thrombocytopenia and red cell fragmentation seen in the peripheral blood film (microangiopathic haemolytic anaemia).

Microscopic haematuria, proteinuria, usually of modest degree (1–3 g daily), and progressive CKD occur. If disease is untreated, fewer than 10% of patients survive 2 years.

Management

The management of benign essential and malignant hypertension is described on page 1048. If treatment is begun before CKD has developed, the prognosis for renal function is good. Stabilization or improvement in renal function, with healing of intrarenal arteriolar lesions and resolution of microangiopathic haemolysis, occurs with effective treatment of malignant-phase hypertension.

Renal hypertension

Hypertension commonly complicates bilateral renal disease such as chronic glomerulonephritis, bilateral reflux nephropathy, polycystic disease and analgesic nephropathy. Two main mechanisms are responsible:

• activation of the renin–angiotensin–aldosterone system

• retention of salt and water as excretory function declines, leading to an increase in blood volume and blood pressure.

As CKD progresses, salt and water overload becomes ever more involved in driving high blood pressure.

Hypertension occurs earlier, is more common and tends to be more severe in patients with glomerular disease (glomerulonephritis) than in those with tubulointerstitial diseases such as reflux or analgesic nephropathy.

Management is described on pages 1047–1048. Meticulous control of the blood pressure
may prevent ongoing or new vascular or parenchymal changes, and further deterioration of renal function. There is good evidence that ACE inhibitors offer additional renoprotective benefits for the same degree of blood pressure control than other agents. In a study of African–Americans with hypertension, intensive blood pressure control (130/78 mmHg) was not superior to standard control (141/86 mmHg) in the prevention of ESKD. However, in the same study, patients with proteinuria benefited more from intensive blood pressure control. However, presence of the APOL1 risk allele was associated with rapid decline of GFR irrespective of achieved blood pressure or baseline proteinuria.

**Renovascular disease**

Renal ischaemia, or a fall in perfusion pressures in the afferent glomerular arterioles, leads to increased production and release of renin from the juxtaglomerular apparatus (see p. 727). This, in turn, causes a consequent increase in angiotensin II, a potent vasoconstrictor, which also triggers aldosterone secretion, stimulates thirst and leads to vascular smooth muscle hypertrophy and fibrosis in the kidney.

In renal artery stenosis, narrowing of the renal artery or arteries causes a fall in renal perfusion pressure on the distal side of the stenosis; in each affected kidney, angiotensin release occurs, and local salt and water reabsorption is increased. Urine from the ischaemic kidney is more concentrated, with a lower sodium concentration than urine from an unaffected kidney. GFR is decreased on the ischaemic side as well.

Narrowing of the renal arteries (renal artery stenosis) is caused by one of two pathologies: **atherosclerotic renovascular disease** or **fibromuscular dysplasia**.

**Atherosclerotic renovascular disease**

Atherosclerotic renovascular disease (ARVD) is a common cause of hypertension and CKD due to ischaemic nephropathy. Its incidence increases with age:

- 5% in those under 60 years of age
- 16% in those over 60 years of age.

In most patients, the atherosclerotic lesion is ostial (within 1 cm of the origin of the renal artery) and usually associated with symptomatic atherosclerotic vascular disease elsewhere. Patients with peripheral vascular disease (39%), coronary artery disease (10–29%), congestive cardiac failure (34%) and aortic aneurysm (38%) are at high risk of developing significant renal artery stenosis.

Many patients are asymptomatic and are discovered incidentally during investigation for other conditions. Aortography experience from the USA shows that 11% of asymptomatic patients have significant unilateral stenosis and 4% have bilateral disease. ARVD results in hypertension (present in 50%), sodium retention (ankle and flash pulmonary oedema), proteinuria (usually in the sub-nephrotic range) and decreased GFR. Beyond the stenosis, affected kidneys demonstrate changes histologically, with vascular sclerosis, tubular atrophy,
interstitial fibrosis with inflammatory cellular infiltrate, atubular glomeruli, cholesterol emboli and secondary FSGS changes. These changes are often described as ‘ischaemic nephropathy’. The affected kidney loses volume (as fibrosis replaces normal tissue), and becomes smaller on ultrasound measurement. These morphological changes are responsible for the associated fall in GFR; the arterial stenosis itself drives hypertension.

Renovascular disease should be considered in:

- patients with hypertension and/or CKD with abdominal or other audible bruits
- patients with renal asymmetry – particularly where ultrasound suggests >1.5 cm difference in length
- recurrent flash pulmonary oedema without cardiopulmonary disease
- progressive CKD in patients with evidence of generalized atherosclerosis.

**Management**

The aim of treatment is to prevent decline in renal function and to reverse salt and water overload. Most patients with ARVD will die a cardiovascular death, and modifiable risk factors should be addressed. All patients with ARVD should be managed with a combination of aspirin, statins and optimal control of blood pressure as prophylaxis against progression of atherosclerosis. Hypertension should be controlled, ideally with an ACE inhibitor. This is the paradox of ARVD: angiotensin drives the renal and cardiac events, so ACE inhibition is ideal medical therapy. However, because ACE inhibitors will cause a fall (often significant) in renal perfusion beyond the stenosis, ACE inhibitors can cause AKI in patients with bilateral, haemodynamically significant ARVD.

Renal artery stenosis can also progress to occlusion, particularly in patients with stenosis of >75%, as shown by serial angiography. Revascularization offers definitive treatment of stenotic lesions in ARVD:

- **Options in renal artery stenosis.** These include transluminal angioplasty to dilate the stenotic region, insertion of stents across the stenosis (sometimes the only endoscopic option when the stenosis occurs close to the origin of the renal artery from the aorta, making angioplasty technically difficult or impossible), reconstructive vascular surgery and nephrectomy.

- **Indications for revascularization.** Vessels with stenosis of >75% and recurrent flash pulmonary oedema, drug-resistant severe hypertension, ARVD affecting solitary functioning kidney, patients with cardiac failure needing ACE inhibitors, unexplained progressive CKD and dialysis-dependent renal failure.

In a number of recent trials, renal artery stenting did not confer a significant benefit with respect to the prevention of clinical events (cardiovascular events, progressive renal insufficiency or the need for renal replacement therapy) when added to comprehensive, multifactorial medical therapy in people with atherosclerotic renal artery stenosis and hypertension or CKD. Up to 30% of renal artery interventions will be complicated by
atheroembolism, which may lead to further functional deterioration.

**Prognosis**

Mortality is high because of other associated co-morbidities, and ARVD patients have generalized endothelial dysfunction. ARVD patients with ESKD have higher death rates than those with other causes of ESKD. Five-year survival is only 18% in patients with ESKD due to ARVD.

**Fibromuscular dysplasia of the renal arteries**

Fibromuscular dysplasia (FMD) is often asymptomatic, occurring in younger women with hypertension. It is far less common than ARVD. FMD affects many arterial beds, including the carotid and coronary arteries. Renal function is often normal.

Magnetic resonance angiography (MRA; gadolinium-enhanced) reveals a characteristic string of beads appearance in the mid-renal artery (rather than affecting the ostium, as seen in ARVD).

Angioplasty (occasionally with stent insertion) or, rarely, surgery was offered to affected individuals. Cure rates were only 36% and 54% after angioplasty and surgery, respectively, in a recent study of over 2000 patients (defining cure as blood pressure <140/90 mmHg without treatment), and the blood pressure outcome was strongly age-related. Procedural complications were common: 12% after angioplasty and 17% after surgery. Current medical antihypertensive therapy is very effective in this group, and angioplasty is now not usually performed.

**Screening for renovascular disease**

- **Radionuclide studies** (see pp. 731–732) can demonstrate decreased renal perfusion on the affected side. In unilateral renal artery stenosis, a disproportionate fall in isotope uptake occurs on the affected side after administration of captopril. A completely normal result makes renovascular disease unlikely.

- **Doppler ultrasound** is sensitive but highly operator-dependent and time-consuming. Higher renal artery velocity on Doppler may mean a higher pressure differential across a stenosis. Doppler also describes the intrarenal vascular resistance, which can be valuable in predicting the success of revascularization procedures. A resistive index of >80 is a predictor of poor response following intervention.

- **MRA** can be used to visualize the renal arteries and there is a good – though not perfect – correlation between MRA findings and those of renal arteriography.

- **CT scanning** permits non-invasive imaging of the renal arteries. It is much less expensive than MRA but does expose the patient to ionizing radiation and to contrast injection, and is less reliable than MRA.
Renal arteriography (see p. 731) is used to confirm the diagnosis of renal arterial disease. It also allows therapeutic intervention if needed at diagnosis.

Further reading

Other Vascular Disorders of the Kidney

Renal artery occlusion

This occurs from thrombosis *in situ*, usually in a severely damaged atherosclerotic vessel, or more commonly from embolization, such as in atrial fibrillation. Both lead to renal infarction, either of a wedge of kidney or of the whole kidney. Occlusion of a small branch artery may produce no effect, but occlusion of larger vessels results in dull flank pain, macroscopic haematuria and varying degrees of CKD. Intra-arterial thrombolytic therapy has been tried with mixed results.

Cholesterol embolization (atheroembolic renal disease)

Showers of cholesterol-rich atheromatous material from ulcerated plaques reach the kidney from the aorta and/or renal arteries, particularly after catheterization of the abdominal aorta or attempts at renal artery angioplasty. Anticoagulants and thrombolytic agents also precipitate non-traumatic cholesterol embolization. Renal failure from cholesterol emboli may be acute or slowly progressive. Clinical features include fever, eosinophilia, back and abdominal pain, and evidence of embolization elsewhere, such as to the retina or digits. The diagnosis can be confirmed by renal biopsy (*Fig. 20.27*). It is more common in males, the elderly (>70 years) and patients with cardiovascular disease. Over 80% have abnormal renal function at baseline. Atheroembolic renal disease (AERD) occurs spontaneously in 25% of the cases. The 2-year mortality is 30% and a similar percentage of patients develop CKD. Baseline co-morbidities – that is, reduced renal function, presence of diabetes, history of heart failure, acute/subacute presentation, and gastrointestinal tract involvement – are significant predictors of event occurrence. The risk of dialysis and death is 50% lower among those receiving statins.
Renal vein thrombosis

This is usually of insidious onset, occurring in patients with the nephrotic syndrome, with a renal cell carcinoma, and in thrombophilia (see p. 575) with an increased risk of venous thrombosis. Anticoagulation is indicated.

Renal Calculi and Nephrocalcinosis

Renal and vesical calculi

Nephrolithiasis, or renal stones, usually occurs in the upper urinary tract. It is very common worldwide, with a lifetime risk of about 10%.

Most stones are composed of calcium oxalate and phosphate; these are more common in men (Box 20.14). Mixed infective stones, which account for about 15% of all calculi, are twice as common in women as in men. The overall male to female ratio of stone disease is 2 : 1.

Stone disease is frequently recurrent, and more than 50% of patients will experience a
second stone within 10 years of their first. The risk of recurrence increases if a metabolic or structural abnormality predisposing to stone formation is present and is not modified by treatment. Nephrolithiasis is not a benign condition; observational studies show an association with an increased risk of ESKD, bone diseases, hypertension and myocardial infarction.

**Aetiology**

Stones form because solute concentrations exceed saturation, often in the context of a trigger or nidus to crystallize around. Inhibitors of crystal formation prevent stone formation in normal urine, despite the concentrations of stone-forming substances exceeding maximum solubility in water. Factors predisposing to stone formation in these so-called ‘idiopathic stone-formers’ are:

- **Chemical composition of urine** that favours stone crystallization.
- **A concentrated urine** resulting from dehydration (particularly in those living or working in a hot climate or environment).
- **Impairment of inhibitors that prevent crystallization** in normal urine. These inhibitors include inorganic magnesium, pyrophosphate and citrate. Organic inhibitors include glycosaminoglycans and nephrocalcin (an acidic protein of tubular origin). Tamm–Horsfall protein may have a dual role in both inhibiting and promoting stone formation. Tamm–Horsfall protein usually inhibits crystallization of urinary oxalate but in an undersialylated form promotes stone formation.

Recognized risk factors for stone formation are listed in **Box 20.15**.

---

**Box 20.15**

**Causes of urinary tract stones**

- Dehydration
- Hypercalcaemia
- Hypercalciuria
- Hyperoxaluria
- Hyperuricaemia and hyperuricosuria
- Infection
- Cystinuria
- Primary renal disease (polycystic kidneys, medullary sponge kidneys, renal tubular acidosis)
- Drugs (see text)

Stones may be single or multiple and vary enormously in size from minute, sand-like
particles to staghorn calculi or large stone concretions in the bladder. They may be located within the renal parenchyma or within the collecting system. Stones regularly cause obstruction, leading to hydronephrosis; a combination of obstruction and infection often causes lasting damage to the kidney.

**Hypercalcaemia**

If the GFR is normal, hypercalcaemia almost invariably leads to hypercalciuria. Common causes of hypercalcaemia leading to stone formation are:

- primary hyperparathyroidism (see p. 1236)
- vitamin D ingestion
- sarcoidosis.

**Hypercalciuria**

This is by far the most common metabolic abnormality detected in calcium stone-formers. Approximately 8% of men excrete more than 7.5 mmol of calcium per day. Calcium stone formation is more common in this group, although the cutoff is entirely arbitrary. In women, a 24-hour calcium excretion of >6.25 mmol tends to make stone formation more likely.

About 90% of ionized calcium filtered by the kidney is reabsorbed in the tubule, controlled largely by PTH. Causes of hypercalciuria include:

- hypercalcaemia
- high dietary intake of calcium
- excessive resorption of calcium from the skeleton, such as occurs with prolonged immobilization or weightlessness
- idiopathic hypercalciuria.

Idiopathic hypercalciuria is a common risk factor for the formation of stones, and can be thought of as accelerated calcium transport, with enhanced gut uptake, and increased urine excretion of calcium.

**Hyperoxaluria**

There are two inborn errors of glyoxylate metabolism that cause increased endogenous oxalate biosynthesis and are inherited in an autosomal recessive manner:

- **type 1**: alanine–glyoxylate aminotransferase deficiency
- **type 2**: glyoxylate reductase hydroxypyruvate reductase deficiency.

In both types, calcium oxalate stone formation occurs. The prognosis is poor, as widespread calcium oxalate crystal deposition in the kidneys leads to CKD in the late teens or early twenties. Successful liver transplantation has been shown to cure the metabolic defect.

Much more common causes of mild hyperoxaluria are:

- excess ingestion of foodstuffs high in oxalate, such as spinach, rhubarb and tea
dietary calcium restriction, with compensatory increased absorption of oxalate
• gastrointestinal disease (e.g. Crohn's), usually with an intestinal resection, associated with increased absorption of oxalate from the colon.

Dehydration secondary to fluid loss from the gut also plays a part in stone formation.

Hyperuricaemia and hyperuricosuria
Uric acid stones account for 3–5% of all stones in the UK, but in Israel the proportion is as high as 40%. Uric acid is the endpoint of purine metabolism. Hyperuricaemia (see pp. 687–689) can occur as a primary defect in idiopathic gout, and as a secondary consequence of increased cell turnover: for example, in myeloproliferative disorders. Increased uric acid excretion occurs in these conditions, and stones will develop in some patients. Some uric acid stone-formers have hyperuricosuria (>4 mmol/24 h on a low-purine diet), without hyperuricaemia.

Dehydration alone may also cause uric acid stones to form. Patients with ileostomies are at particular risk, both from dehydration and from the fact that loss of bicarbonate from gastrointestinal secretions results in the production of an acid urine (uric acid is more soluble in an alkaline medium than in an acid one).

Some patients with calcium stones also have hyperuricaemia and/or hyperuricosuria; it is believed that the calcium salts precipitate on an initial nidus of uric acid in such patients.

Urinary tract infection
Mixed infective stones are composed of magnesium ammonium phosphate together with variable amounts of calcium. Such struvite stones are often large, forming a cast of the collecting system (staghorn calculus). These stones are usually due to urinary tract infection with organisms such as Proteus mirabilis that hydrolyse urea, with formation of the strong base ammonium hydroxide. The availability of ammonium ions and the alkalinity of the urine favour stone formation. An increased production of mucoprotein from infection also creates an organic matrix on which stone formation can occur.

Cystinuria
Cystinuria (see also pp. 1286–1287) results in the formation of cystine stones (about 1–2% of all stones).

Primary renal disease
• Polycystic renal disease (see pp. 789–790) shows a high prevalence of stone disease.
• Medullary sponge kidney involves dilatation of the collecting ducts that leads to urinary stasis and calcification (Fig. 20.28). Approximately 20% of these patients have hypercalciuria and a similar proportion have a renal tubular acidification defect.
**Renal tubular acidosis**, either inherited and acquired, is associated with nephrocalcinosis and stone formation. Persistently alkaline urine and reduced urinary citrate excretion leads to stone formation, as calcium and citrate form a *soluble* complex in urine.

**Drugs**

Some drugs promote calcium stone formation (e.g. loop diuretics, antacids, glucocorticoids, theophylline, vitamins D and C, acetazolamide); some promote uric acid stones (e.g. thiazides, salicylates); and some precipitate into stones (e.g. indinavir, triamterene, sulfadiazine).

**Clinical features**

Most people with urinary tract calculi are asymptomatic.

- Pain is the most common symptom and may be sharp or dull, constant, intermittent or colicky (**Box 20.16**).

**Box 20.16**

**Clinical features of urinary tract stones**

- Asymptomatic
- Pain: renal colic
- Haematuria
- Urinary tract infection
- Urinary tract obstruction

- If the urinary tract is obstructed, fluids or diuretics (including alcohol) make the pain worse as peristaltic flow increases.
- Exertion may cause mobile calculi to move, precipitating pain and, occasionally, haematuria.
Ureteric colic occurs when a stone enters the ureter and either obstructs it or causes spasm during its passage down the ureter. Classically, pain radiates from the flank to the iliac fossa, testis or labia (in the distribution of the first lumbar nerve root). Pallor, sweating and vomiting often occur and the patient is restless, trying to obtain relief from the pain. Haematuria often occurs. Untreated, the pain of ureteric colic typically subsides after a few hours.

When urinary tract obstruction and infection are present, the features of acute pyelonephritis or of a Gram-negative septicaemia may dominate the clinical picture. Calcified papillae may mimic ordinary calculi, so that causes of papillary necrosis such as analgesic abuse should be considered (see p. 768).

Bladder stones

Bladder stones (Box 20.17) are usually associated with bacteriuria and present with frequency, dysuria and haematuria; severe introital or perineal pain may occur if trigonitis is present.

</tbody>
</table>

A calculus at the bladder neck or an obstruction in the urethra may cause bladder outflow obstruction, resulting in anuria and painful bladder distension.

Investigations

• **Dipsticks** for red cells, protein, glucose
• **Chemical analysis** should be employed for passed stones.
• **A mid-stream specimen of urine** should be taken for microscopy (crystals) and culture.
• **Serum urea, electrolyte, creatinine (eGFR) and calcium levels.**
• **Ultrasonography** shows kidney stones and renal pelvis dilatation well but ureteric stones can be missed.
• **Computed tomography of kidneys, ureters and bladder (CT-KUB)** is the best diagnostic test available with a sensitivity of >95%. It involves radiation and in young patients many physicians perform ultrasonographs as the first investigation.

A normal CT excludes the diagnosis of pain due to calculous disease. The CT-KUB
appearances in a patient with acute left ureteric obstruction are shown in Figure 20.29.

![Computed tomography of kidneys, ureters and bladder (CT-KUB) in ureteric stone obstruction. A. Left ureteric calculus (arrow). B. A dilated renal pelvis (arrow) proximal to the ureteric stone in A.](image)

Pure uric acid stones are radiolucent and show as a filling defect after injection of contrast medium if excretion urography is performed. Uric acid stones are readily seen on CT scanning (Fig. 20.30). Mixed infective stones in which organic matrix predominates are barely radiopaque.
Management
Renal colic is painful. Analgesia with an NSAID, such as diclofenac 75 mg i.m. compares favourably with opiates such as diamorphine or pethidine. Stones of <0.5 cm diameter usually pass spontaneously, particularly if hydration is maintained (patients that can drink should aim for >2.5 L intake). Alpha-blockers (e.g. tamsulosin) were thought to help expulsion of distal ureteral stones of <6 mm size (alpha receptors are predominantly present in the distal ureter and detrusor) but a recent RCT has shown no benefit.

Stones of >1 cm diameter usually need urological or radiological intervention. Extracorporeal shock-wave lithotripsy (ESWL) will fragment most stones, which then pass spontaneously. Ureteroscopy with a YAG laser can be used for larger stones. Percutaneous nephrolithotomy is also used. Open surgery is rarely needed.

Investigation of the cause of stone formation
In an elderly patient who has had a single episode with one stone, only limited investigation is required. Younger patients and those with recurrent stone formation need detailed investigation.

- **Renal imaging** excludes structural abnormalities of the urinary tract.
- **Urine culture** excludes significant bacteriuria.
- **Chemical analysis** is performed on any stone passed (required in the diagnosis of cystinuria or uric acid stone formation).
- **Serum calcium** is investigated if hypercalcaemia is present (see p. 754).
- **Serum urate concentration** is often, but not invariably, elevated in uric acid stone-formers.
- **A screening test for cystinuria** should be carried out by adding sodium nitroprusside to a random unacidified urine sample; a purple colour indicates that cystinuria may be present.
Urine chromatography is required to define the diagnosis precisely.

- **Urinary calcium, oxalate and uric acid output** should be measured in two consecutive, carefully collected 24-h urine samples. After aliquots are withdrawn for estimation of uric acid, the urine is acidified to prevent crystallization of calcium salts on the walls of the container, which would give falsely low results for urinary calcium and oxalate.

- **Plasma bicarbonate** is low in renal tubular acidosis. The finding of a urine pH that does not fall below 5.5 in the face of metabolic acidosis is diagnostic of this condition (see pp. 177–178).

### Prevention of recurrent stones

- In all idiopathic stone-formers, where no metabolic abnormality is present, maintain a high intake of fluid throughout the day and night to ensure a daily urine volume of 2–2.5 L. This reduces saturation of solute.

- With idiopathic hypercalciuria, dietary calcium restriction is inappropriate, as restriction results in hyperabsorption of oxalate. Foods rich in oxalate should be avoided (nuts, spinach, chocolate, rhubarb). Patients who live in a hard-water area may benefit from drinking softened water.

- Salt intake should be limited to 50 mmol/day (calcium excretion increases by 0.6 mmol/day for every 100 mmol Na\(^+\) in the urine).

- If hypercalciuria stone formation persists, a thiazide diuretic (e.g. bendroflumethiazide 2.5 or 5 mg each morning) reduces urinary calcium excretion. This indirect effect is due to mild volume contraction resulting in increased calcium absorption in the proximal renal tubule.

- Reduction of animal proteins to 50 g/day is also advisable.

- Where mixed infective stones recur, long-term, low-dose prophylactic antibiotics may prevent bacteriuria.

- Uric acid stones can be prevented by the long-term use of allopurinol to maintain the serum urate and urinary uric acid excretion in the normal range. Uric acid is more soluble at alkaline pH, and long-term sodium bicarbonate supplementation to maintain an alkaline urine is an alternative approach in those few patients unable to take allopurinol (see p. 769). However, alkalinization of the urine facilitates precipitation of calcium oxalate and phosphate.

**Cystine** stones can be prevented and indeed will dissolve slowly with a high fluid intake. To achieve this, up to 5 L of water is drunk in each 24 hours. Patients need to wake twice during the night to drink 500 mL or more of water. Understandably, many patients cannot tolerate this regimen. Alkalinization to a pH of 7 requires high doses of potassium citrate or bicarbonate. An alternative option is the long-term use of the chelating agent penicillamine; this causes cystine to be converted to the more soluble penicillamine–cysteine complex. Side-effects include drug rashes, blood dyscrasias and immune complex-mediated glomerulonephritis. However, it is especially effective in promoting dissolution of cystine stones already present. Other cystine-binding drugs include captopril and tiopronin.
**Monogenic hyperoxaluria** can be managed with oral high-dose pyridoxine if type 1 (though no response will occur with type 2). Unfortunately, there is currently no proven pharmacotherapy for effective treatment of the more common form of ‘idiopathic’ hyperoxaluria present in up to 40% of stone-formers. Probiotic *Oxalobacter formigenes* has shown some promise.

**Nephrocalcinosis**

The term ‘nephrocalcinosis’ means diffuse renal parenchymal calcification that is detectable radiologically (*Fig. 20.31*). The condition is typically painless. Hypertension and CKD commonly occur. The main causes of nephrocalcinosis are listed in *Box 20.18*.

![FIGURE 20.31 X-ray showing nephrocalcinosis.](image)

### Box 20.18

**Causes of nephrocalcinosis**

**Mainly cortical (rare)**
- Renal cortical necrosis (tramline calcification)

**Mainly medullary**
- Hypercalcaemia (primary hyperparathyroidism, hypervitaminosis D, sarcoidosis)
- Renal tubular acidosis (inherited and acquired)
- Primary hyperoxaluria
• Medullary sponge kidney
• Tuberculosis

*Dystrophic calcification* occurs following renal cortical necrosis. In *hypercalcaemia and hyperoxaluria*, deposition of calcium oxalate results from the high concentration of calcium and oxalate within the kidney.

In *renal tubular acidosis* (see pp. 177–178), failure of urinary acidification and a reduction in urinary citrate excretion both favour calcium phosphate and oxalate precipitation, since precipitation occurs more readily in an alkaline medium and the calcium-chelating action of urinary citrate is reduced.

Management and prevention of nephrocalcinosis consist of treating the cause.

**Further reading**

**Urinary Tract Obstruction**

Urinary tract obstruction can occur at any point between the kidney and the urethral meatus. Obstruction can be partial or complete, and leads to delayed transit of urine, rising urinary tract (and intrarenal) pressure, and – if obstructing both kidneys – eventual renal impairment.

**Aetiology**

Obstructing lesions may lie within the lumen, or in the wall of the urinary tract, or outside the wall, causing obstruction by external pressure. Obstruction causing dilatation of the renal pelvis and/or ureter is known as hydronephrosis. The major causes of obstruction are shown in *Box 20.19*. In children, obstruction usually results from congenital abnormalities or urethral valves. In young women, pelvic tumours, pregnancy or stones cause obstruction. In younger men, stones are the dominant cause, but bladder outflow obstruction (prostatic disease) dominates later in life.

**Box 20.19**

Causes of urinary tract obstruction

Within the lumen
• Calculus
• Blood clot
• Sloughed papilla (diabetes; analgesia misuse; sickle cell disease or trait)
• Tumour of renal pelvis, ureter or bladder

**Within the wall**

• Pelviureteric neuromuscular dysfunction (congenital, 10% bilateral)
• Ureteric stricture (tuberculosis, especially after treatment; calculus; after surgery)
• Ureterovesical stricture (congenital; ureterocele; calculus; schistosomiasis)
• Congenital megaureter
• Congenital bladder neck obstruction
• Neuropathic bladder
• Urethral stricture (calculus; gonococcal; after instrumentation)
• Congenital urethral valve
• Pin-hole meatus

**Pressure from outside**

• Pelviureteric compression (bands; aberrant vessels)
• Tumours (e.g. retroperitoneal tumour or glands; carcinoma of colon; tumours in pelvis, e.g. carcinoma of cervix)
• Diverticulitis
• Aortic aneurysm
• Retroperitoneal fibrosis (peri-aortitis)
• Accidental ligation of ureter
• Retrocaval ureter (right-sided obstruction)
• Prostatic obstruction
• Phimosis

---

**Pathophysiology**

Urine continues to be formed despite obstruction to flow. This leads to:

• progressive rise in intraluminal pressure
• dilatation proximal to the site of obstruction
• compression and thinning of the renal parenchyma, eventually reducing it to a thin rim and resulting in a decrease in the size of the kidney.

Acute obstruction is followed by transient renal arterial vasodilatation succeeded by vasoconstriction, probably mediated mainly by angiotensin II and thromboxane A₂. Ischaemic
Interstitial damage mediated by free oxygen radicals and inflammatory cytokines compounds the damage induced by compression of the renal substance.

**Clinical features**

**Symptoms**

Loin pain occurs, which can be dull or sharp, and constant or intermittent. Pain is made worse if urine flow and volume increase, as the collecting system distends. A high fluid intake or diuretics, including alcohol and coffee, may provoke pain.

Complete anuria is strongly suggestive of complete bilateral obstruction or complete obstruction of a single kidney.

Polyuria may occur in partial obstruction, as rising pressures impair renal tubular concentrating capacity; intermittent anuria and polyuria indicate intermittent complete obstruction.

Infection is a major complication, and may give rise to malaise, fever and septicaemia.

Bladder outflow obstruction may occur with few symptoms. Hesitancy, narrowing and diminished force of the urinary stream, terminal dribbling (lower urinary tract symptoms, or LUTS) and a sense of incomplete bladder emptying are typical features (see p. 792). Infection is common (and may precipitate acute retention) with frequency, urgency, urge incontinence, dysuria and the passage of cloudy, smelly urine. Acute bladder retention causes significant discomfort and distress, though in the elderly may present as confusion and agitation alone.

**Signs**

On abdominal palpation, loin tenderness may be present, and occasionally an enlarged hydronephrotic kidney is palpable. In acute or chronic retention, the enlarged bladder can be felt or percussed. Examination of the genitalia, rectum and vagina is performed, since prostatic obstruction and pelvic malignancy are common causes of urinary tract obstruction. However, the apparent size of the prostate on digital examination is a poor guide to the presence of prostatic obstruction.

**Investigations**

- **Urinalysis** is performed for haematuria.
- A mid-stream sample of urine for MC&S to exclude infection.
- **Routine biochemical investigations** may show a raised serum urea or creatinine (or a reduced eGFR), hyperkalaemia, or anaemia of chronic disease. Prostate-specific antigen may be abnormal (see p. 592).
- **Ultrasonography** (see pp. 730–731) is the investigation of choice to confirm or rule out upper urinary tract dilatation. Ultrasound cannot distinguish a baggy, low-pressure, unobstructed system from a tense, high-pressure, obstructed one, so that false-positive scans
are seen. Stones in the ureter can be missed.

- **Plain abdominal X-ray** may detect radiolucent stones/calcification but can miss stones lying over the bone.

- **CT scanning** has a high sensitivity and can visualize uric acid (radiolucent) stones as small as 1 mm, as well as details of the obstruction. CT also allows detection of local mass lesions or lymphadenopathy.

- **Excretion urography** is now seldom used. A characteristic delayed nephrogram is seen on the obstructed side (owing to a reduction in the GFR). With time, the nephrogram on the affected side becomes denser than normal, owing to the prolonged nephron transit time, and the site of obstruction with proximal dilatation is seen (**Fig. 20.32**).

![Figure 20.32](image)

**FIGURE 20.32** Intravenous urographic X-ray taken 24 hours after injection of contrast. A delayed nephrogram and pyelogram are shown on the left side, with dilatation of the system to the level of the block. By this time, contrast medium has disappeared from the normal right side.

- **Radionuclide studies** (see pp. 731–732) have a role in longstanding obstruction to differentiate true obstructive nephropathy from retention of tracer in a baggy, low-pressure, unobstructed pelvicalyceal system.

- **Antegrade pyelography and ureterography** (see p. 731) define the site and cause of obstruction. This technique can be combined with drainage of the collecting system by
percutaneous needle nephrostomy.

• **Retrograde ureterography** (see p. 731) offers the option of relieving ureteric obstruction from below at the time of examination. In obstruction due to neuromuscular dysfunction at the pelviureteric junction or retroperitoneal fibrosis, the collecting system may fill normally from below.

• **Cystoscopy, urethroscopy and urethrogramy** can visualize obstructing lesions within the bladder and urethra directly. Urethrography involves introducing contrast medium into the bladder by catheterization or suprapubic bladder puncture, and taking X-ray films during voiding to show obstructing lesions in the urethra. It is of particular value in the diagnosis of urethral valves and strictures.

**Management**

Treatment aims to:

• relieve the obstruction
• treat the underlying cause
• prevent and treat infection
• preserve renal function.

An obstructed and infected urinary tract is a medical emergency; delay can lead to septicaemia.

• Bladder catheterization offers rapid relief of outflow tract obstruction. If a urinary catheter cannot be passed urethrally, a suprapubic catheter should be placed.

• Obstructed and hydronephrotic kidneys can be relieved by placing a percutaneous nephrostomy under ultrasound guidance.

• It is also possible to relieve obstructed ureters by cystoscopic (retrograde) stenting.

In contrast, with partial urinary tract obstruction, particularly if spontaneous relief is expected – such as by passage of a calculus – there is no immediate urgency. **Surgical management** depends on the cause of the obstruction (see below) and local expertise. Dialysis may be required in the ill patient prior to surgery.

**Post-obstructive diuresis**

This occurs after the relief of obstruction at any site in the urinary tract. Massive diuresis may occur following relief of bilateral obstruction, as prior sodium and water retention, the osmotic effect of retained solutes and defective renal tubular reabsorptive capacity correct. This diuresis is associated with increased blood volume and high levels of atrial natriuretic peptide (ANP). The diuresis is usually self-limiting, but a minority of patients develop severe sodium, water and potassium depletion needing intravenous replacement. In milder cases, oral salt and potassium supplements, together with a high water intake, are sufficient.
Specific causes of obstruction

Calculi

These are discussed on pages 754–757.

Pelviureteric junction obstruction

A functional disturbance in peristalsis of the collecting system, without any mechanical obstruction, causes pelvic hydronephrosis *(Fig. 20.33)*. In patients with recurrent loin pain or progressive kidney damage, surgical correction by open or percutaneous pyeloplasty is indicated. If longstanding obstruction has destroyed kidney function, nephrectomy prevents future pyonephrosis.

*FIGURE 20.33* X-ray showing left pelviureteric junction obstruction (arrow).
Obstructive megaureter

This childhood condition may become evident only in adult life. It results from the presence of a region of defective peristalsis at the lower end of the ureter adjacent to the ureterovesical junction. The condition is more common in males. It presents with urinary tract infection, flank pain or haematuria. The diagnosis is made on imaging with ultrasound, CT or, if necessary, ascending ureterography.

Excision of the abnormal portion of ureter with re-implantation into the bladder is always indicated in children and in adults when the condition is associated with evidence of progressive deterioration in renal function, bacteriuria that cannot be controlled by medical means, or recurrent stone formation.

Retroperitoneal fibrosis (chronic peri-aortitis)

Retroperitoneal fibrosis (RPF) is a descriptive term used when inflammatory fibrotic tissue encases the aorta and ureters; it has a number of underlying causes. RPF is three times more common in men than in women, and is an IgG4-related disease (see p. 145).

Extraluminal ureteric obstruction leads to unilateral or bilateral obstruction. The condition may extend from the level of the second lumbar vertebra to the pelvic brim. In up to 15% of patients, the fibrotic process can extend outside the retroperitoneum, consistent with it being a systemic condition. Mediastinal fibrosis, Riedel fibrosing thyroiditis, sclerosing cholangitis, fibrotic orbital pseudotumour, fibrotic arthropathy, and pleural, pericardial and lung fibrosis have been reported with increasing frequency.

RPF is thought to be either an autoallergic response to leakage of material, probably ceroid, from atheromatous plaques, producing an inflammatory reaction, or a systemic autoimmune disease. There is an association with HLA-DRB1*03, an allele linked to various autoimmune diseases. RPF is possibly initiated as a vasa vasorum vasculitis in the aortic wall, which is often seen in chronic peri-aortitis. This inflammatory process can cause medial wall thinning and promote atherosclerosis, and also extends into the surrounding retroperitoneum with a fibro-inflammatory reaction typical of chronic peri-aortitis. The autoimmune reaction to plaque antigens could be an epiphenomenon of this immune-mediated process. Activating antibodies against fibroblasts (detectable in one-third of patients) have also been implicated in the pathogenesis, as has the presence of IgG4-bearing plasma cells; the latter is a common finding in autoimmune chronic pancreatitis, a disorder sometimes associated with idiopathic retroperitoneal fibrosis. In addition, several infiltrating B cells show clonal or oligoclonal immunoglobulin heavy chain rearrangement. These findings raise the possibility of RPF being a primary B-cell disorder.

Aetiology of RPF

Causes are many:
• **Idiopathic** (in 60–70%).

• **Secondary** causes include:
  
  – drugs (methysergide, lysergic acid, ergot-derived dopamine receptor agonists (cabergoline, bromocriptine, pergolide), ergotamine, methyldopa, hydralazine, beta-blockers)
  
  – malignancy (carcinomas of the colon, prostate, breast, stomach, carcinoid, Hodgkin's and non-Hodgkin's lymphomas, sarcomas)
  
  – infection (tuberculosis, syphilis, histoplasmosis, actinomycosis, fungal infections)
  

Recognized associations include untreated abdominal aortic aneurysm, smoking and asbestosis.

### Clinical features and investigation of RPF

RPF may present with malaise, low back pain, weight loss, testicular pain, claudication and haematuria.

**Laboratory tests** show normochromic anaemia, CKD, a raised erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), and increased serum IgG4 levels. **Imaging** with ultrasound will show a poorly circumscribed peri-aortic mass. The test of choice is contrast-enhanced CT, which will show the mass, lymph nodes and tumour (*Fig. 20.34*). MRI will show similar findings but does not require contrast. Fluorodeoxyglucose-PET (FDG-PET), a functional imaging modality, assesses the metabolic activity of the retroperitoneal mass. FDG-PET also allows whole-body imaging and can detect occult malignant or infectious foci, particularly in secondary retroperitoneal fibrosis.

![FIGURE 20.34 Retroperitoneal fibrosis (peri-aortitis). Note the large mass surrounding the abdominal aorta on this CT scan (arrow).](image-url)
**Management of RPF**

A biopsy is performed to exclude an underlying infection, lymphoma or carcinoma. Initial management may involve decompressing obstructed ureters by stenting (anterograde or retrograde). Corticosteroids may reverse the obstructing inflammatory tissue, if only as a holding measure before definitive treatment of the underlying cause. Response to treatment and disease activity are assessed by serial measurements of ESR and eGFR, and repeat FDG-PET scans can also monitor disease.

Obstruction is relieved surgically by ureterolysis. A long-term ureteric stent or stents can be used with chronic corticosteroid therapy, but regular (usually 6-monthly) changes of the stent(s) are required if the peri-aortic mass does not regress.

Relapse after withdrawal of steroid therapy may occur and treatment may need to be continued for years. Mycophenolate or tamoxifen is also effective. Long-term follow-up is mandatory.

**Benign prostatic hypertrophy**

Benign prostatic hypertrophy is a common cause of urinary tract obstruction. It is described on page 792.

**Prognosis of urinary tract obstruction**

The prognosis depends on the cause and the stage at which obstruction is relieved. Four factors influence the rate at which kidney damage occurs, its extent, and the degree and rapidity of recovery of renal function after relief of obstruction:

- whether obstruction is partial or complete
- the duration of obstruction
- the presence or absence of infection
- the site of obstruction.

Complete obstruction for several weeks will lead to irreversible or only partially reversible kidney damage. If complete obstruction lasts several months, irreversible destruction of the affected kidney occurs. Partial obstruction carries a better prognosis, depending on its severity. Bacterial infection with obstruction rapidly increases kidney damage. Obstruction at or below the bladder neck leads to hypertrophy and trabeculation of the bladder without a rise in pressure within the upper urinary tract, in which case the kidneys are protected from the effects of back-pressure.

**Further reading**

Drugs and the Kidney

The kidney eliminates many drugs, as well as the (often active) products of drug metabolism in the liver. Dosing requires some thought with CKD, particularly in the elderly. Many drugs can further impair renal function, either over time, or acutely if hypovolaemia occurs (with vomiting or diarrhoea, for example), where a prescribed drug (such as an ACE inhibitor) prevents an appropriate response.

Drug-induced impairment of renal function

Renal perfusion falls with drugs that cause:

- hypovolaemia, e.g.:
  - loop diuretics such as furosemide, especially in elderly patients
  - renal salt and water loss, such as from hypercalcaemia induced by vitamin D therapy (since hypercalcaemia adversely affects renal tubular salt and water conservation)
- decrease in cardiac output, which impairs renal perfusion (e.g. beta-blockers)
- decrease in renal blood flow (e.g. ACE inhibitors, particularly in the presence of renovascular disease).

Drugs may directly damage the kidney:

- **Acute tubular necrosis produced by direct nephrotoxicity** from prolonged or high-dose treatment with aminoglycosides (e.g. gentamicin, amikacin), amphotericin B, tenofovir, cisplatin or calcineurin inhibitors. The combination of aminoglycosides with furosemide is particularly nephrotoxic.
- **Crystal nephropathies** caused by antivirals such as aciclovir and indinavir.
- **Acute tubulointerstitial nephritis** (see pp. 767–768), a cell-mediated hypersensitivity nephritis occurring with many drugs, including penicillins, cephalosporins, proton-pump inhibitors, diuretics, sulphonamides and NSAIDs (which have many other effects on the kidney; Box 20.20).

- **Retroperitoneal fibrosis with urinary tract obstruction** – can result from the use of drugs (see pp. 760–761).

### Using drugs in patients with impaired renal function

See **Box 20.21**.

<table>
<thead>
<tr>
<th>Box 20.21</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Safe prescribing in kidney disease</strong></td>
</tr>
<tr>
<td>Safe prescribing in CKD demands knowledge of the clinical pharmacology of the drug and its metabolites in normal individuals and in uraemia. The clinician should ask the following questions when prescribing, and discuss them with the patient:</td>
</tr>
<tr>
<td>1. <em>Is treatment mandatory?</em> Unless it is, it should be withheld.</td>
</tr>
<tr>
<td>2. <em>Can the drug reach its site of action?</em> For example, there is little point in prescribing the urinary antiseptic, nitrofurantoin, in severe CKD since bacteriostatic concentrations will not be attained in the urine.</td>
</tr>
<tr>
<td>3. <em>Is the drug's metabolism altered in uraemia?</em></td>
</tr>
<tr>
<td>4. <em>Will accumulation of the drug or metabolites occur?</em> Even if accumulation is a potential problem, owing to the drug or its metabolites being excreted by the kidneys, it is not necessarily an indication to change the drug given. The size of the loading dose will depend on the size of the patient and is unrelated to renal function. Avoidance of toxic levels of drug in blood and tissues subsequently requires the administration of normal doses of the drug at longer time intervals than usual, or in smaller doses at the usual time intervals.</td>
</tr>
<tr>
<td>5. <em>Is the drug toxic to the kidney?</em></td>
</tr>
<tr>
<td>6. <em>Are the effective concentrations</em> of the drug in biological tissues similar to the toxic concentrations?* Should blood levels of the drug be measured?</td>
</tr>
<tr>
<td>7. <em>Will the drug worsen the uraemic state</em> by means other than nephrotoxicity, e.g. steroids, tetracycline?</td>
</tr>
</tbody>
</table>
8. **Is the drug a sodium or potassium salt?** These are potentially hazardous in uraemia.

Not surprisingly, adverse drug reactions are more than twice as common in patients with CKD as in normal individuals. Elderly patients, in whom unsuspected CKD is common, are particularly at risk. Attention to the above and titration of the dose of drugs employed should reduce the problem.

The dose may be titrated by:

- observation of its clinical effect, e.g. hypotensive agents
- early detection of toxic effects
- measurement of drug levels in the blood, e.g. gentamicin levels.

**Absorption**

Absorption can be unpredictable in uraemia, as gastric emptying may be delayed, and nausea and vomiting are frequent.

**Metabolism**

The rate of drug metabolism by the kidney is reduced as a result of:

- **Reduced drug catabolism.** Insulin, for example, is in part catabolized by the normal kidney. In renal disease, insulin catabolism is reduced. The insulin requirements of diabetics decline as renal function deteriorates, for this reason.

- **Reduced conversion of a precursor to a more active metabolite.** An example is the conversion of 25-hydroxycholecalciferol to the more active 1,25-(OH)$_2$D$_3$. The 1α-hydroxylase enzyme responsible for this conversion is located in the kidney. In renal disease, production of the enzyme declines and deficiency of 1,25-(OH)$_2$D$_3$ results.

**Protein binding**

Reduced protein binding of a drug potentiates its activity and increases the potential for toxic side-effects. Hypoalbuminaemia (in the nephrotic syndrome) leads to increased free drug, as does uraemic toxins binding to albumin (occupying drug-binding sites). Measuring total plasma concentration (albumin-bound and free drug) of such drugs can give misleading results. For example, more free phenytoin than albumin-bound phenytoin is present in CKD, for the same total plasma concentration seen in healthy individuals – and lower levels will control seizures in patients with CKD.

**Volume of distribution**

Salt and water overload or depletion may occur in patients with renal disease. This affects the concentration of drug obtained from a given dose.

**End-organ sensitivity**

The renal response to drug treatment may be reduced in renal disease. For example, mild
thiazide diuretics have little diuretic effect in patients with severe CKD.

**Renal elimination**

In CKD, drugs eliminated by the kidneys are no longer excreted normally. Water-soluble drugs, such as gentamicin, which are poorly absorbed from the gut, typically given by injection and not metabolized by the liver, give rise to far more problems than lipid-soluble drugs such as propranolol, which are well absorbed and principally metabolized by the liver.

**Drugs affecting protein anabolism and catabolism**

Tetracyclines, with the exception of doxycycline, have a catabolic effect. Increased nitrogenous waste products are not well cleared, and uraemia may be more marked. Corticosteroids also have a catabolic effect and may lead to a disproportionate increase in urea compared to creatinine when used in high doses in CKD.

**Problem patients**

Particular problems are presented by patients with rapidly changing renal function, such as those with evolving AKI or recovering acute tubular necrosis. In addition, drugs may be removed by dialysis and haemofiltration, which will affect the dosage required.

**Urinary Tract Infection**

Urinary tract infection (UTI) is common, particularly in women, most often occurring in a normal urinary tract and usually as cystitis; half of all women will experience a UTI in their lifetime. Most UTIs occur in isolation (Fig. 20.35). It is uncommon in men and children; when diagnosed, it often occurs in an abnormal urinary tract. Between 1% and 2% of patients presenting in primary care will have a UTI. UTI is not always uncomplicated; recurrent infection causes considerable morbidity, and infection can lead to life-threatening Gram-negative septicaemia and kidney failure.

![FIGURE 20.35](image.png) The natural history of urinary tract infection.

**Aetiology and pathogenesis**

Infection is most often caused by bacteria from a patient's own bowel flora (Box 20.22), and
infection usually ascends up the urethra. In women, the short urethra makes ascending infection more likely. Rarely, infection may arise from the bloodstream or lymphatics, or by direct extension (e.g. from a vesicocolic fistula).

*a* More common in young women (20–30%).

*b* More common in hospital practice.

---

**Bacterial virulence**

How well an organism adheres to urothelium determines its virulence. The presence of flagella (for motility), aerobactin (used to acquire iron), haemolysin (to form pores) and, above all, the presence of fimbriae (adhesins that attach organisms to the perineum and urothelium) on the bacterial cell surface make *E. coli* such a common pathogen.

**Innate host defence**

Innate host defence prevents UTI in the following ways:

- **Neutrophils.** Bacterial adhesins activate receptors, e.g. Toll receptor 4, on the mucosal surface, resulting in IL-8 production and expression of its receptor, CXCR1, on neutrophil surfaces. Activation of neutrophils is essential for bacterial killing.

- **Urine osmolality and pH.** Urinary osmolality >800 mOsm/kg and low or high pH reduce bacterial survival.

- **Complement.** Complement activation with mucosal IgA production by uroepithelium (acquired immunity) plays a major role in defence against UTI.

- **Commensal organisms.** Eradication of commensal organisms such as lactobacilli, corynebacteria, streptococci and bacteroides by spermicidal jelly or antibiotics results in overgrowth of *E. coli*.

- **Urine flow.** Good urine flow and normal micturition wash out bacteria. Urine stasis promotes
UTI.

- **Uroepithelium.** Mannosylated Tamm–Horsfall proteins (THPs), present in the mucus and glycocalyx covering uroepithelium, have antibacterial properties and interfere with bacterial binding to uroepithelium. Cranberry juice and blueberry juice contain a large-molecular-weight factor (pro-anthrocyanidins) that prevents binding of *E. coli* to the uroepithelium.

- **Blood group antigens.** Women who are non-secretors of ABH blood group antigens are 3–4 times more likely to have recurrent UTIs.

### Risk factors
- Female gender, especially postmenopausal women.
- New sexual activity, particularly in young women.
- Indwelling urinary catheter or instrumentation of the urinary tract.
- Urinary tract stones.
- Urinary tract stasis (incomplete bladder emptying).
- Diabetes mellitus or immunosuppression.
- Dementia.

### Clinical features

The most typical symptoms of (lower) UTI are:

- frequency of micturition by day and night
- dysuria (painful voiding)
- suprapubic pain and tenderness
- haematuria
- smelly urine.

These are the symptoms of bladder and urethral inflammation, or ‘cystitis’. Loin pain and tenderness, with fever, chills, night sweats and rigors, suggest extension of infection to the pelvis and kidney, known as pyelitis or pyelonephritis. Localization of the site of infection on the basis of symptoms alone is unreliable.

UTI can also present with few or no symptoms (particularly in the immunocompromised), or even with abdominal pain, fever or haematuria in the absence of frequency or dysuria. In the elderly, new confusion may be the only symptom of UTI. In small children, who cannot complain of dysuria, symptoms are often ‘atypical’. The possibility of UTI must always be considered in the fretful, febrile, sick child who fails to thrive.

### Diagnosis

Uncomplicated UTIs in younger women (age ≤65) can be diagnosed in those without known urinary tract abnormalities, recent urinary tract instrumentation, or systemic illness if they...
exhibit at least two of three cardinal symptoms – dysuria, urgency or frequency – along with absence of vaginal discharge. Neither urine dipstick testing for leucocyte esterase nor urine culture enhances diagnostic sensitivity. Telephone-based protocols have outcomes similar to those of surgery-based diagnosis and treatment, and such methods are often preferred by patients. Patients with histories of uncomplicated UTIs can be taught to self-diagnose and initiate therapy.

Otherwise, diagnosis is based on culture of a clean-catch mid-stream specimen of urine and the presence or absence of pyuria. The criteria for the diagnosis of UTI, particularly in symptomatic women, are shown in Box 20.23. Most Gram-negative organisms reduce nitrates to nitrites and produce a red colour in the reagent square. False-negative results are common. Dipsticks that detect significant pyuria depend on the release of esterases from leucocytes. Dipstick tests positive for both nitrite and leucocyte esterase are highly predictive of acute infection (sensitivity of 75% and specificity of 82%).

---

**Box 20.23**

**Criteria for the diagnosis of bacteriuria**

**Symptomatic young women**

- $\geq 10^2$ coliform organisms/mL urine plus pyuria ($>10$ white blood cells/mm$^3$)  
  or
- $\geq 10^5$ any pathogenic organism/mL urine  
  or
- Any growth of pathogenic organisms in urine by suprapubic aspiration

**Symptomatic men**

- $\geq 10^3$ pathogenic organisms/mL urine

**Asymptomatic patients**

- $\geq 10^5$ pathogenic organisms/mL urine on two occasions

---

Re-infection versus relapsing infection may be distinguished as follows:

- **Relapse** is diagnosed by recurrence of bacteriuria with the same organism within 7 days of completion of antibacterial treatment. Treatment failure may suggest (Fig. 20.36) associated stones, scarred kidneys, polycystic disease or bacterial prostatitis.
**Re-infection** is when bacteriuria is absent after treatment for at least 14 days, usually longer, followed by recurrence of infection with the same or different organisms. This is not due to failure to eradicate infection, but is the result of re-invasion of a susceptible tract with new organisms. Approximately 80% of recurrent infections are due to re-infection.

Where culture is negative and symptoms persist, consider:

- **Abacteriuric frequency or dysuria (‘urethral syndrome’).** This is caused by bladder trauma after intercourse; vaginitis, atrophic vaginitis or urethritis in the elderly; and *Chlamydia* infection and tuberculosis in symptomatic young women with ‘sterile pyuria’.

- **Interstitial cystitis.** This is uncommon but distressing, affecting women over the age of 40. Patients present with frequency, dysuria and often severe suprapubic pain but cultures are sterile. Cystoscopy shows typical inflammatory changes with ulceration of the bladder base. It is now thought to be an autoimmune disorder. Treatments include oral prednisolone, bladder instillation of sodium cromoglicate or dimethyl sulphoxide, and bladder stretching under anaesthesia. Unfortunately, relief of symptoms can be difficult to achieve.

- **Predominant frequency** and passage of small volumes of urine (‘irritable bladder’). These may occur after previous UTI.

---

**Natural history**

Serious morbidity is unusual. However, renal scarring can result from recurrent UTI and dissemination of infection as septicaemia can be fatal. In patients with a **normal urinary tract (with normal renal imaging)**, outcomes are very good, and persistent or recurrent infection seldom results in serious kidney damage (uncomplicated UTI). In those with **abnormal urinary tracts** (stones or stasis), recurrence is more common and outcomes are less good. The combination of infection and obstruction results in severe, sometimes rapid, kidney damage
(obstructive pyonephrosis) and is a major cause of Gram-negative septicaemia from *Pseudomonas* and *Enterobacter* spp. Complicated and uncomplicated infection is compared in **Figure 20.37**.

**FIGURE 20.37** Complicated versus uncomplicated urinary tract infection.

### Acute pyelonephritis

Fever, loin pain with tenderness and significant bacteriuria usually imply infection of the kidney (acute pyelonephritis). Small renal cortical abscesses and streaks of pus in the renal medulla are often present. Histologically, there is focal infiltration by polymorphonuclear leucocytes and many polymorphs in tubular lumina.

Although, with antibiotics, significant permanent kidney damage in adults with normal urinary tracts is rare, CT scanning can show wedge-shaped areas of inflammation in the renal cortex (**Fig. 20.38**), where renal function will be impaired.
Reflux nephropathy

This was called chronic pyelonephritis or atrophic pyelonephritis, resulting from a combination of:

- vesicoureteric reflux
- infection acquired in infancy or early childhood.

Normally, the vesicoureteric junction acts as a one-way valve (Fig. 20.39), urine entering the bladder from above; the ureter is shut off during bladder contraction, thus preventing reflux of urine. In some infants and children – possibly even in utero – this valve mechanism is incompetent, bladder voiding being associated with variable reflux of a jet of urine up the ureter. A secondary consequence is incomplete bladder emptying, as refluxed urine returns to the bladder after voiding. This latter event predisposes to infection, and the reflux of infected urine leads to kidney damage.
Typically, there is papillary damage, tubulointerstitial nephritis and cortical scarring in areas adjacent to ‘clubbed calyces’.

**Diagnosis** is based on CT scan of the kidneys, which shows irregular renal outlines, clubbed calyces and a variable reduction in renal size. The condition may be unilateral or bilateral, and may affect all or part of the kidney.

Reflux usually ceases around puberty with growth of the bladder base (a thickened bladder wall is able to prevent reflux with bladder contraction). Damage already done persists and progressive renal fibrosis and further loss of function occur in severe cases, even though there is no further infection.

Reflux nephropathy cannot occur in the absence of reflux – it does not begin in adult life. Consequently, women with bacteriuria and a normal urogram can be reassured that kidney damage will not develop.

**Chronic reflux nephropathy** acquired in infancy predisposes to hypertension in later life and, if severe, is a relatively common cause of ESKD in childhood or adult life. Meticulous early detection and control of infection, with or without ureteral re-implantation to create a competent valve, can prevent further scarring and allow normal growth of the kidneys. No proof exists, however, that re-implantation surgery confers long-term benefit.

Continuous antibiotic prophylaxis (CAP), compared with no treatment, significantly reduces the risk of symptomatic UTI in children with chronic reflux nephropathy but at the expense of increased risk for developing antimicrobial-resistant bacterial strains. CAP does not have a significant impact on the occurrence of new renal scarring.

**Special investigations**

Uncomplicated UTI usually does not require imaging. If infection is recurrent or affects men or children, or if there are unusually severe symptoms, it should be investigated further. Patients
with diabetes mellitus and those on immunosuppression benefit from early imaging.

- **Ultrasound** allows the detection of calculi, obstruction, abnormal urinary anatomy and incomplete bladder emptying (post-micturition scan). It is helpful in the assessment of suspected pyelonephritis or an obstructed, infected kidney that may require drainage.

- **CT** is more sensitive for diagnosis and follow-up of complicated renal tract infection. Contrast-enhanced CT allows different phases of excretion to be studied, and can define the extent of disease and identify significant complications or obstruction.

- **MRI** is particularly useful in those with iodinated contrast allergies, offering an ionizing radiation-free alternative in the diagnosis of both medical and surgical diseases of the kidney.

- **Nuclear medicine** has a limited role in the evaluation of UTI in adults. Its main role is in the assessment of renal function and detection of scars by DMSA scan, often prior to surgery.

### Management

#### Management of a single isolated attack

- **The most appropriate antibiotic choices** are trimethoprim–sulfamethoxazole (160/800 mg twice daily for 3–7 days) or nitrofurantoin (100 mg twice daily for 5–7 days). Fluoroquinolones offer no advantage in cure rates; β-lactam antibiotics, such as amoxicillin–clavulanate, are less effective than the first-line recommendations. Most patients who delay antibiotic treatment to encourage spontaneous resolution eventually receive antibiotics and have longer times to resolution. Men with uncomplicated UTIs should be treated as above but for 7–14 days.

- **Shorter 3–5-day courses** with amoxicillin (250 mg three times daily), trimethoprim (200 mg twice daily) or an oral cephalosporin are also used, and modified in light of the result of urine culture and sensitivity testing, and/or the clinical response.

- **Single-shot treatment** with 3 g of amoxicillin or 1.92 g of co-trimoxazole is used for patients with bladder symptoms of <36 hours' duration who have no previous history of UTI.

- **A high (2 L daily) fluid intake** should be encouraged during treatment and for some subsequent weeks. Urine culture should be repeated 5 days after treatment.

- **If the patient is acutely ill with high fever, loin pain and tenderness** (acute pyelonephritis), antibiotics are given intravenously, e.g. aztreonam, cefuroxime, ciprofloxacin or gentamicin, switching to a further 7 days' treatment with oral therapy as symptoms improve. Intravenous fluids may be required to achieve a good urine output.

- **In patients presenting for the first time with high fever, loin pain and tenderness**, urgent renal ultrasound examination is required to exclude an obstructed pyonephrosis. If this is present, it should be drained by percutaneous nephrostomy (see p. 731).

#### Management of recurrent infection

Pre-treatment and post-treatment urine cultures are necessary to confirm the diagnosis and to
establish whether recurrent infection is due to relapse or re-infection.

**Relapse.** A search should be made for a cause (e.g. stones or scarred kidneys), and treatment modified if possible. Intense or prolonged treatment may be required. If this fails, long-term antibiotics are necessary.

**Re-infection.** This implies that the patient has a predisposition to periurethral colonization or poor bladder defence mechanisms. Contraceptive advice should be offered and the use of a diaphragm or spermicidal jelly discouraged. Atrophic vaginitis should be identified in postmenopausal women, who should be treated (see below). Preventative measures may help:

- a 2 L daily fluid intake
- voiding at 2–3-h intervals, with double micturition if reflux is present
- voiding before bedtime and after intercourse
- avoidance of spermicidal jellies and of bubble baths and other chemicals in bath water
- avoidance of constipation, which may impair bladder emptying.

Evidence of impaired bladder emptying on excretion urography/ultrasound requires urological assessment. If UTI continues to recur, treatment for 6–12 months with low-dose alternating monthly prophylaxis (trimethoprim 100 mg, co-trimoxazole 480 mg, cefalexin 125 mg at night or macrocrystalline nitrofurantoin) is required; it should be taken last thing at night when urine flow is low. Intravaginal oestrogen therapy has been shown to produce a reduction in the number of episodes of UTI in postmenopausal women. Cranberry juice is said to reduce the risk of symptoms and re-infection by 12–20% but studies are limited.

### Urinary infections in the presence of an indwelling catheter

Colonization of the bladder by a pathogen is common after a urinary catheter has been in situ for more than a few days, partly due to organisms forming biofilms. So long as the bladder catheter is in place, antibiotics are likely to be ineffective and will encourage the development of resistant organisms. The patient should be treated only if there are symptoms or evidence of infection. The catheter should always be replaced. When changing catheters, a single dose of antibiotic (e.g. gentamicin) is recommended.

Infection by *Candida* is a frequent complication of prolonged bladder catheterization. Treatment should be reserved for patients with evidence of invasive infection and those who are immunosuppressed. The catheter should be removed or replaced. In severe infections, continuous bladder irrigation with amphotericin 50 µg/mL is useful.

### Bacteriuria in pregnancy

Pregnant women should have their urine cultured, as 2–6% have asymptomatic bacteriuria (see p. 1308). Usually harmless in non-pregnant women, bacteriuria in pregnancy can lead to acute pyelonephritis, and in late pregnancy may trigger pre-term labour. Ureteric dilatation in response to hormonal changes may allow ascending infection. **Bacteriuria must always be**
treated and shown to be eradicated. Re-infection may require prophylactic therapy. Tetracycline, trimethoprim, sulphonamides and 4-quinolones are contraindicated in pregnancy. Amoxicillin and ampicillin, nitrofurantoin and oral cephalosporins may be used safely in pregnancy.

### Bacterial prostatitis

Bacterial prostatitis is a relapsing infection that presents as perineal pain, recurrent epididymo-orchitis and prostatic tenderness, with pus in expressed prostatic secretions. Treatment is for 4–6 weeks with drugs that penetrate into the prostate, such as trimethoprim or ciprofloxacin. Long-term, low-dose treatment may be required. Prostatodynia (prostatic pain in the absence of active infection) may persist long after the infection. Amitriptyline and carbamazepine may alleviate the symptoms.

### Renal carbuncle

Renal carbuncle is an abscess in the renal cortex caused by a blood-borne staphylococcus, usually from a boil or carbuncle of the skin. It presents with a high, swinging fever, loin pain and tenderness, and fullness in the loin. The urine shows no abnormality, as the abscess does not communicate with the renal pelvis, more often extending into the perirenal tissue. Staphylococcal septicaemia is common. Diagnosis is by ultrasound or CT scanning. Treatment involves antibacterial therapy with flucloxacillin and surgical drainage.

### Tuberculosis of the urinary tract

Tuberculous infection is on the increase worldwide, partly due to the reservoir of infection in susceptible HIV-infected individuals and the emergence of drug-resistant strains. Tuberculosis of the urinary tract presents with frequency, dysuria or haematuria. In the UK, it is seen mainly in the Asian immigrant population. Cortical lesions result from haematogenous spread in the primary phase of infection. Most heal, but in some, infection persists and spreads to the papillae, with the formation of cavitating lesions and the discharge of mycobacteria into the urine. Infection of the ureters and bladder commonly follows, with the potential for development of ureteral strictures and a contracted bladder. Rarely, cold abscesses may form in the loin. In males, the disease may present with testicular or epididymal discomfort and thickening.

**Diagnosis** depends on constant awareness, especially in patients with sterile pyuria. Imaging may show cavitating lesions in the renal papillary areas, commonly with calcification. There may also be evidence of ureteral obstruction with hydronephrosis. Culture of mycobacteria from early-morning urine samples is not straightforward. Imaging may be normal in diffuse interstitial renal tuberculosis, when diagnosis is made instead by renal biopsy, which demonstrates caseating granulomata with multinucleate giant cells and acid-fast bacilli on
Ziehl–Neelsen staining (*Fig. 20.40*). Some patients present late with small, unobstructed kidneys, when the diagnosis is easy to miss.

*Treatment* is as for pulmonary tuberculosis (see pp. 1110–1113). Renal ultrasonography and/or CT scanning should be carried out 2–3 months after initiation of treatment, as ureteric strictures may first develop in the healing phase.

### Xanthogranulomatous pyelonephritis

This is an uncommon chronic interstitial infection of the kidney, most often due to *Proteus*, in which there is fever, weight loss, loin pain and a palpable enlarged kidney. It is usually unilateral and associated with staghorn calculi and UTI. CT scanning shows up intrarenal abscesses as lucent areas within the kidney. Nephrectomy is the treatment of choice; antibacterial treatment rarely, if ever, eradicates the infection.

### Further reading

### Tubulointerstitial Nephritis

Diseases of the kidney primarily affect the glomeruli, vasculature, or the substance of the renal parenchyma, made up of tubules and the interstitium. Tubular and interstitial injury and recovery tend to go hand in hand.

### Acute tubulointerstitial nephritis

In approximately 70% of the cases, acute tubulointerstitial nephritis (TIN) is a hypersensitivity reaction to drugs (*Box 20.24*), most commonly penicillins, NSAIDs or proton-pump inhibitors.
Common causes of acute tubulointerstitial nephritis

- Drugs (70%):
  - Antibiotics:
    - Cephalosporins
    - Ciprofloxacin
    - Erythromycin
    - Penicillin
    - Rifampicin
    - Sulphonamides
  - Analgesics:
    - Non-steroidal anti-inflammatory drugs
  - Diuretics:
    - Furosemide
    - Thiazides
  - Miscellaneous:
    - Allopurinol
    - Carbamazepine
    - Cimetidine
    - Phenytoin
    - Proton pump inhibitors
    - Valproate
- Infection (15%):
  - Viruses, e.g. hantavirus
  - Bacteria, e.g. streptococci
- Idiopathic (8%)
- Tubulointerstitial nephritis with uveitis (TINU) (5%)
- Systemic inflammatory disorders, e.g.:
  - Systemic lupus erythematosus (2%)
  - IgG4-related disorder

Drug-induced acute TIN

Patients may be wholly asymptomatic (with impaired renal function found incidentally), or present with fever, arthralgia, skin rashes and acute oliguric or non-oliguric kidney injury. Many have eosinophilia and eosinophiluria. Renal histology shows an intense interstitial cellular infiltrate, often including eosinophils, with variable tubular necrosis (Fig. 20.41). Rarely, NSAIDs can cause a glomerular minimal-change lesion in addition to TIN and disease presents as the nephrotic syndrome. Treatment involves stopping the offending drug. High-dose
Prednisolone (60 mg daily) is given but efficacy has not been proven. Patients may require dialysis for management of the AKI. Most patients make a good recovery in terms of kidney function, but some may be left with significant interstitial fibrosis and CKD.

**FIGURE 20.41** Tubulointerstitial nephritis showing diffuse interstitial infiltrate with red staining (arrow).

**Infection causing acute TIN**

Acute pyelonephritis leads to inflammation of the tubules, producing a neutrophilic cellular infiltrate. TIN can complicate systemic infections with viruses (Hantavirus, Epstein–Barr virus, HIV, measles, adenovirus), bacteria (*Legionella*, *Leptospira*, streptococci, *Mycoplasma*, *Brucella*, *Chlamydia*) and others (*Leishmania*, *Toxoplasma*). Hantavirus causes haemorrhagic fever with TIN and can be fatal. Epstein–Barr virus DNA has been found in renal biopsy tissue of cases of idiopathic TIN. In immunocompromised patients, such as those who have had renal transplantation, cytomegalovirus, polyoma (BK) and herpes simplex virus can cause acute TIN in the renal graft. Treatment involves eradication of infection with appropriate antibiotics or antiviral agents; in renal transplantation, the immunosuppressive regimen is modified.

**Acute TIN as part of multisystem inflammatory diseases**

Several non-infectious inflammatory disorders, such as Sjögren syndrome, SLE and granulomatosis, can cause acute or chronic TIN rather than glomerulonephritis. Sjögren syndrome may additionally present as renal tubular acidosis. Sarcoidosis presents as granulomatous TIN in up to 20% of patients. Associated hypercalcaemia causes AKI. These heterogeneous conditions with TIN generally respond to steroids.

**Tubulointerstitial nephritis with uveitis syndrome**

Patients with tubulointerstitial nephritis with uveitis (TINU) syndrome present with uveitis, an acute TIN, weight loss, anaemia and a raised ESR of unknown cause. It is common in childhood but has been reported in adulthood, and is more frequently found in women. It may be associated with autoantibodies directed against modified CRP. A prolonged course of steroids leads to improvement in both renal function and uveitis.
Chronic tubulointerstitial nephritis

The major causes of chronic TIN are given in Box 20.25. Patients present with any of polyuria, nocturia, proteinuria (usually slight, <1 g daily) or uraemia. Chronic TIN may be linked with papillary necrosis (ischaemic damage to the papillae, which then slough into the calyces and urine) when associated with longstanding analgesic use, diabetes mellitus, sickle cell disease or trait. Microscopic or overt haematuria or sterile pyuria also occurs, and occasionally a sloughed papilla may cause ureteric colic or produce acute ureteric obstruction. Histologically, a generalized chronic inflammatory cellular infiltration of the interstitium with tubular atrophy and generalized interstitial oedema or fibrosis is present, and in many cases no cause is found.

---

**Box 20.25**

Causes of chronic tubulointerstitial nephritis

**Drugs and toxins, e.g.**
- All causes of acute tubulointerstitial nephritis, e.g. analgesics
- Ciclosporin
- 5-aminosalicylates
- Cadmium, lead, titanium
- Irradiation

**Systemic disease, e.g.**
- Diabetes mellitus
- Sickle cell disease or trait
- Systemic lupus erythematosus/vasculitis
- Sarcoidosis
- IgG4-related disease

**Metabolic, e.g.**
- Hyperuricaemia
- Nephrocalcinosis
- Hyperoxaluria

**Infection, e.g.**
- Human immunodeficiency virus
- Epstein–Barr virus

**Miscellaneous**
IgG4-related tubulointerstitial nephritis is distinguished by very low concentrations of complement and increased serum IgG4. This may lead to immune complex formation.

The radiological appearances must be distinguished from those of reflux nephropathy (Fig. 20.42) or obstructive uropathy.

**FIGURE 20.42** A comparison of the radiological appearances of papillary necrosis and reflux nephropathy.

Tubular damage to the medullary area of the kidney leads to defects in urine concentration and sodium conservation with polyuria and salt wasting. Fibrosis progressing into the cortex leads to loss of excretory function and urea.

**Analgesic nephropathy**

The chronic consumption of large amounts of analgesics (classically, phenacetin but now
NSAIDs) leads to chronic TIN and papillary necrosis. Analgesic nephropathy is more common in women and typically presents in middle age. Presentation may be with anaemia, CKD, UTIs, haematuria or urinary tract obstruction (owing to sloughing of a renal papilla). Salt- and water-wasting renal disease may occur. Chronic analgesic use also predisposes to the development of uroepithelial tumours. Diagnosis is usually made on clinical grounds combined with the non-pathognomonic appearance on imaging (such as ultrasonography or CT scan), which demonstrates smallish, irregularly outlined kidneys.

Patients should be encouraged to avoid NSAIDs, and if necessary, dihydrocodeine or paracetamol may be offered as a reasonable alternative (this may stop further damage and even achieve an improvement). The development of flank pain or an unexpectedly rapid deterioration in renal function should prompt ultrasonography to screen for urinary tract obstruction due to a sloughed papilla.

Balkan nephropathy

Balkan nephropathy (BN) is a chronic TIN endemic in areas along the tributaries of the River Danube. Inhabitants of the low-lying plains, which are subjected to frequent flooding and where the water supply comes from shallow wells, are affected, whereas the disease does not occur in hillside villages where surface water provides the supply. Chronic dietary poisoning by aristolochic acid (AA) is thought to be responsible for BN and the urothelial cancers that accompany the diagnosis. The disease is insidious in onset, with mild proteinuria progressing to ESKD in 3 months to 10 years. There is no treatment.

Chinese herb nephropathy

Chinese herbal medicines may contain AA, produced as a result of fungal contamination of the product. Histology is similar to that of BN but the clinical course is aggressive, with relentless progression to ESKD and a high incidence of uroepithelial tumours.

Other forms of chronic TIN

These are rare (Box 20.25). Diagnosis of all forms depends on a history of drug ingestion or industrial exposure to nephrotoxins. In patients with unexplained renal impairment with normal-sized kidneys, renal biopsy must always be undertaken to exclude a treatable TIN, such as granulomatous TIN due to renal sarcoidosis (Fig. 20.43), which may be the first presentation of sarcoidosis (see pp. 1118–1120). Renal sarcoidosis generally responds rapidly to steroids.
Hyperuricaemic nephropathy

Acute hyperuricaemic nephropathy (see p. 606), as part of tumour lysis syndrome, causes AKI in patients with very high serum urate concentrations. It may occur prior to treatment of haematological malignancies, but more often supervenes after treatment. As the abundant tumour cells lyse in response to chemotherapy, large amounts of nucleoprotein are released with increased uric acid production. Renal failure is due to intrarenal and extrarenal obstruction caused by deposition of uric acid crystals in the collecting ducts, pelvis and ureters.

There may be flank pain or colic, and oliguria or anuria with increasing uraemia. Plasma urate levels are >0.75 mmol/L and may be as high as 4.5 mmol/L. Diagnosis is based on the hyperuricaemia and the clinical setting. Ultrasound may demonstrate extrarenal obstruction due to stones but may be unremarkable.

Allopurinol 100–200 mg three times daily for 5 days is given prior to and throughout treatment with radiotherapy or cytotoxic drugs. A high rate of urine flow must be maintained by oral or parenteral fluid, and the urine kept alkaline by the administration of sodium bicarbonate 600 mg four times daily and acetazolamide 250 mg three times daily, since uric acid is more soluble in an alkaline than an acid medium. Febuxostat, a non-purine-analogue inhibitor of xanthine oxidase, can be used if allopurinol cannot be tolerated and eGFR is >30 mL/min. Rasburicase, a recombinant urate oxidase (see p. 774), and pegloticase, a pegylated uricase, are successfully used to lower serum urate concentrations rapidly for both treatment and prevention. In severely oliguric or anuric patients, dialysis is required to lower the plasma urate.

There is no convincing direct evidence for chronic hyperuricaemia nephropathy. However, a few observational studies have suggested that elevated levels of uric acid independently increase the risk for new-onset CKD, and that plasma urate reduction with allopurinol has a beneficial effect in slowing the rate of progression of CKD.

Further reading
Acute Kidney Injury

Acute kidney injury (AKI) is defined as follows:

• There is an abrupt deterioration in renal function, usually over hours or days.
• It is usually (but not always) reversible over days or weeks.

AKI may cause sudden, life-threatening biochemical disturbances as a medical emergency. Oliguria is often a feature. The distinction between AKI and CKD, or even acute-on-chronic kidney disease, is not always obvious. AKI is usually recognized by a falling urine output and rising serum urea and creatinine, or both. In some situations, urea and creatinine are less accurate predictors of deteriorating renal function (Box 20.26).

**Box 20.26**

AKI may result from:

• *pre-renal* causes (reduced kidney perfusion leads to a falling GFR)
• *renal* parenchymal disorders (injury to glomerulus, tubule or vessels)
• *post-renal* causes (urinary tract obstruction – functioning kidneys cannot excrete urine with back-pressure affecting function).

The Acute Dialysis Quality Initiative group proposed the **RIFLE classification** (risk, injury, failure, loss, end-stage renal disease) to define AKI better, using either an increase in serum creatinine or a decrease in urine output. RIFLE describes three levels of renal dysfunction (R, I, F) and two outcome measures (L, E). These criteria indicate an increasing degree of renal...
damage and have a predictive value for mortality.

The Acute Kidney Injury Network (AKIN) proposed a modification of the original RIFLE criteria to include less severe AKI and a time constraint of 48 hours, and gives a correction for volume status before classification.

‘R’ in RIFLE is **stage 1** (a serum creatinine rise of ≥26.4 µmol/L – that is, a 1.5-fold increase within 48 hours).

‘I’ is **stage 2** – that is, a 2–3-fold increase in serum creatinine.

‘F’ is **stage 3** – that is, an increase in serum creatinine of >300% (equal to ≥354 µmol/L).

Urine output data are the same.

Using the same criteria of serum creatinine and urine output, a more recent classification (The Kidney Diseases: Improving Global Outcomes (KDIGO) classification) is shown in **Box 20.27**.

*Kidney Diseases: Improving Global Outcomes.

---

**Epidemiology**

Incidence varies widely, depending on the population studied and the definition of AKI used, e.g.:

- Community-acquired AKI on admission to hospital affects approximately 5% in the UK (superimposed on CKD in half of these patients).
- Severe AKI (creatinine >500 µmol/L, often requiring dialysis) affects about 130–140 per million population per year.
- About 25% of patients with sepsis and 50% of patients with septic shock will have AKI.

Outcomes vary: uncomplicated AKI carries a good prognosis, with mortality rates <5–10%. In contrast, AKI complicating non-renal organ system failure (in the intensive treatment unit (ITU) setting) is associated with mortality rates of 50–70%, which have not changed for
several decades. Sepsis-related AKI has a significantly worse prognosis than AKI in the absence of sepsis.

Clinical approach to the patient with AKI

Pre-renal AKI

Falling renal blood flow leads to a falling GFR. This might be due either to changes in the circulation, or to intrarenal vasomotor changes that drop glomerular perfusion pressures. Common causes of a falling effective circulating volume include (Box 20.28):

- hypovolaemia of any cause, including dehydration or haemorrhage
- hypotension without hypovolaemia, including cirrhosis or septic shock
- low cardiac output, including cardiac failure or cardiogenic shock
- combinations of the above.

Box 20.28

Causes of hypovolaemia

- Dehydration
- Reduced intake (nil by mouth, confusion)
- Gut losses (vomiting, nasogastric tube losses, diarrhoea)
- Renal losses (diuretics, hyperglycaemia)
- Burns, sweating
- Haemorrhage
- Third space losses (pancreatitis, peritonitis, bowel obstruction)
- Systemic vasodilatation (septic shock, cirrhosis)
- Cardiac failure or shock (myocardial infarction, arrhythmias, cardiomyopathy, tamponade)

Common intra-renal causes include:

- NSAIDs, ACE inhibitors (Fig 20.44), amphotericin B and calcineurin inhibitors, often in the context of added changes in renal blood flow.
Usually, the kidney maintains glomerular filtration close to normal, despite wide variations in renal perfusion pressure and volume status – so-called ‘autoregulation’ (prostaglandins, nitric oxide and angiotensin acting on afferent and efferent arterioles). Once autoregulation fails, GFR drops and AKI develops. Over time, reduced blood flow may lead to established parenchymal injury, but if renal perfusion is corrected early, AKI will resolve fully.

A few simple biochemical measures have long been used to prove pre-renal AKI (Box 20.29). Urine specific gravity or osmolality will rise, as solutes are concentrated into smaller urine volumes (the kidney is retaining fluid to improve renal blood flow). Urine sodium will be low, as salt is retained for the same reason. The fractional excretion of sodium ($FE_{Na}$) is a more reliable measure of sodium retention. None of these measures is reliable on its own and laboratory tests are no substitute for clinical assessment (Box 20.30).

### Box 20.30
Management of pre-renal AKI

This largely depends on the underlying cause. Most cases of AKI have an element of hypovolaemia, so prompt fluid resuscitation is most often indicated. When there is uncertainty as to the volume status of a patient, a fluid challenge of 250 mL crystalloid will often prove whether hypotension is fluid-responsive. Heart rate, blood pressure and urine output will all guide response to resuscitation. For cardiogenic shock and septic shock, see pages 1154 and 1150–1161, respectively.

Post-renal AKI

Obstruction of the urinary tract may occur at any point from the calyces to the external urethral orifice but commonly takes the form of bladder outflow obstruction (prostate disease in men) or bilateral ureteric obstruction (stones or tumours). The causes and presentation of urinary tract obstruction are dealt with on pages 758–761. Almost every case of unexplained AKI should result in an ultrasound to exclude obstruction, as, once this is relieved (and if acute), renal function will return to baseline.

Renal parenchymal AKI

This is most commonly (80–90%) due to acute tubular necrosis (ATN; see below and Box 20.31). Almost any cause of pre-renal AKI, if prolonged to the point at which renal autoregulation fails (see above), will lead to ischaemic ATN. If not ischaemic, then ATN usually results from direct tubular toxins (Box 20.31). As a result, ATN is common in hospital practice. Other causes of parenchymal AKI include:

• Disease affecting the intrarenal arteries and arterioles, as well as glomerular capillaries, such as vasculitis (see pp. 744–745), accelerated hypertension, cholesterol embolism, haemolytic uraemic syndrome, thrombotic thrombocytopenic purpura (TTP), pre-eclampsia and crescentic glomerulonephritis.

• Acute tubulointerstitial nephritis (see pp. 767–768). This also occurs when renal tubules are acutely obstructed by crystals, e.g. after rapid lysis of certain malignant tumours following chemotherapy (acute hyperuricaemic nephropathy).

• Acute bilateral suppurative pyelonephritis or pyelonephritis of a single kidney, which can
cause acute uraemia.

---

**Box 20.31**

**Some causes of acute tubular necrosis**

- Haemorrhage
- Burns
- Diarrhoea and vomiting, fluid loss from fistulae
- Pancreatitis
- Diuretics
- Myocardial infarction
- Congestive cardiac failure
- Endotoxic shock
- Snake bite
- Myoglobinemia
- Haemoglobinemia (due to haemolysis, e.g. in falciparum malaria, ‘blackwater fever’)
- Hepatorenal syndrome
- Radiological contrast agents (see p. 774)
- Drugs, e.g. aminoglycosides, non-steroidal anti-inflammatory drugs, angiotensin-converting enzyme inhibitors, platinum derivatives
- Abruptio placentae
- Pre-eclampsia and eclampsia

---

**Acute tubular necrosis**

Acute tubular necrosis (ATN) **(Box 20.31)** occurs due to:

- sustained under-perfusion and reduced renal blood flow of renal tubules leads to tubular cell death (hence the name), or

- nephrotoxins causing direct injury and cell death in renal tubules.

Factors involved in the development of ATN include:

- **Intrarenal microvascular vasoconstriction with falling delivery of O₂ and increasing tubular hypoxia:**
  
  - vasoconstriction in response to endothelin, adenosine, thromboxane A₂, leukotrienes and sympathetic nerve activity
  
  - impaired vasodilatation due to reduced sensitivity to nitric oxide, prostaglandins (PGE₂), acetylcholine and bradykinin
• **Increased endothelial and vascular smooth muscle cell structural damage:**
  – increased leucocyte–endothelial adhesion, vascular congestion and obstruction, leucocyte activation and inflammation.

• **Tubular cell injury.** Ischaemic injury results in rapid depletion of intracellular ATP stores resulting in cell death either by necrosis or apoptosis, with:
  – increased cytosolic cell calcium concentration
  – induction of nitric oxide synthases with increased production of nitric oxide, causing cell death
  – increased production of intracellular proteases such as calpain, which cause proteolysis of cytoskeletal proteins and cell wall collapse
  – tubular obstruction by desquamated viable or necrotic cells and casts
  – loss of cell polarity, i.e. integrins located on the basolateral side of the cell are translocated to the apical surface, which, when combined with other desquamated cells, forms casts, with tubular obstruction and back-leak of tubular fluid.

• **Tubular cellular recovery.** Tubular cells have the capacity to regenerate rapidly and to reform the disrupted tubular basement membrane, which explains the reversibility of ATN. Multiple growth factors, including insulin-like growth factor 1, epidermal growth factor and hepatocyte growth factor, and their receptors are upregulated during the regenerative process after injury.

  Once established, renal blood flow is much reduced in ATN, particularly blood flow to the renal cortex. Ischaemic tubular damage contributes to a reduction in glomerular filtration as glomeruli contract through afferent arteriolar spasm, filtrate leaks back towards the glomerulus, and tubular obstruction evolves (Fig. 20.45).

**FIGURE 20.45** Acute tubular necrosis. Effacement and loss of the proximal tubule brush border, patchy loss of tubular cells and focal areas of proximal tubule dilatation (arrow).

Oliguria is common in the early stages; non-oliguric AKI is usually the result of a less severe renal insult. Recovery of renal function typically occurs after 7–21 days, although recovery is delayed by continuing sepsis. The use of intravenous mannitol, furosemide or ‘renal-dose’ dopamine is not supported by controlled trial evidence, and none of these treatments is without risk.
Clinical features of AKI

**Symptoms** of uraemia, such as anorexia, nausea, vomiting and pruritus, develop, followed by intellectual clouding, drowsiness, fits, coma and haemorrhagic episodes. Epistaxis and gastrointestinal haemorrhage are relatively common. **Signs** of the underlying insult are often obvious and infection, in particular, must be sought and excluded. Severe infection may have initiated AKI or have complicated it, owing to impaired immune defences in uraemic patients, or insertion and retention of an unnecessary bladder catheter with complicating UTI and bacteraemia.

- **Hyperkalaemia** is common, particularly with sepsis or muscle trauma.
- **Metabolic acidosis** is usual, unless hydrogen ion loss by vomiting or aspiration of gastric contents is a feature.
- **Hyponatraemia** may be present owing to water overload if patients have continued to drink in the face of oliguria, or if over-enthusiastic fluid replacement with 5% glucose has been carried out.
- **Pulmonary oedema** owing to salt and water retention is not uncommon, particularly after inappropriate attempts to initiate a diuresis by infusion of crystalloid without adequate monitoring of the patient's volume status.

Investigation of AKI

Emergency investigation

The aim is to define the AKI syndrome – pre-renal, renal or post-renal – and decide if the deterioration in function is all acute or acute-on-chronic kidney disease.

**Pre-renal, renal or post-renal AKI?**

Pre-renal AKI is diagnosed largely on clinical examination, and assessing the volume status is vital; it can be difficult to distinguish pre-renal and renal AKI (particularly since prolonged renal hypoperfusion will lead to ATN). Bladder outflow obstruction is ruled out by clinical examination (a large palpable bladder suggests longstanding outflow obstruction), after inserting a urethral catheter (or flushing of an existing catheter) and draining large urine volumes, or on ultrasound of the kidneys and bladder. Absence of upper tract dilatation on renal ultrasonography will, with very rare exceptions, rule out urinary tract obstruction.

**Other investigations** are as follows:

- Urinalysis, urine microscopy, particularly for red cells and red-cell casts (indicative of glomerulonephritis), and urine culture. Urine should be tested for free haemoglobin and myoglobin, where appropriate. Urine protein : creatinine ratio is helpful if parenchymal disease is possible.
- In AKI, it takes 48–72 h before creatinine rises in the plasma; by that time, cell injury is well
established and irreversible. Urinary and plasma biomarkers (e.g. kidney injury molecule 1, neutrophil gelatinase-associated lipocalin) rise within few hours of AKI and may allow earlier treatment.

• Blood tests include measurement of serum urea, electrolytes, creatinine, calcium, phosphate, albumin, alkaline phosphatase and urate concentrations, as well as a full blood count and examination of the peripheral blood film where necessary. Coagulation studies, blood cultures and measurements of nephrotoxic drug blood levels should be carried out.

**Acute or chronic uraemia?**

The distinction between AKI and longstanding CKD depends on the history and duration of symptoms (a long history of nocturia suggests progressive tubular failure). Previous urinalysis or measurement of renal function is often vital in understanding the length of renal injury. Rapid changes in creatinine or GFR over days or weeks suggest an acute process.

Ultrasound is key; renal size (measured as the pole-to-pole length) and reflectivity (or echogenicity) are helpful, as small, scarred (increased echogenicity) kidneys suggest a longstanding process. The reverse is not true; the kidney may remain normal in size in diabetes and amyloidosis, for instance.

An anaemia of chronic disorder, hyperparathyroidism or renal osteodystrophy also suggests CKD.

**Management of AKI**

Early specialist review is advisable. Often unwell, patients with AKI should be monitored in a high-dependency setting.

**General measures**

Good nursing, infection control and physiotherapy are vital. Fluid balance, as intake and output (particularly urine output), will be key to recovery. Daily measurements of weight, lying and standing blood pressure, medication review to withhold nephrotoxins, collateral history and past results will all form part of the management plan.

Specific issues are described below.

**Hyperkalaemia**

This may be life-threatening, leading to cardiac dysrhythmias, particularly ventricular fibrillation. Treatment is outlined in *Box 9.18*.

Intravenous sodium bicarbonate reduces potassium as it corrects acidosis but should not be used in volume-overloaded patients, as the sodium content may trigger or exacerbate pulmonary oedema. Rapid correction of acidosis in a hypocalcaemic patient may also trigger tetany (the ionized calcium fraction falls as albumin binding increases with a normalizing pH). Ion exchange resins can be used to prevent chronic hyperkalaemia, but in many patients, hyperkalaemia will be controlled only by dialysis or haemofiltration.
Pulmonary oedema
Unless a diuresis can be induced with intravenous furosemide, dialysis or haemofiltration will be required.

Sepsis
Infection needs to be treated promptly, avoiding nephrotoxic antibiotics. Use of prophylactic antibiotics or barrier nursing is not usually recommended.

Use of drugs
Nephrotoxins must be avoided and all drug dosing requires thought; GFR may be changing on a day-by-day basis and dose modification needs to follow. There is a particular risk with anticoagulants (oral and heparins; see p. 579).

Fluid and electrolyte balance
Twice-daily clinical assessment is needed. In general, once the patient is euvoalaemic, daily fluid intake should equal urine output plus losses from the gut (including nasogastric loss) plus an allowance of 500 mL daily for insensible loss. Febrile patients will require an additional allowance.

Replacement fluid may be a balanced replacement solution, 0.9% saline (e.g. burns, pancreatitis) or colloids such as 4% albumin. There are no significant differences between them with respect to death rates, organ failure, the need for renal replacement therapy (RRT) or the duration of hospitalization.

Large-volume fluid infusion or changes in daily weight (reflecting changes in fluid balance) make more regular review necessary. When overload is present, loop diuretics may be useful. Non-oliguric patients with AKI fare better than oliguric patients. However, conversion of oliguria to non-oliguria has not been shown to decrease mortality, and diuretics have not been demonstrated to prevent AKI or improve outcomes.

Nutrition
Salt and potassium should be restricted. Protein intake is sometimes limited to approximately 40 g daily (0.5 g/kg/day) to avoid the need for RRT, but this poses the risk of a negative nitrogen balance. Patients on RRT are managed on a 70 g protein (and not >1.5 g/kg/day) diet, with hypercatabolic individuals requiring a greater nitrogen intake. Ideally, nutrition should be by mouth or nasogastric tube, or, as a last resort, by parenteral feeding (with sustained bowel dysfunction >14 days).

Renal replacement therapy – haemodialysis and haemofiltration
The main indications for blood purification and/or fluid removal are:
• symptomatic uraemia (including pericarditis or tamponade)
• hyperkalaemia not controlled by conservative measures
• pulmonary oedema unresponsive to diuresis
• severe acidosis
• for removal of drugs causing the AKI, e.g. gentamicin, lithium, severe aspirin overdose.

Contemporary RRT options include intermittent haemodialysis or haemodiafiltration (HDF), continuous venovenous haemofiltration (CVVHF) or peritoneal dialysis. It is not clear when to start RRT; there is some evidence that early initiation (urea <27 mmol/L) may be associated with better outcomes.

There are no data to favour haemodialysis or CVVHF as a superior mode of therapy in AKI. However, there is a consensus that in haemodynamically unstable patients, particularly those on the ITU, continuous treatments like CVVHF are more widely used for systemically unwell patients with AKI. Fluids (including nutrition, blood products or antibiotics) can be administered as volume is ultrafiltered off, preventing swings in volume and delivering more cardiovascular stability. More RRT is not necessarily better; two large trials have failed to show a survival benefit with augmented doses of RRT in critically ill patients.

Haemodialysis is explained on pages 783–784. CVVHF achieves blood flow using a blood pump to draw and return blood (hence, venovenous) from the lumen of a dual-lumen catheter placed in the jugular, subclavian or femoral vein. Ultrafiltrate (plasma in this case) is continually removed from the patient, usually at rates of up to 1000 mL/h, combined with simultaneous infusion of replacement solution. For instance, in a fluid-overloaded patient, one might remove filtrate at 1000 mL/h and replace at a rate of 900 mL/h, achieving a net fluid removal of 100 mL/h.

Peritoneal dialysis is used infrequently in the management of AKI. Peritoneal dialysis has low efficiency in AKI (removing solutes slowly and less completely), and is not appropriate for patients with intra-abdominal causes or complications of their AKI. Increasing intra-abdominal pressure as peritoneal dialysis fluid is instilled can compromise lung function as well.

Management of the recovery phase
Usually, after 1–3 weeks, renal function improves, with an increase in urine output and better kidney function. Dialysis or haemofiltration, if it has been required, can be discontinued. A characteristic recovery phase, with a large-volume diuresis, develops as GFR recovers ahead of renal tubular reabsorptive capacity for sodium, potassium and water. Intravenous fluids are often needed to support patients, with replacement sodium chloride and potassium. Typically, the diuretic phase lasts for only a few days.

Other causes of AKI

Rhabdomyolysis
Rhabdomyolysis, or ‘crush syndrome’, occurs when skeletal muscle injury provokes the release of intracellular myoglobin, a direct tubular toxin leading to ATN. Causes include
trauma, compartment syndrome, excessive exertion (marathon runners), status epilepticus and muscle toxins (statins, malaria and antimalarials, and snake and insect venom). Rapid rises in potassium, phosphate and lactate accompany elevated muscle enzymes (aspartate aminotransferase (AST)); characteristically, creatine phosphokinase (CK) is massively elevated. Early and vigorous fluid resuscitation is vital (injured muscle sequesters large amounts of fluid, causing hypovolaemic shock). Inflamed, injured muscle may become ischaemic in compartments, and a careful examination for typical ‘woody-hard’ muscle compartments may suggest a need for fasciotomies to release at-risk muscle. Sodium bicarbonate used to alkalinate the urine may limit myoglobin-induced injury.

A similar syndrome can arise with massive haemolysis, where the tubular toxin is haemoglobin rather than myoglobin. As cell breakdown is on a far smaller scale, the biochemical derangements seen with muscle injury may be absent.

### Acute cortical necrosis

Renal hypoperfusion results in diversion of blood flow from the cortex to the medulla, with a drop in GFR. Medullary ischaemic damage is largely reversible because tubular cells have the capacity for regeneration. In contrast, glomerular ischaemic injury does not heal with regeneration but with scarring – glomerulosclerosis. Prolonged cortical ischaemia may lead to irreversible loss of renal function termed ‘cortical necrosis’. This may be patchy or complete. Any cause of ATN, if sufficiently severe or prolonged, may lead to cortical necrosis. Cortical necrosis occurs more commonly where the vasculature and endothelium have been damaged (with or without coagulopathy), such as haemolytic uraemic syndrome and with complications of pregnancy.

### Contrast nephropathy

In patients with impaired renal function, iodinated radiological contrast media may be nephrotoxic, possibly by causing renal vasoconstriction and by exerting a direct toxic effect on renal tubules. The effect is dose-dependent and more commonly seen in procedures that require large amounts of contrast, such as angiography with or without angioplasty. In many patients, the effect is mild, transient and fully reversible. However, it is not benign; even a transient elevation of creatinine following contrast administration is associated with long-term consequences (an increased risk of cardiac events, ESKD and mortality). Risk factors include:

- associated hypovolaemia
- more advanced CKD
- cardiac failure
- diabetic nephropathy
- nephrotoxins (ACE inhibitors and NSAIDs in particular).

Diabetes per se is not a risk factor. However, metformin can precipitate a lactic acidosis
and should be stopped if creatinine is >130 µmol/L and not restarted until renal function returns to the baseline level.

Prevention is key: minimize the dose of contrast administered, use an iso-osmolar or low-osmolality contrast medium, and ensure patients are pre-hydrated with 1 L of 0.9% saline or 1 L of sodium bicarbonate 1.4% peri-procedure and up to 8–12 h post-procedure, avoiding volume overload in susceptible patients. A recently completed trial confirmed that fluid administration guided by left end-diastolic pressure was safe and more effective in the prevention of contrast-induced AKI among high-risk patients undergoing cardiac catheterization.

N-acetylcysteine (a potent antioxidant) given 48 h prior to radiological intervention may be of borderline benefit at best. Dopamine, theophylline (an adenosine antagonist) and prophylactic haemodialysis (removing contrast agent from the circulation) are of no benefit.

## Acute phosphate nephropathy

Administration of oral sodium phosphate solution as bowel preparation for gastrointestinal investigations is a cause of AKI. Oral phosphate solution is contraindicated in patients with CKD, congestive heart failure, gastrointestinal obstruction, and pre-existing electrolyte disorders like hypercalcaemia. Renal biopsy shows abundant calcium phosphate deposits. Treatment is usually supportive and dialysis is carried out if necessary, with good renal recovery.

## Tumour lysis syndrome

Tumour lysis syndrome (TLS; see p. 606) complicates the first treatment of lymphoproliferative tumours; it can occur spontaneously, and can be found with other cancers. Chemotherapy (or even steroids), causing rapid death of malignant cells, sees the release of intracellular and membrane products, including uric acid, potassium and phosphate. A high filtered uric acid load leads to an obstructive crystal uropathy; serum urate may be 4- or 5-fold the upper limit of normal. The danger is hyperkalaemia; at-risk patients should be pre-hydrated to maintain a good urine output (allowing large urinary potassium losses), and xanthine oxidase inhibitors such as allopurinol may prevent uric acid formation. Rasburicase, a recombinant urase oxidase that does not occur in primates, oxidizes uric acid to soluble allantoin; urate levels can be undetectable after administration.

## Hepatorenal syndrome

The renal failure observed in hepatorenal syndrome (HRS) results from profound renal vasoconstriction with histologically normal kidneys (see p. 475). HRS only occurs once portal hypertension and ascites have complicated liver disease. Patients are not hypovolaemic, and renal recovery is usually observed after successful liver transplantation.
Chronic Kidney Disease

The term ‘chronic kidney disease’ (CKD) has replaced terms like chronic renal failure or insufficiency. CKD is a descriptive term and is used for deteriorating kidney function of any underlying cause. CKD implies longstanding (>3 months), potentially progressive, impairment in renal function. However, in most cases of stage 1–3 CKD, kidney function does not continue to decline over time, and patients do not die as a direct result of kidney disease.

In many cases, there is no effective means to reverse the underlying disease process. There are exceptions where reversal is likely:

• relief of urinary tract obstruction
• immunosuppressive therapy for glomerulonephritis or systemic vasculitis
• treatment of accelerated hypertension
• correction of critical narrowing of renal arteries.

In many other cases of CKD, even if the underlying diagnosis cannot be fully treated, the rate of deterioration in renal function can be slowed (see p. 782). A list of causes of CKD is given in Box 20.32.

Box 20.32

Causes of chronic kidney disease

Congenital and inherited disease

• Polycystic kidney disease (adult and infantile forms)
• Medullary cystic disease
• Tuberous sclerosis
• Oxalosis
• Cystinosis
• Congenital obstructive uropathy

Glomerular disease

Primary glomerulonephritides

• Including focal glomerulosclerosis
Secondary glomerular disease

- (Systemic lupus, polyangiitis, granulomatosis with polyangiitis, amyloidosis, diabetic glomerulosclerosis, accelerated hypertension, haemolytic uraemic syndrome, thrombotic thrombocytopenic purpura, systemic sclerosis, sickle cell disease)

Vascular disease

- Hypertensive nephrosclerosis (common in black Africans)
- Renovascular disease
- Small- and medium-sized-vessel vasculitis

Tubulointerstitial disease

- Tubulointerstitial nephritis – idiopathic, due to drugs (especially nephrotoxic analgesics), immunologically mediated
- Reflux nephropathy
- Tuberculosis
- Schistosomiasis
- Nephrocalcinosis
- Multiple myeloma (myeloma kidney)
- Balkan nephropathy
- Renal papillary necrosis (diabetes, sickle cell disease and trait, analgesic nephropathy)
- Chinese herb nephropathy

Urinary tract obstruction

- Calculus disease
- Prostatic disease
- Pelvic tumours
- Retroperitoneal fibrosis
- Schistosomiasis

Staging and prevalence

CKD is staged according to the National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (K/DOQI), and endorsed by International Kidney Disease: Improving Global Outcomes (KDIGO). Staging is intended to reflect patient prognosis and outcomes (Fig. 20.46). Using this MDRD-GFR-based system (see p. 727), high prevalences of CKD are now found in population-based surveys, particularly in elderly patients (Box 20.33).
There is increasing complexity in staging:

- Stage 3 CKD may be divided into two stages, to recognize the increased disease and cardiovascular complications seen with more advanced stage 3 CKD.
- It has been advocated that cystatin C (see pp. 726–727), a more accurate marker of GFR, be used in patients with stage 3 CKD to stratify risk better in this group.
- Some bodies recommend adding measured proteinuria to the staging system, by adding the suffix ‘p’ to any stage if a urine protein:creatinine ratio (PCR) of >45 mg/mmol (see p. 730) or albumin:creatinine ratio (ACR) of >30 mg/mmol is found – so proteinuric kidney disease with a GFR of 42 mL/min would be classed as stage 3Bp. By adding proteinuria into the classification, a more at-risk population is identified.
- Confusingly, people with stage 2 CKD are not thought to have a disease unless they have...
other evidence of kidney damage; this might include haematuria, proteinuria, structurally abnormal kidneys, inherited kidney diseases or biopsy changes consistent with kidney disease.

Between 6% and 11% of people can be defined as having CKD, diagnosis becoming more likely as people live longer. There is wide geographical variation in the incidence, prevalence and causes of CKD across the globe. For instance, the most common cause of glomerulonephritis in sub-Saharan Africa is malaria. Schistosomiasis is a common cause of CKD due to urinary tract obstruction in parts of the Middle East, including southern Iraq.

The incidence of ESKD varies between ethnic groups, being 3–4 times as common in black Africans in the UK and USA as it is in whites, and hypertensive nephropathy is a much more frequent cause of ESKD in this group. The prevalence of diabetes mellitus, and hence of diabetic nephropathy, is higher in some Asian groups than in whites. Age is also of relevance; CKD due to atherosclerotic renal vascular disease is much more common in the elderly than in the young. Over 70% of all cases with CKD are due to diabetes mellitus, hypertension and atherosclerosis.

Progression

CKD tends to progress to ESKD, although the rate of progression may be slow. The speed of decline tends to depend on the underlying nephropathy and on control of blood pressure. Patients with chronic glomerular diseases tend to deteriorate more quickly than those with chronic tubulointerstitial nephropathies. Regardless of cause, there may be common pathways to progression in CKD:

• Each kidney has roughly a million nephrons. In CKD, where many nephrons have failed, and scarred, the burden of filtration falls to fewer functioning nephrons.
• Functioning (‘remnant’) nephrons experience increased flow per nephron (hyperfiltration), as renal blood flow has not changed, and adapt with glomerular hypertrophy and reduced arteriolar resistance.
• Increased flow, increased pressure and increased shear stress set in motion a vicious circle of raised intraglomerular capillary pressure and strain, which accelerates remnant nephron failure.
• Increased flow and strain may be detected as new or increasing proteinuria.

Angiotensin II produced locally modulates intraglomerular capillary pressure and GFR, causing vasoconstriction of postglomerular arterioles, and increasing the glomerular hydraulic pressure and filtration fraction (see Fig. 20.44). In addition, by its effect on mesangial cells and podocytes, it increases the pore sizes and impairs the size-selective function of basement membrane for macromolecules.

Angiotensin II also modulates cell growth directly and indirectly by upregulating transforming growth factor-beta (TGF-β), a potent fibrogenic cytokine, increasing collagen synthesis and epithelial cell transdifferentiation to myofibroblasts that contribute to excessive matrix formation. Angiotensin II also upregulates plasminogen activator inhibitor-1 (PAI-1),
which inhibits matrix proteolysis by plasmin, with accumulation of excessive matrix and scarring in both the glomeruli and interstitium.

Proteinuria itself may be harmful in the tubulointerstitium. Albumin, in disease, may appear in the urinary space carrying bound fatty acids, growth factors and cytokines. When reabsorbed in the proximal tubule and degraded, these carried molecules may themselves then cause proximal tubular cell activation and interstitial scarring.

The prognosis of CKD correlates with:

• hypertension, particularly if poorly controlled
• proteinuria
• on histology, the degree of scarring in the interstitium (but not the changes seen in glomeruli).

Therapy (see Box 20.9) aimed at inhibiting angiotensin II and reducing proteinuria mainly with ACE inhibitors or angiotensin-receptor antagonists offers benefit in slowing the rate of progression of CKD in both diabetic and non-diabetic renal diseases in humans.
Clinical approach to the patient with CKD and renal disease

**History**

- **Duration of symptoms.**
- **Drug ingestion**, including NSAIDs, analgesic and other medications, and unorthodox treatments such as herbal remedies.
- **Previous medical and surgical history**, e.g. previous chemotherapy, multisystem diseases such as SLE, malaria.
- **Previous occasions on which urinalysis or measurement of urea and creatinine might have been performed**, e.g. pre-employment or insurance medical examinations, new patient checks.
- **Family history of renal disease.**

**Clinical features**

The kidneys have a great deal of reserve; as a result, the early stages of CKD are often completely asymptomatic, even as renally cleared metabolites begin to accumulate. It is not clear which metabolites lead to specific symptoms, but they are thought to be products of protein catabolism (nitrogenous waste products). These metabolites, also called uraemic toxins, must be of relatively small molecular size (since haemodialysis, which clears only relatively small molecules, improves symptoms). Little else is known with certainty.

Serum urea and creatinine concentrations are measured in CKD as surrogates of accumulating metabolites (uraemic toxins) because their measurement is easy, and there is a rough correlation between urea and creatinine concentrations and symptoms. These substances are not, however, particularly toxic in themselves.

Symptoms are common when the serum urea concentration exceeds 40 mmol/L but many patients develop uraemic symptoms at lower levels of serum urea. Symptoms include:

- malaise, loss of energy
- loss of appetite, loss of weight
- insomnia
- nocturia and polyuria due to impaired concentrating ability
- itching
- nausea, vomiting and diarrhoea
- paraesthesiae due to polyneuropathy
- ‘restless legs’ syndrome (the overwhelming need to alter the position of the lower limbs
frequently)
• bone pain due to metabolic bone disease
• paraesthesiae and tetany due to hypocalcaemia
• symptoms due to salt and water retention – peripheral or pulmonary oedema
• symptoms due to anaemia
• amenorrhoea in women; erectile dysfunction in men.

In more advanced uraemia CKD stage 5, these symptoms become more severe and central nervous system symptoms are common:
• mental slowing, clouding of consciousness and seizures
• myoclonic twitching.

Urine volume is not a good symptom of advancing CKD. Oliguria is a powerful symptom of sudden kidney injury, but slowly progressive kidney disease can see urine volume actually increase, as failing tubular function leads to a salt- and water-wasting state. As concentrating ability in the tubules fails, urine volume increases through day and night, and so polyuria and nocturia are useful symptoms to suggest the length of time for which CKD has been present.

**Examination**

There are few physical signs specific to uraemia. Findings include short stature (in patients who have had CKD in childhood); pallor (due to anaemia); increased photosensitive pigmentation (which may make the patient look misleadingly healthy); brown discoloration of the nails; scratch marks due to uraemic pruritus; signs of fluid overload (see p. 773); pericardial friction rub; flow murmurs (mitral regurgitation due to mitral annular calcification; aortic and pulmonary regurgitant murmurs due to volume overload); and glove and stocking peripheral sensory loss (rare).

The kidneys themselves are usually impalpable unless grossly enlarged as a result of polycystic disease, obstruction or tumour. Rectal and vaginal examination may disclose evidence of an underlying cause of CKD, particularly urinary obstruction, and should always be performed.

In addition to these findings, there may be physical signs of any underlying disease that may have caused the CKD, for instance:
• cutaneous vasculitic lesions in systemic vasculitides
• retinopathy in diabetes and hypertensive retinopathy in hypertension
• evidence of peripheral vascular disease and associated renal artery stenosis
• evidence of spina bifida or other causes of neurogenic bladder.

An assessment of the central venous pressure, skin turgor, blood pressure both lying and standing and peripheral circulation should also be made. The major symptoms and signs of CKD are shown in **Figure 20.47**.
Investigations

The following investigations are common to all renal patients. This includes individuals with glomerular or non-glomerular disease, renal involvement in systemic diseases, AKI and CKD, as renal symptoms and signs are non-specific.

Urinalysis

- **Haematuria** may indicate glomerulonephritis but other sources must be excluded. Haematuria should not be assumed to be due to the presence of an indwelling catheter.

- **Proteinuria**, if heavy, is strongly suggestive of glomerular disease. Urinary infection may also cause proteinuria. **Glycosuria** with normal blood glucose is common in CKD.

- **Leucocytes or nitrites**, if present, might suggest infection.

Urine microscopy

(See pp. 729–730.)

- **White cells** in the urine usually indicate active bacterial urinary infection but this is an uncommon cause of CKD; sterile pyuria suggests papillary necrosis or renal tuberculosis.
• **Eosinophiluria** is strongly suggestive of allergic tubulointerstitial nephritis or cholesterol emboli.

• **Granular casts** are formed from abnormal cells within the tubular lumen and indicate active renal disease. **Red-cell casts** are highly suggestive of glomerulonephritis.

• **Red cells in the urine** may be from anywhere between the glomerulus and the urethral meatus (see *Fig. 20.7*).

**Urine biochemistry**

• **Proteinuria** is a key finding, and urine PCR or ACR should be performed on an early morning sample (see p. 730).

• **Urinary electrolytes** are unhelpful in CKD. The use of urinary sodium concentration in the distinction between pre-renal and intrinsic renal disease is discussed on pages 770–771.

• **Urine osmolality** is a measure of concentrating ability. A low urine osmolality is normal in the presence of a high fluid intake but indicates renal disease when the kidney should be concentrating urine, such as in hypovolaemia or hypotension.

• **Urine electrophoresis and immunofixation** is necessary for the detection of light chains, which can be present in myeloma without a detectable serum paraprotein.

**Serum biochemistry**

• **Urea, electrolytes, bicarbonate and creatinine** are measured.

• **Calculation of eGFR** is performed.

• **Electrophoresis and immunofixation** are carried out, and **free light chains** for myeloma.

• **Elevations of creatine kinase and a disproportionate elevation in serum creatinine and potassium** compared with urea suggest rhabdomyolysis.

• **Blood glucose and HbA1C** estimate chronic diabetic control.

**Haematology**

• **Eosinophilia** suggests vasculitis, allergic tubulointerstitial nephritis or cholesterol embolism.

• **Markedly raised viscosity** or ESR suggests myeloma or vasculitis.

• **Fragmented red cells and/or thrombocytopenia** suggest intravascular haemolysis due to accelerated hypertension, haemolytic uraemic syndrome or thrombotic thrombocytopenic purpura.

• **Tests for sickle cell disease** should be performed when relevant.

**Immunology**

• **Complement components** may be low in active renal disease due to SLE, mesangiocapillary glomerulonephritis, post-streptococcal glomerulonephritis, and cryoglobulinaemia.

• **Autoantibody screening** is useful in detection of SLE (see pp. 692–695), scleroderma (p.
granulomatosis with polyangiitis and microscopic polyangiitis (p. 1121), and Goodpasture syndrome (p. 1121).

- **Cryoglobulins** are measured in unexplained glomerular disease, particularly mesangiocapillary glomerulonephritis.

- **Antibodies to streptococcal antigens** (antistreptolysin O titre (ASOT), anti-DNAse B) are sought if post-streptococcal glomerulonephritis is possible.

- **Antibodies to hepatitis B and C** may point to polyarteritis or membranous nephropathy (hepatitis B) or to cryoglobulinaemic renal disease (hepatitis C).

- **Antibodies to HIV** raise the possibility of HIV-associated renal disease.

### Radiological investigation

- **Ultrasound** should be performed in every patient (to establish renal size and exclude hydronephrosis).

- **CT** is useful for the diagnosis of calculi, retroperitoneal fibrosis and some other causes of urinary obstruction, and may also demonstrate cortical scarring.

- **Magnetic resonance angiography** is carried out in renovascular disease.

### Renal biopsy

(See p. 732.) This should be performed in every person with unexplained CKD and normal-sized kidneys, unless there are strong contraindications. If rapidly progressive glomerulonephritis is possible, this investigation must be performed within 24 hours of presentation, if at all possible.

### Complications of CKD

#### Anaemia

Anaemia in CKD impairs quality of life and well-being. A normochromic, normocytic anaemia develops by a number of mechanisms:

- **Erythropoietin deficiency** – this is the most significant mechanism.

- **Increased blood loss** – there may be occult gastrointestinal bleeding, repeated blood sampling, blood loss during haemodialysis, or platelet dysfunction.

- **Bone marrow toxins** – these are retained in CKD, or there is fibrosis secondary to hyperparathyroidism.

- **Haematinic deficiency** – there may be decreased iron, vitamin B₁₂ or folate.

- **Increased red-cell destruction** – red cells have a shortened lifespan in uraemia, and haemodialysis itself may cause a degree of haemolysis.

- **ACE inhibitors** – these may cause anaemia in CKD, probably by interfering with the control of endogenous erythropoietin release.
Management

Synthetic (recombinant) human erythropoiesis stimulating agents (ESAs; epoetin-α or β, or the longer-acting darbepoetin-α) have transformed the management of renal anaemia. ESAs can be given subcutaneously or by intravenous injection, at a starting dose of 50 U/kg of epoetin-α three times weekly, or darbepoetin 30 µg weekly. Supplemental intravenous iron may promote a response to erythropoietin and can be given prior to starting ESAs. Haemoglobin is then measured every 2 weeks, and the dose adjusted to maintain a target haemoglobin of 100–120 g/L (see below). As hypertension can be a significant side-effect in 30% of patients new to ESAs, blood pressure should be monitored in the first 6 months, and treated if rising. Peripheral resistance increases in all patients, owing to loss of hypoxic vasodilatation and to an increase in blood viscosity. The rare complication of encephalopathy with fits, transient cortical blindness and hypertension can complicate treatment.

Targets and treatment are as follows:

• **Target haemoglobin** is between 100 and 120 g/L. Studies in pre-dialysis CKD patients have not shown any outcome benefits in patients who were treated to achieve higher haemoglobin targets (>120 g/L).

• Patients who **fail to respond** to 300 U/kg weekly of epoetin-α should be screened to exclude associated iron deficiency, bleeding, malignancy, infection, inflammation, or formation of anti-erythropoietin neutralizing antibodies.

• The increased demand for iron by the bone marrow is enormous when an ESA is started. Functional iron deficiency (poor mobilization of iron, despite adequate iron stores with ferritin >500 µg/L) is a common finding in patients with chronic inflammation. Hepcidin synthesis, as an acute phase reactant produced by the liver in response to cytokines (particularly IL-6), inhibits gastrointestinal iron absorption (see p. 524) and sequesters iron in the liver, preventing its release. Intravenous (rather than oral) iron supplements optimize the response to ESAs in CKD.

• Correcting anaemia with ESAs improves quality of life, exercise tolerance, and sexual and cognitive function in dialysis patients, and leads to regression of left ventricular hypertrophy. By avoiding blood transfusion, the risk is minimized of sensitization to HLA antigens, which may complicate future renal transplantation.

• Several reports of anti-erythropoietin antibody-mediated pure red-cell aplasia in patients receiving subcutaneous ESA therapy (particularly epoetin-α) have been described. Changes in the manufacturing process of the pre-filled syringes used to deliver ESAs have reduced the number of cases; the rubber stoppers interacted with the drug vehicle to act as an immunological adjuvant, stimulating anti-erythropoietin antibody production in hosts.

Several novel erythropoiesis-stimulating agents are in clinical trials. An engineered peptide that stimulates the erythropoietin receptor has been withdrawn because of anaphylaxis in a few patients. Oral agents that inhibit prolyl hydroxylase and prolong the life of hypoxia inducible factors (HIF) 1α, a transcription factor for endogenous production of erythropoietin, have
shown promise in phase 2 trials.

**CKD mineral and bone disorder**

Once called ‘renal osteodystrophy’ but now more appropriately described as a mineral and bone disorder, CKD-MBD describes:

- changes in calcium, phosphorus, PTH and vitamin D metabolism
- the various forms of bone disease that may develop alone or in combination in CKD
- the vascular consequences that accompany it.

Altered bone morphology might be described in CKD (*Fig. 20.48*) as:

- hyperparathyroid bone disease
- osteomalacia
- osteoporosis
- osteosclerosis
- adynamic bone disease.
Most patients with CKD are found on bone biopsy to have mixed bone disease. CKD-MBD is almost universal by late stage 3 CKD. Vascular calcification is common in CKD patients; it is speculated that vascular smooth muscle cells, modulated by uraemia and/or phosphate, differentiate to an osteoblast-like phenotype, able to synthesize and deposit matrix, which is then mineralized. Calcified vessel walls become increasingly stiff and non-compliant (leading to left ventricular hypertrophy over time), cardiac valves calcify, and soft-tissue calcium is deposited widely. There is an association between vascular calcification and mortality in CKD but a causal link has not yet been proved.

### Pathogenesis of CKD-MBD

**Phosphate excretion** falls in the very early stages of CKD. Retained phosphate then results in the release of fibroblast growth factor 23 (FGF23) and other phosphaturic agents by osteoblasts as a compensatory mechanism (see p. 171). FGF23 causes phosphaturia to bring the plasma phosphate level to within the normal range. FGF23 also downregulates renal 1α-
hydroxylase, reducing the action of activated vitamin D in increasing intestinal absorption of phosphate. Despite consistently elevated levels of FGF23, phosphate levels in blood will once again rise as CKD progresses. Elevated FGF23 levels are the strongest independent predictor of mortality in patients with CKD. This underscores the necessity of controlling phosphate levels during the very early stages of CKD.

As CKD progresses, **secondary hyperparathyroidism** develops:

- Decreased renal production of 1α-hydroxylase results in reduced conversion of 25-(OH)₂D₃ to the more metabolically active 1,25-(OH)₂D₃ (1,25-dihydroxycholecalciferol).
- 1,25-(OH)₂D₃ deficiency results in reduced gut calcium absorption and a fall in calcium.
- Reduced activation of vitamin D receptors in the parathyroid glands by 1,25-(OH)₂D₃ increases the release of PTH.
- Calcium-sensing receptors, expressed in the parathyroid glands, react rapidly to acute changes in extracellular calcium concentrations, and a low calcium triggers increased PTH release.
- Retained phosphate also indirectly lowers ionized calcium (and probably directly via a putative but unrecognized phosphate receptor), resulting in increased PTH synthesis and release.
- PTH promotes reabsorption of calcium from bone and increased proximal renal tubular reabsorption of calcium. This mechanism attempts to reverse the hypocalcaemia caused by 1,25-(OH)₂D₃ deficiency and phosphate retention.

This ‘secondary’ hyperparathyroidism leads to increased osteoclastic activity, cyst formation and bone marrow fibrosis (osteitis fibrosa cystica). The typical biochemical findings are hypocalcaemia, hyperphosphataemia, an elevated PTH and a raised serum alkaline phosphatase (as a marker of increased bone turnover). Radiologically, digital subperiosteal erosions and a ‘pepperpot skull’ are seen. Longstanding secondary hyperparathyroidism ultimately leads to hyperplasia of the glands with autonomous or **tertiary hyperparathyroidism**. PTH release now occurs independently of calcium or 1,25-(OH)₂D₃ control, and high turnover in bone leads to hypercalcaemia.

Longstanding hyperparathyroidism causes increased bone density (**osteosclerosis**), seen particularly in the spine, where alternating bands of sclerotic and porotic bone give rise to a characteristic ‘ruger jersey’ appearance on X-ray.

Deficiency of 1,25-(OH)₂D₃ and hypocalcaemia can also result in impaired mineralization of osteoid (**osteomalacia**).

‘**Adynamic bone disease**’ describes a state in which both bone formation and resorption are depressed and the skeleton becomes inert. Bone turnover is reduced, usually where there is over-treatment with active vitamin D, low PTH (after surgical parathyroidectomy), accumulation of aluminium used as a phosphate binder, or diabetes. There may be hypercalcaemia, particularly if calcium intake is high (excess calcium cannot be laid down in bone); the serum alkaline phosphatase is normal and the PTH is low. X-rays and dual X-ray
absorptiometry (DXA) scans show osteopenia. No treatment is of proven benefit.

**Osteoporosis** is commonly found in CKD, often after transplantation and the use of corticosteroids. Monitoring is with yearly DXA scanning.

### Management of CKD-MBD

The aim is to keep serum calcium and phosphate in the normal range as CKD progresses, and once dialysis is needed, to control PTH within 2- to 9-fold the upper limit of normal. This is to ensure that bone turnover continues and adynamic bone does not develop (see above). The less well-understood goal is to limit vascular calcification as well, by maintaining good bone health and avoiding calcium exposure.

Calcium, phosphate and PTH should be measured 3-monthly, and some would define the extent of vascular calcification (e.g. by X-ray of the lumbar spine or of the abdomen). Treatment and targets, then, aim to reduce phosphate (and preferably limit calcium load), and to control PTH and achieve a normal calcium.

### Reduction of phosphate and limiting of calcium load

- **Dietary restriction.** This is seldom effective alone because so many foods are phosphate-rich
- **Gut phosphate binders.** Sevelamer carbonate, lanthanum carbonate, calcium carbonate and calcium acetate all reduce phosphate absorption and serum phosphate levels when taken with meals. Sevelamer (unlike calcium-containing binders) attenuates vascular calcification and lowers cholesterol levels by 10%; it has not been shown to reduce mortality.
- **Aluminium-containing gut phosphate binders.** These are very effective but absorption of aluminium poses the risk of aluminium bone disease and development of cognitive impairment. They are rarely used in the developed countries but are still employed in developing countries because they are extremely cheap.
- **Nicotinamide.** An alternative to phosphate binders, nicotinamide blocks the intestinal sodium/inorganic phosphate (Na/Pi) co-transporter. It reduces phosphate levels and PTH levels alongside improvement in the lipid profile in dialysis patients.

### Control of PTH and achievement of normal calcium

- **Calcitriol (1,25-dihydroxycholecalciferol), vitamin D analogues** such as alfacalcidol, or novel vitamin D metabolites (22-oxacalcitriol, paricalcitol, doxercalciferol). These are given orally to suppress PTH once the level is three times or more above the upper limit of normal. Newer vitamin D analogues, such as paricalcitol (19-nor-1,25 dihydroxyvitamin D₃), may be less likely to lead to hypercalcaemia, but their usefulness over the conventional but less expensive calcitriol or alfacalcidol remains to be established.
- **Calcimimetic agents** (e.g. cinacalcet, a calcium-sensing receptor agonist; see p. 1237). These have also been tried in established secondary hyperparathyroidism with successful suppression of PTH levels and lowering of calcium × phosphate product. Calcimimetics act
by activating the calcium-sensing receptor, leading the parathyroid to respond as though serum calcium levels were high, reducing PTH synthesis and release. The long-term safety and efficacy of these agents have been confirmed; however, a recent controlled trial to assess potential survival benefits on treatment was non-conclusive.

**Calciphylaxis**

Also known as calcific uraemic arteriolopathy, this is a rare but serious life-threatening complication in CKD patients. It presents as painful skin patches, plaques and ulcers, with non-healing eschars, panniculitis and dermal necrosis. The characteristic feature on histology is vascular calcification and superimposed small-vessel thrombosis (Fig. 20.49). Risk factors include hyperparathyroidism, elevated serum phosphate, morbid obesity and warfarin use. Control of hyperparathyroidism is either with surgical intervention or with a calcimimetic agent, aiming to drop both calcium and phosphate to low–normal ranges. Despite treatment, subsequent infection escalates the risk, as patients are often already frail, and many die within a year of diagnosis.

**Cardiovascular disease**

CKD is a major risk factor for cardiovascular disease, and the greatly increased (16-fold) incidence of cardiovascular disease in CKD compared with the normal population has a significant impact on life expectancy. Sudden cardiac death, myocardial infarction, cardiac failure, stroke and peripheral vascular disease all occur in excess as GFR declines (and the presence of proteinuria adds further to this risk). Renal transplantation reverses the risk seen with stage 5 CKD.

**Risk factors**

- Hypertension (very common in CKD).
• Diabetes mellitus (the most common cause of CKD).
• Dyslipidaemia (universal in uraemic patients).
• Smoking – as common as in the general population.
• Male gender – over-represented in patients with CKD.

Also clustering with CKD, ventricular hypertrophy is common, as is systolic and diastolic dysfunction. Left ventricular hypertrophy is a risk factor for early death in CKD, as in the general population. Systolic dysfunction is also a marker for early death. Myocardial fibrosis, abnormal myocyte function, calcium overload and hyperparathyroidism, and carnitine and selenium deficiencies all contribute to the systolic dysfunction seen with the uraemic cardiomyopathy.

**Coronary artery and generalized vascular calcification**

Traditional risk factors (e.g. smoking, diabetes) only partly explain the increased cardiovascular risk in patients with CKD. Coronary artery calcification is more common in patients with ESKD than in normal individuals and it is likely that this contributes to cardiovascular mortality. Peripheral vessel calcification *increases vascular stiffness (reduced compliance)*, which manifests as increased pulse pressure, increased pulse wave velocity, and an increased afterload with advancing left ventricular hypertrophy. Risk factors related to calcification include the following:

• A *raised (calcium × phosphate) product* promotes calcification.

• **Hyperparathyroidism** increases intracellular calcium.

• **Uraemia leads to loss of constitutive inhibitors of calcification**, with vascular smooth muscle cells acquiring osteoblast-like characteristics.

• **Inflammation** further inhibits fetuin (a glycoprotein synthesized by liver, and a potent inhibitor of vascular calcification).

Plain abdominal X-ray (demonstrating ‘pipe-stem’ calcification of large arteries), electron beam or multislice CT of the coronaries, and vascular Doppler can all identify and quantify vascular calcification.

Risk factor modification is similar to that undertaken in patients without CKD, although clear evidence of benefit is less obvious.

**Other cardiovascular risk factors**

Hyperhomocysteinaemia, *Chlamydophila pneumoniae* infection, malnutrition, inflammation, insulin resistance, oxidative stress and elevated endogenous inhibitor of nitric oxide synthase and asymmetric dimethyl arginine (ADMA) all contribute to increased cardiovascular events. High ADMA levels in uraemia are caused, in part, by oxidative stress and can possibly explain the 52% increase in the risk of death and 34% increase in the risk of cardiovascular events in uraemic patients. The use of antioxidants, vitamin E or acetylcysteine has been associated with a significant reduction in all-cause and cardiovascular mortality. However, trials to reduce
levels of homocysteine with folic acid, B₆ and B₁₂ supplementation have been unsuccessful.

The conclusion from a study of heart and renal protection (SHARP) in over 9500 CKD patients was that around one-quarter of all heart attacks, strokes and revascularizations could be avoided in CKD by using a combination of ezetimibe and simvastatin to lower blood cholesterol. This combination did not, however, confer any survival advantage or prevent the development of ESKD.

**Pericarditis**
This is common and occurs in two clinical settings:

- Uraemic pericarditis is a feature of severe, pre-terminal uraemia or of under-dialysis. Haemorrhagic pericardial effusion and atrial arrhythmias are often associated. There is a danger of pericardial tamponade, and anticoagulants should be used with caution. Pericarditis usually resolves with intensive dialysis.
- Dialysis pericarditis occurs as a result of an intercurrent illness or surgery in a patient receiving apparently adequate dialysis.

**Skin disease**
Pruritus (itching) is common, and is caused by:

- accumulating nitrogenous waste products of protein catabolism (and itching improves following dialysis)
- hypercalcaemia and hyperphosphataemia
- an elevated calcium \( \times \) phosphate product
- hyperparathyroidism (even if calcium and phosphate levels are normal)
- iron deficiency.

In dialysis patients, inadequate dialysis is a treatable cause of pruritus. However, for many, the cause of itching is unknown and no effective treatment exists.

Many patients with CKD suffer from dry skin, for which simple aqueous creams are helpful. CKD may also cause porphyria cutanea tarda (PCT), a blistering, photosensitive skin rash. This results from a decrease in hepatic uroporphyrinogen decarboxylase combined with a decreased clearance of porphyrins in the urine or by dialysis. Pseudoporphyria, a condition similar to PCT but without enzyme deficiency, is also seen in CKD with increased frequency.

**Nephrogenic systemic fibrosis**
See *Box 20.34*.

---

**Box 20.34**

*Nephrogenic systemic fibrosis (NSF)*
NSF is a systemic fibrosing skin disorder seen only in patients with moderate to severe CKD (eGFR <30 mL/min), particularly those on dialysis. Gadolinium-containing contrast agents, which are excreted exclusively by the kidney, have been implicated in the causation of over 95% cases of NSF (see p. 1365).

The diagnosis is based on biopsy of an involved site, showing proliferation of dermal fibrocytes with excessive collagen deposition. Special testing may show gadolinium.

NSF is chronic and unremitting, with 30% having no improvement, 20% having modest improvement and 30% dying. No single or combination therapy offers benefit, except for improving renal function following transplantation. Prevention is key, so gadolinium-based contrast agents should be avoided in patients with eGFR <30 mL/min or those on dialysis.

### Gastrointestinal complications

Decreased gastric emptying, and an increased risk of reflux oesophagitis, gastritis and peptic ulceration are all common (hypergastrinaemia increases as GFR declines); gastrointestinal tract bleeding is more frequently seen as a result. Constipation is particularly common in patients on continuous ambulatory peritoneal dialysis (CAPD).

Acute pancreatitis occurs more frequently, though elevations of serum amylase of up to three times normal may be found in CKD without any evidence of pancreatic disease, owing to retention of high-molecular-weight forms of amylase normally excreted in the urine.

### Metabolic abnormalities

#### Gout

Urate is retained as GFR declines, and many drugs used to manage CKD increase the risk of gout. Nephrotoxic NSAIDs are less useful in treatment, though colchicine is useful for the acute attack. Reduced-dose allopurinol is effective in the prevention of further attacks.

#### Insulin

Insulin is catabolized by, and to some extent excreted via, the kidneys. Moreover, renal glucose production is diminished with progressive CKD. For these reasons, insulin requirements in diabetic patients decrease as CKD progresses. By contrast, end-organ resistance to insulin is a feature of advanced CKD, resulting in modestly impaired glucose tolerance. Insulin resistance may contribute to hypertension and lipid abnormalities.

#### Lipid metabolism

Abnormalities in lipid metabolism are common in CKD and include:

- impaired clearance of triglyceride-rich particles
- hypercholesterolaemia (particularly in advanced CKD).
The situation is further complicated in ESKD, when regular heparinization (in haemodialysis), excessive glucose absorption (in CAPD) and immunosuppressive drugs (in transplantation) may all contribute to lipid abnormalities.

### Endocrine abnormalities

These include:

- Hyperprolactinaemia, which may present with galactorrhoea in men as well as women.
- Decreased serum testosterone levels (only seldom below the normal level). Loss of libido, erectile dysfunction and decreased spermatogenesis are common.
- Menstrual irregularities, oligomenorrhoea or amenorrhoea (very few women on dialysis will have periods), which are common, as is loss of libido (see p. 1175).
- Complex abnormalities of growth hormone secretion and action, resulting in impaired growth in uraemic children (pharmacological treatment with recombinant growth hormone and insulin-like growth factor is used)
- Altered protein binding (and increased thyroid-binding globulin loss with proteinuria). These make thyroid function tests difficult to interpret. Thyroid-stimulating hormone (TSH) is the best test of thyroid function. True hypothyroidism occurs with increased frequency in CKD.

Posterior pituitary gland function is normal in CKD.

### Muscle dysfunction

Uraemia appears to interfere with muscle energy metabolism but the mechanism is uncertain. Decreased physical fitness (cardiovascular deconditioning) also contributes.

### Nervous system abnormalities

Uraemia affects the **central nervous system** as depressed cerebral function, a decreased seizure threshold, asterixis, tremor and myoclonus. Anxiety, depression and impaired cognition also occur. In people with profound uraemia, and high blood urea prior to their first dialysis, the sudden correction of urea can cause **dialysis disequilibrium** (urea does not equilibrate rapidly across the blood–brain barrier and, as blood urea falls on dialysis in advance of central nervous system urea, rapid movement of water into the higher-urea environment within the central nervous system leads to osmotic cerebral swelling and even fits). This can be avoided by correcting uraemia gradually by short, repeated haemodialysis treatments or by the use of peritoneal dialysis.

Increased circulating catecholamines lead to downregulation of α-receptors, impaired baroreceptor sensitivity and impaired efferent vagal function in the **autonomic nervous system**. Overactivity of the sympathetic nervous system may contribute to the hypertension seen in CKD. These abnormalities correct to some extent with regular dialysis, and resolve after
successful renal transplantation.

**Peripherally**, median nerve compression in the carpal tunnel is common, usually due to \( \beta_2 \)-microglobulin-related amyloidosis (see p. 1289). Advanced uraemia leads to a symmetrical polyneuropathy (which may recur in inadequately dialysed patients).

# Management of CKD

## General measures

- As always, make a diagnosis, and treat any modifiable underlying cause.
- Address cardiovascular risk factors – in particular, smoking cessation, exercise and weight loss.
- Avoid nephrotoxic drugs (see below).
- Arrange systematic follow-up, depending on the stage of CKD, to identify those most likely to progress early.

As stage 3 CKD progresses to stage 4 CKD, attention should be paid to correcting the complications described above: anaemia, CKD-MDB and metabolic abnormalities. Primary prevention of cardiovascular disease is a major part of CKD management at this stage.

## Renoprotection

The multidrug approach to chronic nephropathies has been formalized in an international protocol (see Box 20.9).

## Correction of specific complications

**Hyperkalaemia** often responds to dietary restriction of potassium intake. Drugs that cause potassium retention (see p. 168) should be stopped. Occasionally, it may be necessary to prescribe ion-exchange resins to remove potassium in the gastrointestinal tract. Two new orally active drugs, patiromer and sodium zirconium cyclosilicate, have been successful in controlling hyperkalaemia in phase 3 trials and will be available soon for use in clinical practice. Emergency treatment of severe hyperkalaemia is described on page 168.

**Correction of acidosis** helps to address hyperkalaemia in CKD and may also decrease muscle catabolism. Sodium bicarbonate supplements are effective (4.8 g (57 mmol) of \( \text{Na}^+ \) and \( \text{HCO}_3^- \) daily), without significant risk of oedema or hypertension. Correcting metabolic acidosis with sodium bicarbonate at a mean dose of 1.8 g/day also reduces the rate of decline of GFR (slowing progression) in advanced (stage 4 and 5) CKD. Calcium carbonate, also used as a calcium supplement and phosphate binder, has a beneficial effect on acidosis.

**Drug therapy** should be reviewed and nephrotoxins avoided in patients with CKD. These include:

- Tetracyclines (with the possible exception of doxycycline).
- Drugs excreted by the kidneys, such as gentamicin. These should be prescribed only in the
absence of any alternative, and drug levels monitored if feasible.

• NSAIDs.
• Potassium-sparing agents, such as spironolactone and amiloride. These pose particular dangers, as do artificial salt substitutes, all of which contain potassium.

Antibiotics, anticoagulants (particularly anti-thrombin oral anticoagulants, which currently lack a practical monitoring measurement of effect), beta-blockers, oral hypoglycaemics, insulin, antidepressants and analgesics (particularly opioids, which can accumulate, leading to an opiate narcosis) often need dose adjustment when prescribed for patients with CKD.

Early referral

Patients need time to adjust to the demands of CKD and its treatment, and to absorb information. Those who share in the decisions about their care, who are able to understand and choose treatments, make the best transition to dialysis or transplantation. As GFR declines below 20 mL/min/1.73 m², a dedicated team should counsel patients as to their diet, review medication, encourage risk factor modification, and support men and women to RRT (or the choice not to undertake dialysis).

If the patient opts for regular haemodialysis, an arteriovenous fistula should be fashioned well in advance of the need for dialysis (when serum creatinine is in the order of 400–500 µmol/L in non-diabetics, and at an even earlier stage in diabetics with poorer vasculature). Such fistulae require several weeks to mature and become usable for vascular access. Veins required for future arteriovenous fistulae should not be rendered useless by cannulation (Fig. 20.50). Patients choosing peritoneal dialysis might have a buried catheter placed and left subcutaneously for some time, able to be externalized on the day dialysis starts.

Where suitable, patients should be offered and prepared for pre-emptive living donor transplantation as the best option for RRT.
Renal replacement therapy

About 3 million people across the globe either are treated by haemodialysis or peritoneal dialysis, or live with a functioning renal transplant. In the UK, around 53,000 people receive treatment for ESKD; around 50% have been transplanted, 42% are on haemodialysis and 8% are on peritoneal dialysis. Dialysis aims to mimic the excretory function of normal kidneys by:

- eliminating (nitrogenous and small molecular) wastes
- maintaining normal electrolyte concentrations
- preventing systemic acidosis
- maintaining a normal extracellular volume.

Initiation of dialysis

It is not widely agreed when to start dialysis in patients with stage 5 CKD, and trials have suggested that early initiation of dialysis is not associated with improved survival or clinical outcomes. There is a general tendency to start dialysis at an eGFR closer to 15 mL/min rather than below 10 mL/min, but this decision is best shared with an individual patient, taking into account symptoms and life plans.

An informed choice

Many people, particularly if they are frail or living with other comorbidities, will choose not to undergo RRT if able to make a shared, informed decision with their physician and families. For some, the quantity of extended life offered by dialysis is not matched by the perceived impact on the quality of their lives. For others, events and complications of dialysis can make the daily experience of treatment difficult to endure, and they may choose to withdraw from dialysis. Support through their last illness, good symptom control, and respect for the individual's informed choices can allow patients a comfortable end of life after a period of long illness.

A difficult choice

Across the globe, RRT (like other treatments) can be an expensive option. For many societies, health resources may be allocated to other pressing priorities, or may be available for a defined time period only, or one form of RRT may be preferred over others. The drive for more cost-effective and low-technology solutions to treat renal failure is a pressing need for the specialty worldwide.

Haemodialysis

Basic principles

Anticoagulated blood from a patient is pumped around an extracorporeal circuit and through a biocompatible, semipermeable membrane (the dialyser, or ‘artificial kidney’) before being returned to the circulation. In the dialyser, ultrapure dialysate flowing in the opposite direction
is in close contact with blood. Small solutes (but not cells and larger-molecular-weight proteins) can cross the membrane, and move by diffusion down a concentration gradient (**Fig. 20.51**). A transmembrane pressure allows controlled fluid removal by ultrafiltration (and with fluid, more solute removal by convection). Over a standard 4-hour session, up to 80 L of blood (at around 300 mL/min) is circulated through the dialyser; even so, this only provides an equivalent GFR of 10–12 mL/min/m². **Box 20.35** describes a typical dialysate; dialysis is individually prescribed for any particular patient to obtain optimal results.

**Access**

Effective dialysis needs blood flows of between 250 and 450 mL/min. In order to achieve this, a surgically fashioned arteriovenous fistula (AVF; **Fig. 20.52**) is formed, using the radial or brachial artery and the cephalic vein. Large-bore needles are inserted into the arterialized vein of the AVF to take blood to and from the dialysis machine. In patients with poor-quality veins or arterial disease (e.g. diabetes mellitus), synthetic arteriovenous grafts offer an alternative.
For many, an AVF is not an immediate or appropriate solution, and a **semipermanent dual-lumen venous catheter** can be inserted under a skin tunnel into the jugular or femoral vein. Although easy to place and offering immediate use, there is a significant risk of bloodstream infection (with a foreign body directly accessing the circulation), catheter malfunction (thrombosis), or venous stenosis or occlusion.

For urgent dialysis, a temporary (and untunneled) large-bore, double-lumen dialysis catheter may be inserted into a central vein – usually the subclavian, jugular or femoral vein.

**Aims**

- **Maintain euvolaemia** – the ideal (or ‘dry’) weight. Fluid gains (in kilograms) between each dialysis session are the sum of fluid intake less fluid losses over a 48-h interdialytic interval. A patient who is anuric (with no urine output) who drinks 2 L/day will gain 4 kg if no insensible or stool losses occur. If a patient is weighed before and after each session (with the post-dialysis weight described as the ‘dry’ weight), dialysis can deliver long-term volume and blood pressure control.

- **Maintain electrolytes** in balance. A low dialysate potassium (of 1–3 mmol/L) allows rapid control of hyperkalaemia and a negative potassium balance (of 1–2 mmol/kg/session) over a treatment. Dialysate sodium is carefully controlled to prevent large fluid shifts (at 137–141 mmol/L, although this can be individualized), and calcium fixed to mimic the ionized fraction (and prevent net calcium gain during dialysis).
• **Prevent acidosis.** Dialysate is buffered with bicarbonate at (for example) 36 mmol/L. This will diffuse into blood to correct acidosis during treatment.

• **Balance frequency and duration with quality of life.** Between 4 and 5 h of treatment three times a week is considered ‘adequate’ to maintain volume and solute balance over time. Shorter or less frequent dialysis is usually only sufficient if a patient has considerable **residual renal function** (usually assessed by measuring 24- or 48-h urine volumes and clearances, then adding this to the dialysis clearance). Recent evidence is pointing towards more frequent dialysis (up to 5–6 dialysis sessions per week) or longer treatment duration (6–8 h three times weekly) as offering more benefit in terms of quality of life, solute clearance and cardiovascular health.

• **Deliver enough dialysis** (adequacy). The size, number and nature of ‘uraemic toxins’ are not clear, and the only true measure of adequacy is patient mortality and morbidity. Symptoms of under-dialysis are non-specific and include insomnia, itching and fatigue (despite adequate correction of anaemia), restless legs and a peripheral sensory neuropathy. Formal measures using urea as a surrogate calculate the urea reduction ratio (URR, targeting >65% per session) or the \( eKt/V \) (where \( K \) is the dialyser clearance, \( t \) is the duration of dialysis in minutes, and \( V \) is the urea distribution volume estimated as total body water) as minimum thresholds required for well-nourished dialysis patients dialysed three times per week. It is unclear whether a higher \( eKt/V \) (more dialysis than is thought of as adequate) associates with better outcomes; initial trial data suggest not.

**Specific complications**

• Access (either AVF or catheter) malfunction, thrombosis or bleeding

• Bloodstream infections, which may disseminate to soft tissue (septic arthritis), cardiac valves (endocarditis) or spinal column (vertebritis).

• Dialysis disequilibrium, when dialysis is initiated with too rapid early urea removal. Subsequent movement of fluid towards the higher urea seen across the blood–brain barrier can cause cerebral oedema and fitting.

• Intradialytic hypotension (where too rapid fluid removal exceeds refill of the circulation from the extravascular space).

• Dialysis-related amyloidosis, where failure of clearance of \( \beta_2 \)-microglobulin, a molecule of 11.8 kDa, leads to amyloid deposits, median nerve compression in the carpal tunnel, a dialysis arthropathy, bone cysts and fractures, pseudotumours and gastrointestinal bleeding.

**Haemofiltration**

Haemofiltration differs from haemodialysis in that there is no dialysate; rather, plasma water (and suspended solutes) is removed by convection across a high-flux semipermeable membrane. Substitution fluid (with the desired biochemical composition) is then infused to replace (large) fluid losses (*Fig. 20.53*). Haemofiltration may be preferred in the acute setting, where haemodynamic instability is common (particularly on ITUs). Modern dialysis machines
have built-in facilities to generate online ultra-pure water, which has minimized the cost of the procedure. It has also given the clinician the option to use this technique either as haemofiltration or in combination with dialysis as **haemodiafiltration** to increase middle molecule clearance (e.g. $\beta_2$-microglobulin) and prevent long-term dialysis complications such as dialysis-related amyloidosis, particularly in young, highly sensitized, non-transplantable patients.

**FIGURE 20.53** Principles of haemofiltration.

### Peritoneal dialysis

Peritoneal dialysis uses the peritoneal membrane as a semipermeable membrane, avoiding the need for extracorporeal circulation of blood. It is a very simple, low-technology (and effective) treatment compared to haemodialysis (**Fig. 20.54**).

- A soft catheter is placed through a skin tunnel into the peritoneal cavity through the midline of the anterior abdominal wall (**Fig. 20.55**).
- Dialysate is run into the peritoneal cavity, usually under gravity.
- Urea, creatinine, phosphate and other uraemic toxins pass into the dialysate down their concentration gradients.
- Water (with solutes) is attracted into the peritoneal cavity by osmosis, depending on the osmolarity of the dialysate. This is determined by the glucose or polymer (icodextrin) content of the dialysate (**Box 20.36**). More hypertonic solutions (rising from around 1.5% to 4% glucose) will improve fluid removal.
- The fluid is exchanged regularly to repeat the process.
**FIGURE 20.54** Principles of peritoneal dialysis. Water is attracted into the peritoneal cavity, depending on the osmolarity of the dialysate.

**FIGURE 20.55** The siting of a Tenckhoff peritoneal dialysis catheter.

\(^a\)Glucose content is often expressed as g/dL of anhydrous glucose (e.g. 1.36% = 77 mmol/L). An even more hypertonic dialysate (6.36%) is available for acute (intermittent) peritoneal dialysis. CAPD, continuous ambulatory peritoneal dialysis.

**Continuous ambulatory peritoneal dialysis (CAPD)** has dialysate present within the peritoneal cavity continuously, except during an exchange (done 3–5 times a day using a sterile no-touch technique to connect 1.5–3-L bags of dialysate to the peritoneal catheter; each exchange takes 20–40 min.

**Automated peritoneal dialysis (or nightly intermittent peritoneal dialysis)** has a simple exchange machine performing continuous low-volume exchanges each night while the patient is asleep. Sometimes dialysate is left in the peritoneal cavity during the day in addition, to increase the time during which biochemical exchange is taking place.

**Specific complications**

- Bacterial peritonitis, presenting as fever, abdominal pain, and a cloudy peritoneal dialysate effluent (>100 cells/mm\(^3\) on microscopy is suggestive) progressing to frank peritonitis, occurs at the rate of about one episode for every 2 patient-years. Once peritoneal effluent is sent for culture, empirical antibiotic treatment is started. Common causative organisms are listed in **Box 20.37**.

\(^a\)In approximately 20%, no bacteria are found. CAPD, continuous ambulatory peritoneal dialysis.
• Catheter exit-site infections may progress to skin tunnel infections and peritonitis.
• Constipation may impair flow of dialysate in and out of the pelvis.
• Hernias are caused by raised intra-abdominal pressure, and dialysate ‘leaks’ into the pleural cavity or scrotum (down a patent processus vaginalis).
• Sclerosing peritonitis is a potentially fatal complication of CAPD, where long-term patients develop progressive thickening of the peritoneal membrane. This occurs in association with adhesions and strictures, turning the small bowel into a mass of matted loops and causing repeated episodes of small bowel obstruction.

Adequacy
Most clinicians aim for a weekly $Kt/V$ of 2.0 (see above), coupled with a creatinine clearance of 60 L per week. Once patients stop passing urine (and have no residual renal function), peritoneal dialysis inadequacy becomes common, and a switch in technique to haemodialysis may be required.

Dialysis in the frail
Dialysis can prolong life, but the benefit to any individual, and particularly to frail patients, varies widely. Outcomes in frail elderly people who are undergoing dialysis are poor. Small studies suggest that mortality or quality-of-life outcomes do not differ significantly among selected patients who elect to undergo dialysis, compared to those who decide against dialysis. In one study, over 50% died within the first year of initiating dialysis and around 30% had a decrease in functional status.

Renal transplantation
Successful renal transplantation offers the potential for almost complete rehabilitation in ESKD.
• Survival is significantly better compared to dialysis patients on transplant waiting lists.
• Transplantation allows freedom from dietary and fluid restrictions.
• Anaemia and infertility are corrected.
• Any need for parathyroidectomy is reduced.

It is the treatment of choice for any appropriate patients with ESKD. However, the supply of donor organs (in the UK, 44 per million population per year) is exceeded by demand. Donor organs are a scarce and valuable resource that must be used optimally.

Kidney transplantation involves the anastomosis of an explanted human kidney, usually either from a deceased donor or from a living related or unrelated donor, on to the iliac vessels of the recipient (Fig. 20.56). The donor ureter is placed into the recipient's bladder. Unless the donor is genetically identical (i.e. an identical twin), immunosuppressive treatment is needed,
for as long as the transplant remains in place, to prevent rejection. Patient and graft survival has steadily improved with:

- more appropriate patient selection and assessment
- better donor–recipient compatibility
- improvements in surgical techniques
- more efficient immunosuppressive regimens.

Some 80% of grafts now survive for 5–10 years in the best centres, and 50% for 10–30 years. However, the half-life of renal allografts is still 13–16 years. The three most common causes of late graft loss are death of patients with a functioning graft, recurrence of the original (or new) renal disease, and chronic allograft nephropathy.

**Considerations in successful kidney transplantation**

ABO (blood group) compatibility between donor and recipient is preferred. ABO-incompatible renal transplants (where donor and recipient have different blood groups) are successful with directed immunosuppression (including immunoadsorption to remove pre-formed antibodies, splenectomy, anti-CD20 antibodies to remove B lymphocytes, and intravenous pooled immunoglobulins for immunomodulation or anti-idiotypic antibodies).

Donor and recipient HLA mismatches should ideally be minimized. Nationwide matching schemes for kidneys retrieved from deceased donors form the basis for kidney transplant offers. Complete compatibility at A, B and DR loci offers the best long-term outcomes when compared to multiply mismatched organs (i.e. antigens possessed by the donor and not possessed by the recipient). However, transplanting completely mismatched kidneys, particularly with living donation, is routine and results are as good as, if not better than,
properly matched deceased donor kidneys.

Pre-formed (historical) anti-HLA antibodies in recipients, resulting from either sensitization from prior blood transfusions, kidney transplants or past pregnancy in women, tend to predict less good outcomes. This is particularly true if these existing antibodies are donor-specific (or recipient anti-HLA antibodies against donor antigens). Transplantation can still be successful but pre-transplant strategies to minimize these antibodies (with plasmapheresis, intravenous immunoglobulin and/or the anti-B cell monoclonal antibody, rituximab) are necessary.

Organs may be retrieved from donors who have sustained brainstem death or even cardiac arrest. Most countries allow the removal of kidneys and other organs from patients who have suffered irretrievable brain damage (‘brainstem death’) while the heart is still beating (donation after brainstem death, DBD; see pp. 1172–1173). Due to the shortage of solid organs and increasing numbers of patients waiting for them, several countries now allow the retrieval of organs after cardiac death (donation after cardiac death, DCD), with comparable results to ‘heart-beating’ donations. Expanded criteria donors (ECD), aged >60 years, or those between the ages of 55 and 59 years but with co-morbidity such as hypertension, diabetes, pre-retrieval AKI and intracranial haemorrhage as a cause of death, are also increasingly used.

Living related or unrelated donation offers the best kidney outcomes. Potential living donors undergo comprehensive preoperative evaluation to ensure that they will come to no harm through donating a kidney to another person. Recent evidence suggests that live donors carry a statistically increased risk of CKD/ESKD post donation but the inherent risk is too low for it to be of clinical significance. Young women donors are at increased risk of gestational hypertension or pre-eclampsia in subsequent pregnancies, though without any ill-effects on their children. As a result, all living donors should be monitored regularly.

Timing transplantation so that it takes place prior to dialysis initiation (pre-emptive transplantation) offers benefits to both the recipient and the graft.

Immunosuppression for transplantation

Long-term inhibition of the recipient immune system is needed to prevent immune-mediated injury to grafts recognized as non-self. This is almost universally the case, except where living related donation from an identical twin occurs. Some degree of immunological tolerance does develop, and the risk of rejection is highest in the first 3 months after transplantation. In the early months, rejection episodes occur in less than 20% of cadaver kidney recipients on current immunosuppression protocols, and most cases are reversible. A combination of immunosuppressive drugs is usually used (Box 20.38). Individualizing immunosuppression to a specific recipient remains an inexact science, and preventing the complications of over-immunosuppression is as necessary as preventing rejection. Therapeutic drug monitoring is useful in delivering the most intense immunosuppression in the early post-transplant phase, and allows lower target ranges further out.

### Early complications

#### Early (technical) failure
Occlusion or stenosis of the arterial anastomosis, occlusion of the venous anastomosis, and urinary leaks owing to damage to the lower ureter or to defects in the anastomosis between ureter and recipient bladder can occur despite best surgical technique.

**Acute tubular necrosis**

Delayed graft function resulting from ATN is the most common cause of deceased donor graft dysfunction (up to 40–50%), particularly in kidneys from DCD or ECD donors (see above). Hypotension or loss of cardiac output will have an understandable impact on the retrieved organ. A prolonged ‘cold ischaemia time’ (the period during which the retrieved organ is cooled on ice in transit and awaits implantation) also leads to delayed graft function due to ATN. Finally, calcineurin inhibitors used to prevent rejection are themselves nephrotoxic where high peak and trough concentrations cause tubular injury.

**Acute rejection**

Acute rejection is seen in between 10% and 30% of transplant recipients and usually presents with declining renal function within the first 3 months. Renal biopsy (Fig. 20.57A) can confirm the diagnosis and also assesses the severity and type of rejection, but sampling errors do occur. Urinary measurement of RNA is also being used to detect acute cellular rejection (T-cell or antibody-mediated, with or without endothelial injury – so-called ‘vascular rejection’).

![FIGURE 20.57](https://example.com/image.png)

**FIGURE 20.57** Histology of kidney in rejection. A. Acute vascular rejection: the mononuclear inflammatory cell infiltrate is limited to the expanded intima and does not involve the entire vascular wall as in systemic vasculitis. B. Antibody-mediated rejection: an acute tubular necrosis with capillary glomerulitis and peritubular and glomerular capillary C4d positivity.

Cellular rejection may respond to high-dose intravenous corticosteroids, increased or switched calcineurin inhibition, or the use of T-cell-depleting agents such as anti-thymocyte globulin (ATG) or anti-lymphocyte globulin (ALG). Antibody-mediated rejection (diagnosed by the presence of circulating donor-specific anti-HLA antibodies and evidence of complement activation on renal biopsy by C4 staining; Fig. 20.57B) is usually treated empirically by a combination of intravenous immunoglobulin (to neutralize and promote the clearance of anti-HLA antibodies), plasmapheresis (to remove antibodies) and anti-CD20 antibody administration (to deplete B lymphocytes), with variable success.
More than one rejection within the first 3 months, vascular and/or antibody-mediated rejection, delayed rejection (requirement of dialysis within the first week after transplantation), and failure of serum creatinine to return to baseline (<130 µmol/L) after a rejection episode are associated with worse long-term outcome.

Infection

• Bacterial infections occur early (<1 month postoperatively), as urinary tract, wound and chest infections.

• Cytomegalovirus (CMV) infection develops weeks or months after transplantation in 70% of CMV-seronegative recipients receiving grafts from a seropositive donor, and in patients receiving biological agents (antibodies) as induction or therapy for rejection, unless prophylaxis with valganciclovir is given. Opportunistic infections, such as those with *Pneumocystis jiroveci*, occur and prophylactic co-trimoxazole is given in the early months. These infections also occur in the months after transplantation and associate with heavier immunosuppressant burdens.

• Polyomavirus infection (*BK nephropathy*) causes an often aggressive tubulointerstitial nephritis that may lead to graft loss. The only existing therapy is minimization of immunosuppression in the hope of spontaneous viral clearance.

Late complications

• *Post-transplantation lymphoproliferative disorders* (PTLD), often associated with Epstein–Barr virus, are malignancies more frequent in patients who received profound immunosuppression. Immunization is minimized and standard chemotherapy offered, with mixed outcomes.

• *Immunosuppressive therapy* increases the risk of skin tumours, including basal and squamous cell carcinoma. Other cancers that occur at increased frequency include renal, cervical and vaginal malignancies.

• *Cardiovascular disease* causes 50% of patient deaths after transplantation. Increased hypertension, obesity, diabetes and insulin resistance, and lipid disorders all play a role, as does an often long history of CKD.

• *Post-transplant osteoporosis* may occur as a result of steroid use.

• *Recurrent renal disease* is surprisingly common. Primary FSGS often recurs and causes early graft loss. Mesangiocapillary GN, diabetic nephropathy and IgA nephropathy also commonly recur, with variable effects on long-term graft survival.

Most grafts fail eventually through lasting immunological injury, the toxicities of immunosuppressant drugs, or even both. A common histological finding is interstitial fibrosis and tubular atrophy, a lesion once called chronic allograft nephropathy. There is a growing understanding of the role of subclinical chronic antibody-mediated rejection due to existing or *de novo* donor-specific antibodies, but non-immunological factors play an important part as well. Progressive irreversible decline in graft function is associated with mild to modest
proteinuria (<3 g/day), and interventions to change this trajectory currently lack evidence of benefit.

Renal transplantation in HIV patients

Modern antiretroviral therapy (ART) offers patients with HIV infection a near-normal life expectancy. However, an increasing number develop ESKD, and HIV was considered to be a contraindication to renal transplantation. However, a study of outcomes for 150 HIV-infected patients undergoing renal transplantation has shown that kidney transplantation is safe and effective in these individuals, at least in the short term. The patients in the study had CD4+ T-cell counts of ≥200 cells/mm³ and undetectable plasma levels of HIV type 1 RNA while on stable ART during the 16 weeks before renal transplantation. Median follow-up was 1.7 years. Survival rates at 1 year (95%) and 3 years (88%) were worse in HIV-infected patients than in the general population of kidney transplant recipients, but better than those in patients aged ≥65 years. Many rejection episodes were glucocorticoid-resistant, suggesting an aggressive response to donor antigens.

Further reading

http://www.ctsu.ox.ac.uk/~sharp/ The SHARP study.
Cystic Renal Disease

Solitary or multiple renal cysts are common, especially with advancing age; 50% of those over 50 years of age have one or more such cysts. They have no special significance except in the differential diagnosis of renal tumours (see pp. 791–792). These cysts are often asymptomatic and are found on ultrasound examination performed for some other reason. Occasionally, they may cause pain and/or haematuria if large, or bleeding may occur into the cyst. Cystic degeneration (the formation of multiple cysts that enlarge with time) occurs regularly in the non-functioning kidneys of patients with ESKD treated by dialysis and/or transplantation. These acquired cysts have malignant potential.

Autosomal dominant polycystic kidney disease

Autosomal dominant polycystic kidney disease (ADPKD) is an inherited disorder that usually presents in adulthood. It is characterized by the development of multiple renal cysts, variably associated with extrarenal (mainly hepatic and cardiovascular) abnormalities. ADPKD is by far the most common inherited nephropathy, with a prevalence rate ranging from 1:400 to 1:1000 in white populations. It accounts for 3–10% of all patients commencing regular dialysis in the West (see ciliopathies, pp. 92–93).

Mutations in PKD1 (on chromosome 16) are responsible for 85% of cases, with mutations on PKD2 (on chromosome 4) accounting for the remainder. These genetic abnormalities are distinct from the autosomal recessive form of polycystic disease (due to mutations in the PKHD1 gene on chromosome 6p21.1-p12), which is often lethal in early life.

PKD1 encodes polycystin 1, involved in cell–cell and/or cell–matrix interactions. PKD2 encodes polycystin 2, which functions as a calcium ion channel. The polycystin complex occurs in cilia, responsible for sensing flow in the tubule. Disruption of the polycystin pathway results in reduced cytoplasmic calcium, which, in principal cells (see p. 175) of the collecting duct, causes defective ciliary signalling and disoriented cell division, resulting in cyst formation. Progressive loss of renal function is usually attributed to mechanical compression, apoptosis of the healthy tissue and reactive fibrosis. Renal function declines at a variable rate, depending on the growth and size of cysts; patients with rapidly growing cysts on MRI lose renal function more rapidly. Strategies to slow the growth rate of cysts have been very effective in preserving renal function in animal models. These therapies include the vasopressin V₂ receptor inhibitors (vaptans, to reduce cyclic adenosine monophosphate (cAMP) in the principal cells), roscovitine (a cyclin-dependent kinase inhibitor) and antiproliferative therapy with sirolimus (mammalian target of rapamycin (mTOR) inhibitor).

Clinical features

Presenting symptoms occur from any point in the second decade onwards:

- loin pain and/or haematuria from haemorrhage into a cyst, cyst infection or urinary tract stone
formation

- loin or abdominal discomfort as the size of the kidneys increases
- subarachnoid haemorrhage associated with berry aneurysm rupture
- complications of hypertension
- complications of associated liver cysts (occurs in around 50%)
- symptoms of uraemia and/or anaemia associated with CKD.

**Complications and associations**

- Pain from large cysts can be difficult to manage, with surgical decompression of some benefit in about two-thirds of affected patients.

- Cyst infection is most effectively treated with lipophilic antibiotics that penetrate into infected cysts and are active against Gram-negative bacteria, such as co-trimoxazole and fluoroquinolones.

- Renal calculi occur in 10–20% and are often composed of uric acid and are radiolucent (see Fig. 20.30).

- Hypertension is an early and very common feature of ADPKD. Intrarenal activation of the renin–angiotensin system is thought to be contributory, so ACE inhibitors are logical first-line agents in treatment. Early control of blood pressure is essential as left ventricular hypertrophy is common, and cardiovascular complications are a major cause of death in ADPKD.

- Progressive CKD is the most serious complication of ADPKD. At glomerular filtration rates below 50 mL/min, the rate of decline in GFR averages 5 mL/min each year, which is more rapid than in other primary renal disorders. The probability of being alive without requiring dialysis or transplantation by the age of 70 years is in the order of 30%. Survival rates on regular haemodialysis and after renal transplantation in ADPKD are better than those in patients with other primary renal diseases.

- Approximately 30% of patients have hepatic cysts, occasionally massive enlargement of the polycystic liver with pain, infection and, more rarely, compression of the bile duct, portal vein or hepatic venous outflow.

- Some 10% of ADPKD patients have an asymptomatic intracranial aneurysm (see p. 839). The prevalence is twice as high if a family history of aneurysms or intracranial haemorrhage is present. Screening for intracranial aneurysm in ADPKD is recommended for patients aged 18–40 years who have a positive family history.

- Mitral valve prolapse is found in 20% of individuals with ADPKD.

**Diagnosis and screening**

Physical examination commonly reveals large, irregular kidneys and possibly hepatomegaly. Definitive diagnosis is established by ultrasound examination (Fig. 20.58 and Box 20.39).
However, such renal imaging techniques may be equivocal, especially in subjects under the age of 15 years. A number of conditions can mimic the clinical and radiological appearance of ADPKD (Box 20.40).

![Ultrasound scan of a polycystic kidney. An enlarged kidney is shown, with many cysts of varying size.](image)

**FIGURE 20.58**

### Box 20.39

**Ultrasonographic diagnostic criteria for testing individuals at risk of autosomal dominant polycystic kidney disease (ADPKD)**

In at-risk individuals, a diagnosis of ADPKD is established if patients meet the following criteria:

- 15–39 years: ≥3 cysts (unilateral or bilateral)
- 40–59 years: ≥2 cysts in each kidney
- ≥60 years: ≥4 cysts in each kidney

ADPKD is excluded in patients meeting the following criteria:

- ≥40 years: <2 cysts
- 30–39 years: 0 cysts (this excludes ADPKD in 98% of cases).

At <30 years, a negative renal ultrasound scan does not exclude a diagnosis of ADPKD; other imaging techniques, such as CT and MRI, may be useful and molecular genetic testing might be needed.

### Box 20.40

**Conditions that clinically and radiologically mimic polycystic kidney disease**

- *Tuberous sclerosis*: includes lymphangiomomatosis and lymphangioleiomyomatosis, and can be associated with the TSC2–PKD1 contiguous gene syndrome
- von Hippel–Lindau syndrome
- **Multicystic dysplastic kidney:** a non-heritable unilateral syndrome or a systemic syndrome (e.g. prune belly syndrome)
- **Juvenile nephronophthisis** and medullary cystic kidney disease: can be autosomal recessive (presenting in the second decade of life) or autosomal dominant (presenting in the third to fourth decades)
- **Glomerulocystic kidney disease:** involves the expansion of Bowman's space and is autosomal dominant
- **Acquired cystic disease:** involves end-stage kidney disease and hypokalaemia
- **Renal-cell carcinoma:** involves cystic changes

The children and siblings of patients with established ADPKD should, in general, be offered screening. Affected individuals should have regular blood pressure checks and should be offered genetic counselling. Gene linkage analysis can be utilized in many families.

### Management

No definitive therapy is yet available. Potential strategies include:

- **Vasopressin receptor antagonists**, which act by inhibiting cAMP in principal cells, reduce cyst growth and slow the rate of progression of renal failure. Liver toxicity has limited widespread use.
- **Octreotide**, a long-acting somatostatin analogue (which also inhibits cAMP), has been beneficial in halting the growth of both liver and renal cysts.
- In the HALT-PKD study A, patients with early PKD and eGFR >60 mL/min, when randomized to a low blood pressure group (95/60–110/75 mmHg), had slower annualized increase in total kidney volume, lower albuminuria and left ventricular mass index compared to the standard blood pressure group (120/70–130/80 mmHg). In late-stage PKD (with eGFR of 25–60 mL/min), adding an angiotensin receptor blocker to an ACE inhibitor (dual blockade) did not confer additional benefit at 5–8-year follow-up.
- Two studies of mTOR inhibitors, e.g. rapamycin, in PKD were essentially negative for the primary end-point of cyst growth and preservation of renal function, but studies of patients with early disease are in progress.

### Medullary cystic disease ('juvenile nephronophthisis')

Juvenile nephronophthisis develops early in childhood and is inherited in an autosomal recessive manner. Mutations in the genes *NPHP1–4*, encoding nephrocystin and inversin (both co-localized in the cilia of the renal tubules) leads to multiple cyst formation. Polyuria, polydipsia and growth retardation result from impaired tubular function. A similar condition
developing later in childhood (medullary cystic disease) is inherited as an autosomal dominant trait, but sporadic cases occur in both conditions. The dominant histological findings are interstitial inflammation and tubular atrophy, with later development of medullary cysts.

Diagnosis is based on family history and renal biopsy, the cysts rarely being visible on imaging.

---

**Medullary sponge kidney**

Medullary sponge kidney is an uncommon cystic condition presenting as intermittent renal colic, the passage of small stones and haematuria. Although it is most often sporadic, a few affected families have been reported. Dilatation of the collecting ducts in the papillae occurs, sometimes with cystic change. In severe cases, the medullary area has a sponge-like appearance. The condition may affect one or both kidneys, or only part of one kidney. Cyst formation is commonly associated with the development of small calculi within the cyst. In about 20% of patients, there is associated hypercalciuria or renal tubular acidosis (see pp. 177–178). Hemi-hypertrophy of the skeleton has been described in this condition.

CT or IVU (see Fig. 20.28) is diagnostic. Renal function is usually well maintained and CKD is unusual, except where obstructive nephropathy develops owing to the presence of stones in the pelvis or ureters.

---

**Tumours of the Kidney and Genitourinary Tract**

**Renal cell carcinoma**

Renal cell carcinomas (RCCs) arise from proximal tubular epithelium. They are the most
common renal tumour in adults (accounting for 1–2% of all malignancies), and affect men more often than women (2 : 1). They usually present after 50 years of age (and rarely before the age of 40).

RCCs are highly vascular tumours; microscopically, most tumours are composed of large cells containing clear cytoplasm.

**Clinical features**

- RCCs are often asymptomatic and discovered incidentally.
- Haematuria, loin pain and a mass in the flank occur.
- Malaise, anorexia and weight loss may be present (30%).
- Some 5% of patients have polycythaemia (see pp. 548–550).
- Around 30% of patients have hypertension (due to secretion of renin by the tumour) and anaemia, due to depression of erythropoietin in approximately the same number.
- Pyrexia occurs in about 20% of patients.
- Approximately one-third present with metastases.
- Rarely, a left-sided varicocele may be associated with left-sided tumours that have invaded the renal vein and caused obstruction to drainage of the left testicular vein.

**Diagnosis**

Ultrasound may demonstrate a solid lesion. CT scanning is used to identify the renal lesion and involvement of the renal vein or inferior vena cava. MRI is better than CT for tumour staging. Urine cytology for malignant cells is of no value. The ESR is usually raised. Liver biochemistry may be abnormal, returning to normal after surgery.

**Management**

Medical management of RCC is discussed on pages 640–641. A nephrectomy is performed unless bilateral tumours are present or the contralateral kidney functions poorly, in which case conservative surgery, such as partial nephrectomy, may be indicated. If metastases are present, nephrectomy may still be warranted, since regression of metastases has been reported after removal of the main tumour mass.

Von Hippel–Lindau (VHL) disease is an autosomal dominant disorder presenting with bilateral RCCs, retinal and cerebellar haemangioblastomas, phaeochromocytomas, pancreatic neuroendocrine tumours and renal cysts. VHL protein acts as a tumour suppressor by tagging hypoxia-inducible gene products (VEGF, TGF) for degradation. Inactivating mutations of the VHL gene lead to uncontrolled angiogenesis and neoplasia. Mutations of the same tumour suppressor gene are responsible for RCC and VHL.
Nephroblastoma (Wilms' tumour)

Seen within the first 3 years of life, Wilms' tumour presents as an (occasionally bilateral) abdominal mass, rarely with haematuria. Diagnosis is established by ultrasound, CT and MRI. A combination of nephrectomy, radiotherapy and chemotherapy has much improved survival rates, even in children with metastatic disease. Overall, the 5-year survival rate is 90%.

Urothelial tumours

The calyces, renal pelvis, ureter, bladder and urethra are lined by transitional cell epithelium. Transitional cell cancers account for about 3% of deaths from all forms of malignancy. These tumours are uncommon below the age of 40 years, and more common in men (the male : female ratio is 4 : 1). Bladder tumours are about 50 times as common as those of the ureter or renal pelvis. Predisposing factors include:

- cigarette smoking
- exposure to industrial carcinogens such as β-naphthylamine and benzidine (workers in the petroleum, chemical, cable and rubber industries are at particular risk) or ingestion of aristolochic acid found in some herbal weight-loss preparations
- exposure to drugs (e.g. phenacetin, cyclophosphamide)
- chronic inflammation (e.g. schistosomiasis, usually associated with squamous carcinoma).

Clinical features

Painless haematuria is the most common presenting symptom (80%) of bladder malignancy, although pain may occur owing to clot retention. Symptoms suggestive of UTI develop in the absence of significant bacteriuria. In patients with bladder cancer, pain also results from local nerve involvement. Presenting symptoms may result from local metastases. Flank pain may occur with urinary tract obstruction in ureteric lesions.

Investigations

- Urine cytology for malignant cells.
- Urinary tumour markers.
- Cystoscopy to assess the tumour burden and for biopsy.
- CT or MRI of the pelvis.

Management

Medical management of urothelial and testicular tumours is discussed on pages 641 and 642–643, respectively.
Diseases of the Prostate Gland

Benign enlargement of the prostate gland

Benign prostatic enlargement occurs most often in men over the age of 60 years. The aetiology is not established, but the condition is unknown with hypogonadism, confirming the androgen dependency of the condition. Microscopically, hyperplasia affects the glandular and connective tissue elements of the prostate. Enlargement of the gland stretches and distorts the urethra, obstructing bladder outflow.

Clinical features

Frequency of urination, usually first noted as nocturia, is a common early symptom. Difficulty or delay in initiating urination, with variability and reduced forcefulness of the urinary stream and post-void dribbling, are often present (so-called ‘LUTS’, or lower urinary tract symptoms). Acute retention of urine (see below) or retention with overflow incontinence may occur. Occasionally, severe haematuria results from rupture of prostatic veins or is a consequence of bacteriuria or stone disease.

Examination and investigations

Abdominal examination for bladder enlargement, together with digital rectal examination, is performed (a benign prostate characteristically feels smooth). Investigations should include urine culture, a serum prostate-specific antigen (PSA), renal function, ultrasound and pressure flow studies of bladder emptying.

Management and prognosis

Patients with mild to moderate symptoms are managed by lifestyle change alone, as symptoms following therapy are sometimes greater than those with no therapy at all.

Individuals with moderate prostatic symptoms can be treated with:

- alpha-blockers (such as tamsulosin, which relaxes prostate and bladder smooth muscle tone)
- 5α-reductase inhibitors (e.g. finasteride, which blocks the conversion of testosterone to dihydrotestosterone, the androgen primarily responsible for prostatic growth and enlargement)

- combination therapy.

Surgical treatment includes:

- laser therapy (enucleation or vaporization)
- trans-urethral needle ablation (TUNA)
- trans-urethral resection of the prostate (TURP)
• open prostatectomy.

Deterioration in renal function or the development of upper tract dilatation usually requires surgery.

In acute retention or retention with overflow, the priorities are to relieve pain and catheterize (and drain) the bladder. If urethral catheterization is impossible, a suprapubic catheter can be placed.

### Prostatic carcinoma

Prostatic carcinoma accounts for 7% of all cancers in men and is the sixth most common cancer in the world. Malignant change within the prostate becomes increasingly common with advancing age. By the age of 80 years, 80% of men have malignant foci within the gland but most of these appear to lie dormant. Histologically, the tumour is an adenocarcinoma.

### Pathogenesis

Risk factors for prostate cancer include advancing age, race (common in the black population in the USA and rare in China and Japan) and a family history. The first degree relatives of men with prostate cancer have twice the risk compared to the general population. This is higher in those diagnosed below the age of 60 years and 50% higher in monozygotic twins. Genetic studies have shown that the homeobox gene *HOXB13* is a predisposition gene. Genome-wide association studies have identified about 77 SNPs associated with prostate cancer. *BRCA2* confers a 5–7 times higher risk.

Hormonal factors also play a role in aetiology.

### Clinical features

Presentation is usually with LUTS if there is local disease, or back and skeletal pain, weight loss or anaemia if metastatic. The diagnosis is also made by the incidental finding of a hard, irregular gland on digital rectal examination, or as an unexpected histological result after prostatectomy for what was believed to be benign prostatic enlargement.

In developed countries, patients now present as a result of screening for prostate cancer by measurement of serum PSA. However, on the evidence available, national screening programmes are not justified. Treatment of well people carries a high morbidity of urinary incontinence and sexual dysfunction, with no evidence as yet of increased overall survival. In future, screening of ‘at-risk’ groups may be useful:

- PSA >4 ng/mL: this is abnormal but a measurement of between 4 and 10 ng/mL can be due to benign hypertrophy and cancer.
- PSA >10 ng/mL: a prostatic biopsy will show cancer in >50% of cases.

### Investigations
These include trans-rectal ultrasound (TRUS) of the prostate and extended sampling prostatic biopsy. A histological diagnosis is essential before treatment. The Gleason scoring system is based on the histological appearances. If metastases are present, serum PSA levels usually are markedly elevated (>16 ng/mL) but can be normal; it is a myth that elevated levels occur as a result of rectal examination.

Ultrasonography and TRUS are also of value in defining the size of the gland and staging any tumour present. Endorectal coil MRI helps to detect extraprostatic extension. The upper renal tracts can be examined by ultrasonography for evidence of dilatation. Bone metastases appear as osteosclerotic lesions on X-ray and are also detected by isotopic bone scans.

Management

Non-surgical treatment of prostatic carcinoma is discussed on pages 641–642. Microscopic, impalpable tumours can sometimes be managed expectantly. Treatment for disease confined to the gland is radical prostatectomy (provided the patient is fit for the procedure), now performed by robotic surgery or radiotherapy. Metastatic disease can be treated with orchidectomy but many men refuse.

Further reading

The Urinary Tract in the Elderly

Progressive sclerosis of glomeruli occurs with ageing and this, together with the development of atheromatous renal vascular disease, accounts for the progressive reduction in GFR seen as people age. A GFR of 50–60 mL/min (about half the normal value for a young adult) may be regarded as ‘normal’ in patients over 80 years of age. The reduction in muscle mass often seen with ageing may mask this deterioration in renal function as creatinine falls despite a falling GFR. Accurate estimation of GFR in the elderly is necessary, particularly when prescribing drugs wholly or partly excreted by the kidney.

Urinary tract infections

UTIs are common in the elderly, where impaired bladder emptying (due to prostatic disease in men) or a neuropathic bladder (especially common in women) is frequently found. Symptoms may be atypical, with confusion, incontinence, nocturia, smelly urine or a vague change in well-being with little in the way of dysuria more common (see p. 763).
Urinary incontinence

This is defined as involuntary passage of urine sufficient to be a health or social problem; 25% of women and 15% of men over 65 describe the problem.

- **Urge incontinence** is usually due to detrusor muscle overactivity with leakage of urine because the bladder is sensed as full. It may occur as an isolated event, secondary to local factors (e.g. bladder infection or stones) or to central factors (e.g. stroke, dementia or Parkinson's disease).

- **Stress incontinence** occurs when the intra-abdominal pressure is increased, e.g. after a cough or sneeze, with a weak pelvic floor musculature or urethral sphincter. It is more common in women after childbirth.

- **Overflow incontinence** occurs with leakage of urine from a full, distended bladder. It occurs commonly in men with prostatic obstruction, following spinal cord injury, or in women with cystocele or after gynaecological surgery.

- **Functional incontinence** involves the passage of urine that occurs owing to inability to get to a toilet because of disability, e.g. stroke, trauma, the unavailability of toilet facilities or dementia.

Management

Examine for local problems, such as prostatic enlargement in men and gynaecological disorders in women, and for central problems, such as neurological disorders or dementia. Urine analysis (note glycosuria) and culture should be carried out to exclude UTI. Treat contributing causes, such as constipation, drug therapy and other co-existing disease.

- **Urge incontinence** – bladder training, antimuscarinics, e.g. oxybutynin, tolterodine, solifenacin and darifenacin.

- **Stress incontinence** – pelvic floor exercises. Trans-urethral injections of autologous myoblasts can aid in regeneration of the rhabdosphincter, and fibroblasts in reconstruction of the urethral submucosa. Mid-urethral slings are increasingly used for the treatment of stress incontinence; either the retropubic or the trans-obturator approach is used, with comparable efficiency.

- **Overflow incontinence** – removal of the obstruction.

- **Functional incontinence** – improvement facilities, regular urine voiding, absorbent padding.

In patients who do not respond to simple measures, pressure flow studies (urodynamics) should be performed. Incontinence is distressing, and an expert and committed incontinence advisory and treatment service combining nursing and medical skills can be of real benefit. For established incontinence, catheterization may be necessary, but should be avoided if at all possible.

Introduction

Neurology is a large and diverse subject that covers many conditions requiring long-term coordinated care and having serious effects on the daily lives of patients and their families. Neurology includes conditions as diverse as cognitive disorders involving higher-level mental functioning and disorders of peripheral nerve and skeletal muscle. It is a specialty requiring
good clinical skills and examination technique, which cannot be replaced with investigations or imaging techniques alone.

Some 17% of general practitioner consultations and 10% of Emergency Department visits are for neurological symptoms; 19% of all hospital admissions are for neurological disorders and 25% of chronic disability in adults below the age of 64 is due to neurological disorders (Box 21.1).

Clinical Approach to the Patient with Neurological Disease

**Clinical features of neurological disease**

Pattern recognition in neurology – interpretation of history, symptoms and examination – is very reliable. Practical experience is vital. There are three critical questions in formulating a clinical diagnosis:

• What is/are the site(s) of the lesion(s)?
• What is the likely pathology?
• Does a recognizable disease fit this pattern?

**Difficulty walking and falls**

Change in walking pattern is a common complaint (Box 21.2). Arthritis and muscle pain make
walking painful and slow (antalgic gait). The **pattern** of gait is valuable diagnostically.

### Box 21.2

**Spasticity and hemiparesis**

Spasticity (see pp. 812–813), more pronounced in extensor muscles and with or without weakness, causes stiff, effortful and slow walking. Toes of shoes become scuffed, catching level ground. Pace shortens; a narrow base is maintained. Clonus – involuntary extensor rhythmic leg jerking – may occur.

In a hemiparesis, when spasticity is unilateral and weakness marked, the stiff, weak leg is circumducted and drags.

**Parkinson's disease: shuffling gait**

Stride length shortens and, in advanced forms, the gait slows to a shuffle. Posture is stooped and arm swing reduced (initially, unilateral). Gait becomes festinant (hurried) with short, rapid steps. There is difficulty turning quickly (count the number of steps to turn around). Eventually, gait initiation difficulty and freezing episodes (sudden involuntary halts, such as when passing through a doorway) may develop. Falls are uncommon, except in late-stage disease, and may indicate a ‘Parkinson’s plus’ syndrome.

**Cerebellar ataxia: broad-based gait**

In lateral cerebellar lobe disease (see p. 814), stance becomes broad-based, unstable and tremulous. Ataxia describes this incoordination. When walking, the person tends to veer to the side of the affected cerebellar lobe.

In disease of midline structures (cerebellar vermis), the trunk becomes unsteady without limb ataxia, and there is a tendency to fall backwards or sideways – truncal ataxia.
Sensory ataxia: stamping gait

Peripheral sensory loss (e.g. polyneuropathy; see pp. 883–886) causes ataxia because of loss of proprioception (position sense). A broad-based, high-stepping, ‘stamping’ gait develops as feet are placed clumsily, relying in part on vision, so balance is worse in the dark. Romberg's test, first described in sensory ataxia of tabes dorsalis (see p. 866), becomes positive.

Lower limb weakness: high-stepping and waddling gaits

When weakness is distal, affecting ankle dorsiflexors, such as in a common peroneal nerve palsy (see p. 883), gait becomes high-stepping to avoid tripping. The sole returns to the ground with an audible slap.

Weakness of proximal leg muscles (e.g. polymyositis, muscular dystrophy) causes difficulty rising from sitting. Walking becomes a waddle, the pelvis being poorly supported by each leg.

Gait apraxia

With frontal lobe disease (e.g. diffuse cerebrovascular disease, normal-pressure hydrocephalus), walking skills become disorganized, despite normal motor and sensory function when examined on the couch. The gait is shuffling with small steps (marche à petits pas), gait ignition failure and hesitancy with fear of falling. Unlike in the gait of Parkinson's disease, arm swing and posture are normal. Urinary incontinence and dementia are often present.

Falls

Falls are a major health problem in elderly people, often leading to hospital admission; they are frequently a reason for requiring residential care. A third of people over the age of 65 will fall each year and 10% sustain serious injury, such as hip fracture or head injury. Falls are the leading cause of injury-related death in elderly people.

The cause of falls is usually multifactorial and a multidisciplinary approach to assessment and prevention is essential, taking into account both intrinsic medical risk factors and external environmental factors, such as rugs, stairs, footwear, poor lighting and so on. Medical risk factors for falls (Box 21.3) are additive, with multiple factors substantially increasing the risk of falling. Prevention of falls relies on identification of those at risk, treatment of medical risk factors where possible (e.g. rationalization of medications, treatment of postural hypotension), modification of environmental hazards in the home, patient education and training, and mitigation of the consequences of falls: for example, treating osteoporosis to reduce risk of fracture, and use of hip protectors, aids such as walking frames, and personal alarms. Involvement of physiotherapy and occupational therapy colleagues is a part of the assessment and management of falls.

Box 21.3
Medical risk factors for falls in the elderly

- Cognitive impairment (dementia and delirium)
- Arthritis, muscle weakness
- Disorders of balance and gait, e.g. Parkinsonism, ataxia, stroke
- Visual impairment
- Postural hypotension and syncope
- Vestibular disorders
- Polypharmacy, especially with sedative drugs, neuroleptics, antihypertensives and anticonvulsants
- Alcohol excess
- Peripheral neuropathy
- Effects of ageing on strength, postural stability and reaction time
- Use of walking aid

Dizziness, vertigo and blackouts

Dizziness covers many complaints, from a vague feeling of unsteadiness to severe, acute vertigo. It is frequently used to describe light-headedness (e.g. due to hypotension), panic, anxiety, palpitations and chronic ill-health. The real nature of this symptom must be determined.

Vertigo (see p. 809) means the illusion of movement, a sensation of rotation or tipping. The patient feels the surroundings are spinning or moving. This is distressing and often accompanied by nausea or vomiting.

Blackout, like dizziness, is simply descriptive, implying either altered consciousness (see epilepsy, pp. 846–850, and syncope, p. 851), transient visual disturbance as part of presyncope or falling, or hypoglycaemia in a diabetic patient. A good history is essential.

Collapse is a vague term but often used. It should be avoided.

Fatigue is common. When it is an isolated symptom, it rarely indicates neurological disease, although it may be a symptom of many neurological disorders. General medical causes, such as anaemia and endocrine disorders, should be excluded. No serious disease is found in many (>20%) patients referred with symptoms suggestive of possible neurological conditions.

Examination and formulation

Following a short or detailed examination, relevant findings are summarized in a brief formulation, which becomes the basis for investigation, transfer of information and management (Boxes 21.4–21.6).

3. *Cognitive function* – orientation, recall, level of intellect, language, other cortical problems, e.g. apraxia
4. *Gait and balance tests*, including tandem walking and Romberg's test
5. *Neck* – stiffness, palpation and auscultation of carotids
6. *Cranial nerves* (see Box 21.8)
7. *Motor system*
   - Upper limbs:
     - Wasting and fasciculation
     - Posture of arms: drift, rebound, tremor
     - Tone: spasticity, clonus, extrapyramidal rigidity
     - Power: 0–5 scale (see Box 21.6)
     - Tendon reflexes: + or ++ normal; +++ pathological; 0 = absent with reinforcement
   - *Thorax and abdomen*:
     - Respiration
     - Thoracic and abdominal muscles
     - Abdominal reflexes
   - Lower limbs:
     - Wasting and fasciculation
     - Tone, power and tendon reflexes
     - Plantar responses
8. *Coordination and fine movements*
9. *Sensory system*
   - Chart area of sensory loss; start in area with abnormal sensation and move stimulus towards normal area to demarcate boundaries
   - *Posterior columns*:
     - Vibration (128 Hz tuning fork)
     - Joint position – small movements of distal interphalangeal joints in toes and fingers
     - Light touch – use cotton wool
     - Two-point discrimination (normal: 2–4 mm fingertips, 2 cm soles)
   - *Spinothalamic tracts*:
     - Pain: use a split orange-stick or a sterile pin (never a hypodermic needle)
– Temperature: warm and cold objects

*Cortical sensory loss – dysgraphaesthesia and astereognosis*

10. *Specialized tests* as required e.g. Hallpike for vertigo, Phalen's test and so on

**Functional Neuroanatomy**

**The neurone and synapse**

The neurone is the functional unit of the entire nervous system (*Fig. 21.1*). Its cell body and axon terminate in a synapse. The size and type of each group of neurones vary. A thoracic spinal cord α-motor neurone has an axonal length of >1 metre and innervates between several hundred and 2000 muscle fibres in one leg – a motor unit. By contrast, some spinal or intracerebral interneurones have axons <100 µm long, terminating on one neuronal cell body.
FIGURE 21.1 The functional unit: neurone and neurotransmitters. (a) The action potential – that is, the nerve impulse – travels down the axon. Microtubules carry neurotransmitters to nerve endings. (b) Action potential I depolarizes the synaptic membrane, opening voltage-gated calcium channels. (c) Influx of calcium ions causes vesicles to fuse with the membrane, allowing neurotransmitter binding to receptors (i) and activation of secondary messengers that modulate gene transcription and also open ligand-gated channels (ii). This allows ions to enter, depolarize the membrane and initiate action potential II.

Neurotransmitters

Neurotransmitters are excitatory (acetylcholine, noradrenaline (norepinephrine), adrenaline (epinephrine), 5-hydroxytryptamine (5-HT, serotonin), dopamine, glutamate and aspartate) or inhibitory (γ-aminobutyric acid (GABA), histamine and glycine). Neuropeptides, such as vasopressin, adrenocorticotropic hormone (ACTH), substance P and opioid peptides, as well as the purines adenosine triphosphate (ATP) and adenosine monophosphate (AMP) are both excitatory and inhibitory.

Synaptic transmission is mediated by neurotransmitters released by action potentials passing down an axon. Neurotransmitters activate postsynaptic receptors and are removed by transporter proteins. The neurotransmitter–receptor reaction increases ionic permeability and propagates a further action potential. Axonal electrical activity and synaptic chemical release are the basis of neurological function.
Clinical features of focal brain lesions: general mechanisms

The symptoms and signs suggest the area of the brain that is malfunctioning (e.g. aphasia – the left frontal lobe, hemiparesis – the internal capsule, or a Bell's palsy – VIIth cranial (facial) nerve).

Focal lesions of the cortex, and lesions throughout the nervous system, cause symptoms and signs by two processes:

- Suppression or destruction of neurones and surrounding structures (Fig. 21.2). This is the most common process: part of the system simply fails to work.
- **Synchronous discharge of neurones** by irritative lesions (Fig. 21.3), e.g. cortical lesions, causes epilepsy, either partial or generalized.

---

** FIGURE 21.2 **  Principal features of destructive cortical lesions in a right-handed individual.
Localization within the cerebral cortex

This subject causes unnecessary difficulty. Work on neuronal networks, functional imaging and plasticity questions the traditional views of highly specific localization of cortical function. The following paragraphs summarize areas of clinical relevance.

The dominant hemisphere (usually left)
The concept of cerebral dominance arose from a simple observation: right-handed stroke patients with acquired language disorders had destructive lesions within the left hemisphere. Right-handed (and 70% of left-handed) people have language function on the left.

More specifically, destructive lesions within the left fronto-temporo-parietal region cause disorders of communication:

- spoken language – aphasia, also called dysphasia
- writing – agraphia
- reading – acquired alexia.

Developmental dyslexia describes delayed, disorganized reading and writing ability in children, usually with normal intelligence.

Aphasia
Aphasia is loss of, or defective language from damage to, the speech centres within the left hemisphere. Numerous varieties have been described.

**Broca's (expressive, anterior) aphasia**

Damage in the left frontal lobe causes reduced speech fluency with relatively preserved comprehension. The patient makes great efforts to initiate language, which becomes reduced to a few disjointed words with failure to construct sentences (sometimes described as *telegrammatic*). Patients who recover say they knew what they wanted to say but could not get the words out.

**Wernicke's (receptive, posterior) aphasia**

Left temporo-parietal damage leaves fluency of language but words are muddled. This varies from insertion of a few incorrect or non-existent words into speech to a profuse outpouring of jargon (non-existent words). Severe jargon aphasia is bizarre and often mistaken for psychotic behaviour.

Patients who recover from Wernicke's aphasia say that they found speech, both their own and others', like an unintelligible foreign language – that is, incomprehensible – but they could neither stop speaking nor understand speech.

**Nominal (anomic) aphasia**

This means difficulty in naming objects. Naming difficulty is an early feature in all types of aphasia. This is often tested in practice by asking patient to name parts of a watch; a more sensitive test utilizes pictures to test low-frequency words, such as rhinoceros, violin, tricycle or ladybird.

**Global (central) aphasia**

This means the combination of the expressive problems of Broca's aphasia and the loss of comprehension of Wernicke's, with loss of both language production and understanding. It is due to widespread damage to speech areas and is the most common aphasia after a severe left hemisphere infarct. Writing and reading are also affected.

**Dysarthria**

Dysarthria is disordered articulation – slurred speech. Language is intact. Paralysis, slowing or incoordination of the muscles of articulation causes various patterns of dysarthria. Examples are the *gravelly* speech of pseudobulbar palsy (see p. 811), the *jerky*, ataxic speech of cerebellar lesions, the hypophonic *monotone* of Parkinson's, and speech in myasthenia that *fatigues* and dies away. Many aphasic patients are also dysarthric.

**The non-dominant hemisphere**

Disorders in right-handed patients with right hemisphere lesions are often difficult to recognize. There are abnormalities of perception of internal and external space. Examples are
loss of the way in familiar surroundings, failure to put on clothing correctly (dressing apraxia), or inability to draw simple shapes – constructional apraxia.

**Memory and its disorders**

Like most brain functions, memory has a modular organization, with different aspects of memory dependent on functionally and anatomically distinct brain networks. Three distinct processes are required: learning, storage and subsequent retrieval of learned information. There is a fundamental distinction between *explicit* memory, which can be consciously accessed, such as long-term memory for events (*episodic* memory) and knowledge of word meaning (*semantic* memory) on the one hand, and *implicit* memory, which is not conscious: for example, how to ride a bike (*Fig. 21.4*). Short-term memory is frequently misunderstood and refers to *working* memory lasting seconds only: for example, phone numbers.

Disorders of memory can result from damage to the medial structures of the temporal lobes and their brainstem connections – the hippocampi, fornices and mammillary bodies, as well as from damage to the thalamus and frontal lobe. The distributed anatomical basis of memory means that bilateral lesions are necessary to cause *amnesia*. Impairment of episodic memory usually results in a temporal memory gradient: recent and new memories are mainly affected, with relative preservation of distant memories.

Memory loss (the amnestic syndrome) is frequently a symptom of dementia, especially Alzheimer's disease (see pp. 876–878), but also occurs as an isolated entity (*Box 21.7*).
Causes of an amnestic syndrome

- Dementia (note: multiple cognitive domains affected, not memory in isolation)
- Amnestic mild cognitive impairment (see p. 876)
- Alcohol – thiamine deficiency (Wernicke–Korsakoff syndrome)
- Head injury (severe)
- Anoxic brain damage and that following carbon monoxide poisoning
- Stroke, including bilateral thalamic infarction, subarachnoid haemorrhage, diffuse small-vessel disease, and post cardiac surgery
- Viral, paraneoplastic and autoimmune encephalitis
- Drugs – psychotropics, anticholinergics and solvent abuse
- Bilateral invasive tumours
- Temporal lobe epilepsy and temporal lobectomy
- Following hypoglycaemia
- Temporary amnesia: transient global amnesia, transient epileptic amnesia, post-traumatic amnesia
- Dissociative (functional/psychogenic)

---

Amnesia must be distinguished from delirium.

Essential elements of neuroanatomy

For clinical purposes, the complexity of neuroanatomy must be reduced to its core elements:

- cranial nerves
- three systems of motor control:
  - corticospinal or pyramidal system
  - extrapyramidal system
  - cerebellum
- motor unit
- reflex arc
- sensory pathways and pain
- control of the bladder and sexual function.

Cranial Nerves
See Box 21.8.

**I: Olfactory nerve**

This sensory nerve arises from olfactory (smell) receptors within nasal mucosa. Branches pierce the cribriform plate and synapse in the olfactory bulb. The olfactory tract passes to the olfactory cortex.

Anosmia (loss of the sense of smell) is caused by head injury (shearing of olfactory neurones as they pass through the cribriform plate at the skull base) or tumours of the olfactory groove (e.g. meningioma). Olfaction is temporarily (or permanently, on occasion) lost or diminished after upper respiratory infections and with local disorders of the nose. Many patients with gradual-onset anosmia over many years may be unaware of the deficit: for example, in Parkinson's disease, where anosmia precedes motor symptoms by many years but is often not noticed by the patient.

Detailed smell testing is difficult in routine clinical practice and rarely performed. Adequate testing requires use of commercially available kits, such as scratch and sniff cards or odour-filled pens with forced multiple choice identification.

**II: Optic nerve and visual system**

Light regulated by the pupillary aperture is converted into action potentials by retinal rod, cone and ganglion cells (see pp. 1323–1324). The lens, under control of the ciliary muscle,
produces the image (inverted) on the retina. Axons in the optic nerve (1 on Fig. 21.5) decussate at the optic chiasm (2), and fibres from the nasal retina cross and join with uncrossed fibres originating in the temporal retina to form the optic tract (3). Each optic tract thus carries information from the contralateral visual hemifield.

From the lateral geniculate body, fibres pass in the optic radiation through the parietal and temporal lobes (4 and 5) to reach the visual cortex of the occipital lobe (6 and 7), which is somatotopically organized with macular vision located at the occipital pole.

Beyond the visual cortex, visual information is further processed by neighbouring visual association areas to detect lines, orientation, shapes, movement, colour and depth; there is even a distinct area responsible for face recognition.

**Visual acuity**

Visual acuity (see p. 1324) is assessed in each eye with a Snellen chart and/or Near Vision Reading Types, corrected for refractive errors with lenses or a pinhole. The patient should stand 6 metres from a well-lit chart. Acuity is recorded as distance in metres from the chart.
over distance at which the line should be legible, e.g. 6/6 indicates ‘normal’ acuity and 6/60 very poor acuity.

**Visual field defects**

Visual fields are assessed at the bedside by confrontation – comparing the examiner's and patient's fields, one eye at a time and quadrant by quadrant. Patience and good technique are required to produce reliable results. White and red targets (traditionally, hatpins) are used to assess peripheral and central fields, respectively, although in practice a fingertip is often substituted as a cruder screening test. More detailed quantification of fields may be obtained using Goldmann (manual) or Humphrey (automated) perimetry testing.

Field defects are described as hemianopic when half the field is affected and quadrantanopic when a quadrant is affected. Lesions posterior to the optic chiasm produce **homonymous** field defects, indicating involvement of the same part of the visual field in both eyes, as information from the two visual hemifields is separated beyond this point. Lesions damaging decussating nasal fibres at the optic chiasm cause bitemporal defects.

**Retinal and local eye lesions**

See pages 1333–1334.

**Optic nerve lesions**

Unilateral visual loss, commencing with a central or paracentral (off-centre) scotoma, is the hallmark of an optic nerve lesion. Because most fibres in the optic nerve subserve macular vision, lesions within the nerve disproportionately affect central vision and colour vision. A total optic nerve lesion causes unilateral blindness with loss of pupillary light reflex. Examination findings in optic neuropathy are:

- reduced acuity in the affected eye
- a scotoma (usually central)
- impaired colour vision (assess with Ishihara plates)
- an afferent pupillary defect (see below)
- optic atrophy – pale disc (develops late).

Causes are listed in **Box 21.9**.

---

**Box 21.9**

**Causes of optic neuropathy**

- Inflammatory (optic neuritis), e.g. demyelination, sarcoidosis, vasculitis
- Optic nerve trauma or compression, e.g. glioma, meningioma, aneurysm, bone disorders affecting orbit
Papilloedema and its causes (see Box 21.10)

Papilloedema

Papilloedema means swelling of the optic disc. Causes are shown in Box 21.10. The earliest signs of swelling are disc pinkness, with blurring and heaping up of disc margins, nasal first. There is loss of spontaneous pulsation of retinal veins within the disc. The physiological cup becomes obliterated, and the disc is engorged with dilated vessels. Small haemorrhages often surround the disc.

Box 21.10

Causes of optic disc swelling

- Raised intracranial pressure (papilloedema)
- Brain tumour, abscess or haemorrhage
- Idiopathic intracranial hypertension, hydrocephalus
- Optic nerve disease
- Optic neuritis, e.g. multiple sclerosis
- Ischaemic optic neuropathy, e.g. giant cell arteritis
- Toxic optic neuropathy, e.g. methanol
- Venous occlusion
- Venous sinus thrombosis
- Central retinal vein thrombosis
- Orbital mass lesions
- Retinal vascular disease
- Malignant hypertension
- Vasculitis, e.g. systemic lupus erythematosus
- Metabolic causes
- Hypercapnia, chronic hypoxia, hypocalcaemia
- Disc infiltration
Various conditions simulate true disc swelling. Marked hypermetropic (long-sighted) refractive errors make a disc appear pink, distant and ill defined. Myelinated nerve fibres at disc margins and hyaline bodies (drusen; see p. 1334) can be mistaken for disc swelling.

**Disc infiltration** also causes a swollen disc with raised margins (e.g. in leukaemia).

When there is doubt about disc oedema, intravenous fluorescein angiography is diagnostic; retinal leakage is seen with papilloedema.

Papilloedema produces few, if any, visual symptoms other than momentary visual obscurations with changes in posture. The underlying disease is the source of the patient's symptoms. The blind spot is enlarged but this is not noticed by the patient. However, over time, progressive and permanent constriction of visual fields occurs, ultimately culminating in optic atrophy.

**Inflammatory optic neuropathy (optic neuritis)**

Optic neuritis is one of the most common causes of subacute visual loss. Symptoms may vary from a mild fogging of central vision with colour desaturation to a dense central scotoma, but very rarely complete blindness. Pain on eye movements is almost universal. The optic disc usually appears normal, despite severe visual loss (unless the inflammation is at the optic nerve head, in which case the disc may appear swollen in the acute phase).

A plaque of demyelination within the optic nerve is the most common cause in Western populations. Dedicated magnetic resonance imaging (MRI) of the optic nerves may show the inflammatory plaque, and imaging of the brain may show additional inflammatory lesions, which confer a higher risk of developing multiple sclerosis (MS). Approximately 50% of patients go on to develop MS with prolonged follow-up (see pp. 858–862). Recovery of visual acuity to 6/9 or better occurs in 95% of cases over months; recovery time is improved by high-dose intravenous steroids given acutely.

Optic neuritis may be caused by infective or other inflammatory disorders, such as sarcoidosis or vasculitides (see Box 21.9).

**Anterior ischaemic optic neuropathy**

The anterior part of the optic nerve is supplied by the posterior ciliary arteries, occlusion or hypoperfusion of which leads to infarction of all or part of the optic nerve head. There is sudden or stuttering altitudinal visual loss (typically, the lower half of the visual field) with disc swelling, later replaced by optic atrophy. The other eye is affected later in one-third of cases.

Individuals with small hypermetropic discs seem to be predisposed, and often there are relatively few vascular risk factors. Less commonly, arteritis is the cause (see p. 694).

**Optic atrophy**

Optic atrophy means disc pallor, from loss of axons, glial proliferation and decreased
vascularity. This may eventually develop following any type of optic neuropathy of sufficient severity to damage axons extensively within the nerve, including chronic papilloedema.

**Optic chiasm**

*Bitemporal hemianopia or quadrantanopia* occurs with compression of the chiasm from above or below. Common causes are:

- pituitary tumours (see pp. 1182–1183)
- meningioma
- craniopharyngioma.

**Optic tract and optic radiation**

Optic tract lesions (rare) cause a homonymous hemianopia (loss of the contralateral visual field in both eyes). Optic radiation lesions cause homonymous quadrantanopic defects. Temporal lobe lesions (e.g. tumour, infarction) cause upper quadrantic defects, and parietal lobe lesions cause lower quadrantic defects.

**Occipital cortex**

Homonymous hemianopic defects are produced by unilateral posterior cerebral artery infarction (see p. 834). The macular cortex (at each occipital pole) may be spared.

Widespread bilateral occipital lobe damage by infarction (‘*top of the basilar*’ syndrome, occlusion of the rostral basilar artery), trauma or coning causes *cortical blindness* (Anton syndrome). The patient cannot see but characteristically lacks insight into this; he or she may even deny it. Pupillary responses remain normal (see p. 834).

**The pupils**

A slight difference between the size of each pupil (up to 1 mm) is common (*physiological anisocoria*) and does not vary with differing light levels. The pupil tends to become smaller and irregular in old age (senile miosis); anisocoria is more pronounced. *Convergence* becomes sluggish with ageing.

Pupillary reactions to light and accommodation may be tested (*Fig. 21.6*). A bright torch (not an ophthalmoscope light!) should be used to test the pupillary light reaction.
**Afferent pupillary defect (APD).** A complete optic nerve lesion causes a dilated pupil and an APD. For a left APD:

- The pupil is unreactive to light (i.e. the direct reflex is absent).
- The consensual reflex (constriction of the right pupil when the left is illuminated) is absent. Conversely, the left pupil constricts when light is shone in the intact right eye: that is, the consensual reflex of the right eye remains intact.

**Relative afferent pupillary defect (RAPD).** This occurs with incomplete damage to one optic nerve relative to the other. An RAPD is a sensitive sign of optic nerve pathology and can provide evidence of an optic nerve lesion, even after recovery of vision. For a left RAPD:

- Direct and indirect reflexes are intact in each eye but differ in relative strength.
- When the light is swung from one eye to the other, the left pupil *dilates* slightly when illuminated and *constricts* slightly when the right eye is illuminated (the consensual reflex is stronger than the direct).

**Horner syndrome**

The sympathetic nervous supply to the eye is a three-neurone pathway originating in the hypothalamus and descending by way of the brainstem and cervical cord to the T1 nerve root, paravertebral sympathetic chain and, on via the carotid artery wall, to the eye. Damage to any part of the pathway results in Horner syndrome (*Box 21.11*). This is significant not only
because it affects vision but also because it may indicate serious underlying pathology.

**Box 21.11**

**Causes of Horner syndrome**

**Hypothalamic, hemisphere and brainstem lesions**
- Massive cerebral infarction
- Brainstem demyelination or lateral medullary infarction

**Cervical cord**
- Syringomyelia and cord tumours

**T1 root**
- Apical lung tumour or tuberculosis
- Cervical rib
- Brachial plexus trauma

**Sympathetic chain and carotid artery in neck**
- Following thyroid/laryngeal/carotid surgery
- Carotid artery dissection
- Neoplastic infiltration
- Cervical sympathectomy

**Miscellaneous**
- Congenital
- Cluster headache, usually transient
- Idiopathic

The clinical features of Horner syndrome are:
- unilateral miosis (constricted pupil)
- partial ptosis
- loss of sweating on the same side (extent depending on the level of the lesion)
- possible subtle conjunctival injection and enophthalmos.

The miosis is most easily seen in low light, as the pupil cannot dilate, and may not be apparent in bright light.

**Myotonic pupil (Holmes–Adie pupil)**
This is a dilated, often irregular, pupil and more frequent in women; it is common and usually
unilateral. There is no (or very slow) reaction to bright light and also incomplete constriction to convergence. This is due to denervation in the ciliary ganglion, of unknown cause, and has no other pathological significance. A myotonic pupil is sometimes associated with diminished or absent tendon reflexes.

**Argyll Robertson pupil**

Now rarely seen in clinical practice, an Argyll Robertson pupil is small and irregular; it is fixed to light but constricts on convergence. The lesion is in the brainstem surrounding the aqueduct of Sylvius. Once considered diagnostic of neurosyphilis, it is now only occasionally seen in diabetes or MS.

**III, IV, VI: Oculomotor, trochlear and abducens nerves**

These cranial nerves supply the extraocular muscles and disorders commonly result in abnormal eye movements and diplopia (double vision) due to breakdown of conjugate (yoked) eye movements. Diplopia may also occur with local orbital lesions or myasthenia gravis.

**Examination of eye movements**

Pursuit (slow) eye movements and saccadic (fast) eye movements are tested separately. The examiner assesses the range of eye movements in all directions and asks the patient to report double vision. Jerky pursuit movements with saccadic intrusion (i.e. brief, fast saccades interspersed with slower pursuit movements) overshoot on saccadic movements, and nystagmus may indicate cerebellar or brainstem pathology.

**Control of eye movements**

Fast voluntary eye movements originate in the frontal lobes. Fibres descend and cross in the pons to end in the centre for lateral gaze (paramedian pontine reticular formation, PPRF), close to the VIth nerve nucleus. Each PPRF also receives input from:

- the ipsilateral occipital cortex – pathway concerned with tracking objects
- the vestibular nuclei – pathways linking eye movements with position of the head and neck (vestibulo-ocular reflex)

Conjugate lateral eye movements are coordinated from each PPRF via the medial longitudinal fasciculus (MLF; *Fig. 21.7*). Fibres from the PPRF pass both to the ipsilateral VIth nerve nucleus (lateral rectus) and, having crossed the midline, to the opposite IIIrd nerve nucleus (medial rectus and other muscles) via the MLF, thus linking the eyes for lateral gaze.
Abnormalities of conjugate lateral gaze

A destructive lesion on one side allows the eyes to be driven by the intact opposite pathway. A left frontal destructive lesion (e.g. an infarct) leads to failure of conjugate lateral gaze to the right. In an acute lesion, the eyes are often deviated to the side of the lesion, past the midline, and therefore look towards the left (normal) limbs; there is usually a contralateral (i.e. right) hemiparesis.

In the brainstem, a unilateral destructive lesion involving the PPRF leads to failure of conjugate lateral gaze towards that side. There is usually a contralateral hemiparesis, and lateral gaze is deviated towards the side of the paralysed limbs.

Internuclear ophthalmoplegia

Damage to one MLF causes internuclear ophthalmoplegia (INO), a common complex brainstem eye movement disorder seen frequently in MS. In a right INO, there is a lesion of the right MLF (Fig. 21.7). On attempted left lateral gaze, the right eye fails to adduct or does so slowly as compared to the abducting eye. The left eye develops nystagmus in abduction. The side of the lesion is on the side of impaired adduction, not on the side of the (obvious, unilateral)
nystagmus. Bilateral INO is almost pathognomonic of MS.

One and a half syndrome
Pontine infarction involving the PPRF, VIth nerve nucleus and MLF on one side results in an ipsilateral horizontal gaze palsy and an INO, so that abduction of the opposite eye (with nystagmus) is the only horizontal eye movement possible. Vertical gaze and convergence are preserved, as they have distinct neural control mechanisms.

Vestibulo-ocular (doll's eye) reflexes
Examination is of diagnostic value in coma (see p. 1172) and assessment of vertigo (see p. 809).

Abnormalities of vertical gaze
Failure of up-gaze may be caused by dorsal midbrain lesions, such as pinealoma or infarct. When the pupillary light reflex fails in addition, this is called Parinaud syndrome. Defective up-gaze also develops in certain degenerative disorders (e.g. progressive supranuclear palsy). Some impairment of up-gaze occurs as part of normal ageing.

Nystagmus
Nystagmus is rhythmic oscillation of eye movement; it is a sign of disease of the retina, cerebellum and/or vestibular systems and their connections. Nystagmus is either jerk or pendular. Nystagmus must be sustained within binocular gaze to be of diagnostic value; a few beats at the extremes of gaze are normal.

Jerk nystagmus
Jerk nystagmus (usual in neurological disease) is a fast/slow oscillation. This is seen in vestibular, VIIIth nerve, brainstem and cerebellar lesions. The direction of nystagmus is decided by the fast component, a reflex attempt to correct the slower, primary movement.

- **Horizontal or rotary jerk nystagmus** may be either of peripheral (vestibular) or central origin (VIIIth nerve, brainstem, cerebellum and connections).
  - In peripheral lesions, nystagmus is usually acute and transient (minutes or hours) and associated with severe prostrating vertigo.
  - In central lesions, nystagmus tends to be long-lasting (weeks, months or more). Vertigo caused by central lesions tends to wane after days or weeks, the nystagmus outlasting it.

- **Vertical jerk nystagmus** is typically caused by central lesions.

- **Down-beat jerk nystagmus** is a rarity caused by lesions around the foramen magnum (e.g. meningioma, cerebellar ectopia).

Pendular nystagmus
Pendular describes movements to and fro, similar in velocity and amplitude. Pendular nystagmus is usually vertical and present in all directions of gaze. The causes are generally ocular (e.g. poor visual fixation from longstanding, severe visual impairment) or congenital.

### III: Oculomotor nerve lesions

The nucleus of the IIIrd nerve lies ventral to the aqueduct in the midbrain. It supplies four external ocular muscles (superior, inferior and medial recti, and inferior oblique) and levator palpebrae superioris (which lifts the eyelid), and effects parasympathetic constriction of the pupil. Causes of a IIIrd nerve lesion are listed in **Box 21.12**.

<table>
<thead>
<tr>
<th><strong>Box 21.12</strong></th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Some causes of a IIIrd nerve lesion</strong></td>
</tr>
<tr>
<td>• Aneurysm of the posterior communicating artery</td>
</tr>
<tr>

</tr>
<tr>
<td>• Coning of the temporal lobe</td>
</tr>
<tr>
<td>• Midbrain infarction</td>
</tr>
<tr>
<td>• Midbrain tumour (primary or secondary)</td>
</tr>
</tbody>
</table>

Signs of a complete IIIrd nerve palsy include:

• unilateral complete ptosis (levator weakness)
• deviation of the eye down and out (unopposed lateral rectus and superior oblique)
• a fixed and dilated pupil.

Patients do not complain of diplopia as the ptosis effectively covers the eye. *Sparing of the pupil* indicates that parasympathetic fibres are undamaged; these run in a discrete bundle on the surface of the nerve, and so the pupil is of normal size and reacts normally. Diabetic IIIrd nerve infarction is usually painless and pupil-sparing, unlike compression by a posterior communicating artery aneurysm.

### IV: Trochlear nerve lesions

The trochlear nerve supplies the superior oblique muscle. The patient complains of torsional diplopia (two objects at an angle) when attempting to look down (e.g. descending stairs); the head is tilted away from that side. The most common cause is head injury, often with bilateral trochlear nerve palsies occurring.

### VI: Abducens nerve lesions
The abducens nerve supplies the lateral rectus muscle (abduction). Lesions cause horizontal diplopia when looking into the distance, which is maximal when looking to the side of the lesion. The eye cannot be fully abducted and an esotropia (inward eye deviation) may be visible in the primary position.

The VIth nerve has a long intracranial course. It can be damaged in the brainstem (e.g. by MS or infarction). In raised intracranial pressure, it is compressed against the tip of the petrous temporal bone (this may be bilateral). The nerve sheath may be infiltrated by tumours, particularly nasopharyngeal carcinoma. Microvascular ischaemia of the nerve may occur in diabetes with acute onset, followed by recovery within 3 months in most cases.

**Complete external ophthalmoplegia**

Complete external ophthalmoplegia describes an immobile eye when IIIrd, IVth and VIth nerves are paralysed at the orbital apex (e.g. by metastasis) or within the cavernous sinus (e.g. by sinus thrombosis or meningioma).

Wernicke's encephalopathy due to thiamine deficiency (see p. 885) may cause a complex eye movement disorder or complete ophthalmoplegia, as may neuromuscular junction disorders such as myasthenia, botulism and some myopathies or metabolic disorders.

**V: Trigeminal nerve**

The trigeminal is the largest cranial nerve; it is mainly sensory with a motor component to the muscles of mastication.

Sensory fibres (*Fig. 21.8*; see also *Figs 21.13* and 21.14) of the three divisions – ophthalmic (V₁), maxillary (V₂) and mandibular (V₃) – pass to the trigeminal (Gasserian) ganglion at the apex of the petrous temporal bone. Ascending fibres transmitting light touch enter the fifth nucleus in the pons. Descending central fibres carrying pain and temperature form the spinal tract of V, to end in the spinal fifth nucleus that extends from the medulla into the cervical cord.
Clinical features of a Vth nerve lesion

A complete Vth nerve lesion causes unilateral sensory loss on the face, scalp anterior to the vertex, and the anterior two-thirds of the tongue and buccal mucosa; the jaw deviates to that side as the mouth opens (motor fibres). Diminution of the corneal reflex is an early and sometimes isolated sign of a Vth nerve lesion.

Aetiology

- **Brainstem pathology** (infarction, demyelination or tumour) may damage the nucleus, with light touch and spinothalamic pathways sometimes being differentially involved.
- **Cerebellopontine angle tumours** (acoustic neuroma or meningioma) may compress the nerve and also affect the VIIth and VIIIth nerves, producing facial weakness and deafness.
- **Cavernous sinus and skull base pathology** (tumour or infection) may affect the ganglion and proximal branches.
- **Peripheral branches** may be picked off individually, e.g. the ‘numb chin syndrome’ seen with a breast cancer metastasis in the mandible.

Trigeminal neuralgia
Trigeminal neuralgia is discussed with facial pain (see p. 845).

### Trigeminal sensory neuropathy

This causes gradually progressive, unilateral, facial sensory loss and tingling with normal imaging. The condition is probably heterogeneous in aetiology but may have an autoimmune basis, with inflammation of the trigeminal ganglion, occurring mainly in association with mixed and undifferentiated connective tissue disease and primary Sjögren syndrome.

### VII: Facial nerve

The VIIth nerve is largely motor, supplying muscles of facial expression. It carries sensory taste fibres from the anterior two-thirds of the tongue via the chorda tympani and supplies motor fibres to the stapedius muscle. The VIIth nerve (Fig. 21.8) arises from its nucleus in the pons and leaves the skull through the stylomastoid foramen. Neurones in each VIIth nucleus supplying the upper face (principally frontalis) receive bilateral supranuclear innervation.

### Unilateral facial weakness

**Upper motor neurone (UMN) lesions.** These cause weakness of the lower part of the face on the opposite side. Frontalis is spared: normal furrowing of the brow is preserved; eye closure and blinking are largely unaffected. The earliest sign is slowing of one side of the face: for example, on baring the teeth. There is sometimes relative preservation of spontaneous emotional movement (e.g. smiling) compared with voluntary movement.

**Lower motor neurone (LMN) lesions.** A complete unilateral LMN VIIth lesion causes weakness (ipsilateral) of all facial expression muscles. The angle of the mouth falls; unilateral dribbling develops. Frowning (frontalis) and eye closure are weak. Corneal exposure and ulceration occur if the eye does not close during sleep. Taste sensation is frequently also impaired.

### Causes of facial weakness

The most common cause of a UMN lesion is hemispheric stroke with hemiparesis on the opposite side. At lower levels, lesion sites are recognized by LMN weakness with additional signs.

**Pons.** Here the VIIth nerve loops around the VIth (abducens) nucleus (Fig. 21.8), leading to a lateral rectus palsy (see p. 806) with unilateral LMN facial weakness. When the neighbouring PPRF and corticospinal tract are involved, there is the combination of:

- LMN facial weakness
- failure of conjugate lateral gaze (towards lesion)
- contralateral hemiparesis.

Causes include pontine tumours (e.g. glioma), MS and infarction.
**Cerebellopontine angle (CPA).** The neighbouring Vth, VIth and VIIIth nerves are compressed with VII in the CPA: for example, by acoustic neuroma, meningioma or metastasis.

**Petrous temporal bone.** The nerve may be damaged within the bony facial canal, within which lies the sensory geniculate ganglion (receiving taste fibres from the anterior two-thirds of the tongue via the chorda tympani). As well as LMN facial weakness, lesions in this region cause:

- loss of taste on the anterior two-thirds of the tongue
- hyperacusis (loud noise distortion – paralysis of stapedius).

Causes include:

- Bell's palsy
- trauma
- middle ear infection
- herpes zoster (Ramsay Hunt syndrome; see p. 808)

**Skull base, parotid gland and within the face.** The facial nerve can be compressed by skull base tumours and in Paget's disease of bone. Branches of VII may be damaged by parotid gland tumours as the nerve traverses the parotid, and by sarcoidosis (see pp. 1118–1120) and trauma.

**Bell's palsy**

This common (37 per 100,000 incidence), acute facial palsy is thought to be due to viral infection/reactivation (often herpes simplex) causing swelling of nerve within the tight petrous bone facial canal. Unilateral LMN facial weakness develops over 24–48 hours, sometimes with lost or altered taste on the tongue, and hyperacusis. Pain behind the ear is common at onset. Patients often suspect a stroke and may be very distressed. Vague altered facial sensation is often reported, although examination of facial sensation is normal.

Diagnosis is made on clinical grounds and tests are usually not required. The ear (and palate) should be examined for vesicles (see Ramsay Hunt syndrome below), hearing loss or evidence of local pathology such as cholesteatoma or malignant otitis externa; parotid tumours should be excluded. Involvement of other cranial nerves means facial weakness is not due to Bell's palsy. Lyme disease may account for one-quarter of cases of facial palsy in endemic areas and HIV seroconversion is the most common cause in parts of Africa.

*(Bell's phenomenon is the upward conjugate eye movement that occurs normally when the eyes are closed but is accentuated when the orbicularis oculi muscle is weak.)*

**Management and prognosis**

Complete, or almost complete, recovery over 4–12 weeks occurs in at least 85% of patients, even without specific treatment. Patients should be reassured that the prognosis is good and that the condition is unlikely to recur.

Inability to blink in severe facial weakness may lead to exposure keratitis. Use of
lubricating eye ointment is often required and patients should be advised to tape the eye closed carefully at night. For more severe facial weakness with complete inability to close the eye, early ophthalmological assessment is necessary and lateral tarsorrhaphy and/or insertion of a gold weight into the upper lid may be required until recovery occurs.

Early treatment with corticosteroids (prednisolone 50 mg for 10 days) improves outcome if started within 72 hours of onset. The latest evidence does not support use of antiviral agents.

Recovery sometimes takes up to a year if axons have to regrow rather than just remyelinate, in which case aberrant re-innervation of facial muscles (e.g. mouth twitching with blinking) is a frequent late complication. Plastic surgery may be helpful where recovery is not complete. Bell's palsy rarely recurs; if it does, this should prompt a search for an alternative cause.

**Ramsay Hunt syndrome**

This is herpes zoster (shingles) of the geniculate ganglion. There is a facial palsy (identical to Bell's) with vesicles around the external auditory meatus and/or the soft palate (sensory twigs from VII). Deafness and vertigo/unsteadiness may occur. Complete recovery is less likely than in Bell's. Antiviral treatment (aciclovir/valaciclovir) is usually given with steroids.

**Bilateral facial weakness**

Bilateral facial palsy is rare, accounting for less than 1% of cases of facial palsy, but is more likely than unilateral palsies to have an identifiable underlying cause. Paradoxically, bilateral weakness is often less obviously apparent than unilateral weakness, as there is no facial asymmetry.

Causes include:

- infections:
  - Lyme disease (bilateral in 25% – Bannwarth syndrome)
  - viral: human immunodeficiency virus (HIV) seroconversion, Epstein–Barr virus
  - mastoiditis (bilateral)
  - diphtheria and botulism (rare)
- sarcoidosis
- skull-base trauma and tumours
- pontine lesions, e.g. gliomas
- neuromuscular disorders as part of more generalized weakness:
  - Guillain–Barré syndrome
  - myasthenia
  - myotonic dystrophy and facioscapulohumeral dystrophy
- congenital and genetic causes (Gelsolin gene mutations).

**Hemifacial spasm**
Hemifacial spasm (HFS) is an irregular, painless unilateral spasm of facial muscles, usually occurring after middle age. It starts in the orbicularis oculi and usually progresses gradually over the years to involve other facial muscles on the same side. It varies from a mild to a severe, disfiguring spasm.

HFS is usually caused by compression of the root entry zone of the facial nerve, generally by vascular structures such as the vertebral or basilar arteries or their branches (a mechanism similar to that of trigeminal neuralgia; see p. 845). Other mass lesions in the cerebellopontine angle, including tumours, are the cause in approximately 1% of cases.

Occasionally, HFS may occur with ipsilateral trigeminal neuralgia, one symptom usually preceding the other: a combination called tic convulsif. The paroxysms of pain and spasm occur independently. A compressive cause, such as a vascular loop or other structural lesion, is usually identified.

**Management**

Mild cases require no treatment. Botulinum toxin injection into affected muscles every 3–4 months is now the standard treatment. Drugs (e.g. carbamazepine) are of little value. Decompression of the VIIth nerve in the CPA is sometimes helpful. Surgical decompression of the facial nerve in the posterior fossa involves interposing a non-resorbable sponge between the nerve and any adjacent vascular loop identified at operation. The procedure results in complete resolution of symptoms in up to 90% of cases but is associated with a risk of facial weakness or deafness.

**Other involuntary facial movements**

*Myokymia of orbicularis oculi* is an irritating twitch, usually of the lower eyelid. It is a normal phenomenon but sometimes a cause of anxiety. More extensive facial myokymia may result from intrinsic brainstem pathology.

*Tics and tardive dyskinesia* frequently involve facial or perioral muscles (see pp. 856–857).

*Blepharospasm* is a form of focal dystonia affecting orbicularis oculi (see p. 857).

**VIII: Vestibulo-cochlear nerve and cochlear nerve**

Auditory fibres from the spiral organ of Corti within the cochlea pass to the cochlear nuclei in the pons. Fibres from these nuclei cross the midline and pass upwards via the medial lemnisci to the medial geniculate bodies and then to the temporal cortex.

Symptoms of a cochlear nerve lesion are deafness and tinnitus (see p. 1317). Sensorineural and conductive deafness can be distinguished with tuning fork tests, e.g. Rinne's and Weber's (using a 256 Hz, not 128 Hz, tuning fork; see p. 1313).

**Basic investigations of cochlear lesions**
• Pure tone audiometry and auditory thresholds.
• Auditory evoked potentials (recording responses from repetitive clicks via scalp electrodes; lesion levels are determined from the response pattern).

Causes of deafness
These are listed in Box 21.13 and Box 30.2.

D, hearing loss; V, vertigo.

Vertigo and the vestibular system
The vestibular system of the inner ear detects head movements and has three primary functions:
• to stabilize gaze during head movements, e.g. looking ahead while running (the vestibulo-ocular reflex)
• to control posture and balance
• to facilitate perception of orientation and motion.

Nerve impulses generated by movement of hair cells within the three semicircular canals detect head motion in the three planes (yaw/pitch/roll). Balance is maintained by integrating
information from:
• the vestibular system
• the visual system
• the somatosensory system – proprioception from limbs, trunk and neck.

The **main symptoms** of vestibular lesions are vertigo and loss of balance.

---

**Vertigo**

Vertigo is the illusion of movement of the subject or surroundings, typically rotatory, and should be distinguished from other causes of non-specific dizziness. It can be described to patients as being similar to the sensation one feels after getting off a child's roundabout or after spinning on the spot and suddenly stopping.

Vomiting frequently accompanies acute vertigo of any cause. Vertigo is always made worse by head movements and patients prefer to remain still and maintain visual fixation. Walking is unsteady. Nystagmus (see p. 806) is the principal sign.

**The dizzy patient**

Complaints of ‘dizziness’ require careful history taking and may be caused by:
• vertigo
• pre-syncopal sensations due to transient cerebral hypoperfusion, e.g. orthostatic light-headedness
• unsteadiness or disequilibrium, e.g. cerebellar or postural stability disorders
• non-specific ‘dizziness’, e.g. due to medication or anxiety and hyperventilation.

**Causes of vertigo**

Vertigo indicates a disturbance of the vestibular apparatus or brainstem and associated neural pathways (Box 21.13). Causes:

• **Peripheral causes** (vestibular system) are common. Deafness and tinnitus accompanying vertigo indicate involvement of the ear or cochlear nerve (see pp. 1313–1317).

• **Central causes** (brainstem and connections) are rarer. Other clinical features, such as diplopia, weakness, cerebellar signs or cranial nerve palsies, may help localize the lesion.

---

**Peripheral (vestibular) disorders**

Vestibular disorders are fully discussed elsewhere (see pp. 1316–1317). Attack duration and frequency, as well as trigger factors, help the clinician distinguish on history between different pathological causes. The ability to perform a Hallpike test (see pp. 1316–1317), head impulse test and Epley particle repositioning manoeuvre are invaluable skills for all clinicians (see pp. 1316–1317; **Fig. 21.9** and see **Fig. 30.8**).
The most commonly encountered vestibular disorders presenting with vertigo are:

- **benign paroxysmal positional vertigo** (BPPV) – frequent attacks lasting seconds only (see pp. 1316–1317).
- **vestibular neuronitis** – acute onset lasting days or weeks; non-recurrent
- **Ménière’s disease** – recurrent attacks lasting minutes or hours, usually accompanied by hearing loss, tinnitus and a feeling of fullness in the ear
- **trauma** – vestibular disruption following head injury.

### Central causes of vertigo

Vertigo may be a manifestation of brainstem pathology, including:

- **infarcts involving the vestibular nuclei** in the medulla (e.g. the lateral medullary syndrome)
- **demyelination** involving the brainstem
- **posterior fossa mass lesions** – e.g. tumours, haemorrhage or vascular malformations
- **migrainous vertigo** (see p. 843) – lasts hours, occurring every few weeks or months
- **CPA mass lesions** and tumours compressing the vestibular nerve (technically, these should be classified as ‘peripheral’ disorders, but are distinct from disorders of the vestibular apparatus)
- **drugs** – e.g. anticonvulsant toxicity and alcohol.

Although vertigo occasionally occurs in isolation with brainstem pathology, it is more typically a single component of a more complex clinical picture, associated with other symptoms or examination findings. The brainstem nuclei and tracts are tightly packed into a small space and most pathological processes affect multiple contiguous neural pathways, resulting, for example, in diplopia, eye movement disorders, cranial nerve palsies, cerebellar signs or hemiparesis.

Slowly growing CPA tumours, such as vestibular nerve schwannomas, may cause vertigo but rarely do so in the absence of unilateral deafness and tinnitus.
**Basic investigations for vestibular problems**

Bedside assessment is usually sufficient to make a diagnosis in the majority of patients:

- examination of eye movements for nystagmus (see p. 806)
- assessment of hearing and otoscopic examination of the ear (see p. 808)
- head impulse (thrust) test – to assess the vestibulo-ocular reflex (VOR) and identify a unilateral vestibulopathy
- Hallpike manoeuvre – a positioning test to stimulate the posterior semicircular canal and trigger an attack in BPPV (see *Fig. 30.8*).

Specialist testing is occasionally required to assess vestibular function and hearing. This includes:

- caloric testing – irrigation of the external auditory meatus with cold and then warm water to stimulate the horizontal semicircular canal and induce nystagmus; labyrinthine function is tested in each ear separately
- electro-nystagmography – to quantify and characterize nystagmus under different conditions, e.g. in a rotating chair
- posturography – assesses body sway on a moving platform
- pure-tone audiograms
- high-definition MRI – provides the best structural imaging of the brainstem and CPA, and is useful where a central cause of vertigo is suspected.

**Vestibular neuronitis**

Vestibular neuronitis is a common but poorly understood problem. It is an acute attack of isolated vertigo with nystagmus, often with vomiting, and is believed to follow viral infections. The disturbance lasts for several days or weeks, is self-limiting and rarely recurs. Vestibular neuronitis is sometimes followed by BPPV (see pp. 1316–1317). Deafness is absent. Acute treatment is with vestibular sedatives. Similar symptoms can be caused by MS or brainstem vascular lesions. Other signs are usually apparent.

**Lower cranial nerves IX, X, XI, XII**

The glossopharyngeal (IX), vagus (X) and accessory (XI) nerves arise in the medulla and leave the skull through the jugular foramen. The hypoglossal (XII) arises in the medulla, to leave the skull base via the hypoglossal foramen. Outside the skull, the four cranial nerves lie together, close to the carotid artery and sympathetic trunk.

**Glossopharyngeal (IX)**

This nerve is largely sensory, supplying sensation and taste from the posterior third of the
tongue and the pharynx (afferent pathway of gag reflex). Motor fibres supply some pharyngeal muscles, and parasympathetic fibres supply the parotid.

**Vagus (X)**

The vagus is a mixed nerve, largely motor, which supplies striated muscle of the pharynx (efferent gag reflex pathway), larynx (including vocal cords via recurrent laryngeal nerves) and upper oesophagus. There are sensory fibres from the larynx. Parasympathetic fibres supply the heart and abdominal viscera.

**Accessory (XI)**

The accessory nerve, a complex motor nerve, supplies the trapezius and sternomastoid muscles.

**Hypoglossal (XII)**

The hypoglossal nerve is a motor nerve to tongue muscles.

---

**IXth and Xth nerve lesions**

Principal causes of IXth, Xth, XIth and XIIth nerve lesions are listed in *Box 21.14*.

---

**Box 21.14**

**Principal causes of IXth, Xth, XIth and XIIth nerve lesions**

**Within brainstem**

- Infarction
- Syringobulbia
- Motor neurone disease (motor fibres)

**Around skull base**

- Nasopharyngeal carcinoma
- Glomus tumour
- Neurofibroma
- Jugular venous thrombosis
- Trauma

**Within neck and nasopharynx**

- Nasopharyngeal carcinoma
- Metastases
- Carotid artery dissection (XII)
Isolated lesions of IXth and Xth nerves are unusual, since disease at the jugular foramen affects both nerves and sometimes XI.

A unilateral IXth nerve lesion causes diminished sensation on the same side of the pharynx and is hard to recognize in isolation. A Xth nerve palsy produces ipsilateral failure of voluntary and reflex elevation of the soft palate (which is drawn to the opposite side) and ipsilateral vocal cords.

Bilateral lesions of IXth and Xth nerves cause palatal weakness, reduced palatal sensation, an absent gag reflex, dysphonia and choking with nasal regurgitation. **Bulbar palsy** is a general term describing palatal, pharyngeal and tongue weakness of LMN or muscle origin.

**Recurrent laryngeal nerve lesions.** Paralysis of this branch of each vagus causes hoarseness (dysphonia) and failure of the forceful, explosive part of coughing (‘bovine cough’). There is no visible palatal weakness; vocal cord paralysis is seen endoscopically. Bilateral acute lesions (e.g. postoperatively) cause respiratory obstruction – an emergency.

The left recurrent laryngeal nerve (looping beneath the aorta) is damaged more commonly than the right.

Causes of recurrent laryngeal nerve lesions include:

- mediastinal primary tumours (e.g. thymoma)
- secondary spread from bronchial carcinoma
- aortic aneurysm
- trauma or surgery of neck or thorax.

### IXth nerve lesions

IXth nerve lesions cause weakness of sternomastoid (rotation of the head and neck to the opposite side) and trapezius (shoulder shrugging). Nerve section (e.g. following lymph node biopsy in the neck posterior triangle) is followed by persistent neuralgic pain.

### XIIth nerve lesions

LMN lesions of XII lead to unilateral tongue weakness, wasting and fasciculation. The protruded tongue deviates towards the weaker side. Bilateral supranuclear (UMN) lesions produce slow, limited tongue movements and a stiff tongue that cannot be protruded far. Fasciculation is absent.

### Bulbar and pseudobulbar palsy
Bulbar palsy
This is LMN weakness of muscles whose cranial nerve nuclei lie in the medulla (the bulb). Paralysis of bulbar muscles is caused by disease of lower cranial nerve nuclei, lesions of IXth, Xth and XIIth nerves (*Box 21.14*), malfunction of their neuromuscular junctions (e.g. myasthenia gravis, botulism) or disease of muscles themselves (e.g. dystrophies).

Pseudobulbar palsy
Describes bilateral supranuclear (UMN) lesions of lower cranial nerves producing weakness of the tongue and pharyngeal muscles. This resembles, superficially, a bulbar palsy: hence pseudobulbar. Findings are a stiff, slow, spastic tongue (not wasted), dysarthria and dysphagia. Gag and palatal reflexes are preserved and the jaw jerk exaggerated. Emotional lability (inappropriate laughing or crying) often accompanies pseudobulbar palsy. Principal causes are:

- motor neurone disease, often both UMN and LMN lesions (i.e. elements of both pseudobulbar and bulbar palsy)
- cerebrovascular disease, typically following multiple infarcts
- neurodegenerative disorders such as progressive supranuclear palsy (see p. 855)
- severe traumatic brain injury
- MS, mainly as a late event.

Difficulty swallowing, dysarthria and drooling also develop in later stages of Parkinson's disease.

Dropped head syndrome
As the name suggests, weakness of neck extensors causes neck flexion and inability to hold the head up. Seen mainly in the elderly, it is often due to isolated neck extensor myopathy of uncertain cause but may be a presenting feature of motor neurone disease, myasthenia or various myopathic disorders.

Further reading

Motor Control Systems
There are three systems, each of which interacts by feedback loops with the other two, with sensory input from the reticular formation:

- *The corticospinal (or pyramidal) system* enables purposive, skilled, intricate, strong and organized movements. Defective function is recognized by a distinct pattern of signs – loss of skilled voluntary movement, spasticity and reflex change – seen, for example, in a
hemiparesis, hemiplegia or paraparesis.

- **The extrapyramidal system** facilitates fast, fluid movements that the corticospinal system has generated. Defective function produces slowness (bradykinesia), stiffness (rigidity) and/or disorders of movement (rest tremor, chorea and other dyskinesias). One feature (e.g. stiffness, tremor or chorea) will often predominate.

- **The cerebellum** and its connections have a role coordinating smooth and learned movement, initiated by the pyramidal system, and in posture and balance control. Cerebellar disease leads to unsteady and jerky movements (ataxia), with characteristic limb signs of past-pointing, action tremor and incoordination, gait ataxia and/or truncal ataxia.

**Corticospinal (pyramidal) system**

The corticospinal tracts originate in neurones of the cortex and terminate at motor nuclei of cranial nerves and spinal cord anterior horn cells. The pathways of particular clinical significance (*Fig. 21.10*) congregate in the internal capsule and cross in the medulla (decussation of the pyramids), passing to the contralateral cord as the lateral corticospinal tracts. This is the pyramidal system, disease of which causes UMN lesions. ‘Pyramidal’ is simply a descriptive term that draws together anatomy and characteristic physical signs; it is used interchangeably with the term UMN.
A proportion of the corticospinal outflow is uncrossed (anterior corticospinal tracts). This is of no relevance in practice.

**Characteristics of pyramidal lesions**

Signs of an early pyramidal lesion may be minimal *(Box 21.15)*. Weakness, spasticity or changes in reflexes can predominate, or be present in isolation.
Features of upper motor neurone lesions

- Drift of upper limb
- Weakness with characteristic distribution
- Changes in tone: flaccid–spastic
- Exaggerated tendon reflexes
- Extensor plantar response
- Loss of skilled finger/toe movements
- Loss of abdominal reflexes
- No muscle wasting
- Normal electrical excitability of muscle

Pyramidal drift of an upper limb

Normally, the outstretched upper limbs are held symmetrically, when the eyes are closed. With a pyramidal lesion, when both upper limbs are held outstretched, palms uppermost, the affected limb drifts downwards and pronates. This sign, with slowing of fast finger movements, is an early one, sometimes occurring before weakness and/or reflex changes become apparent.

Weakness and loss of skilled movement

A unilateral pyramidal lesion above the decussation in the medulla causes weakness of the opposite limbs. When acute and complete, this weakness will be immediate and total: a hemiplegia – for example, following an internal capsule infarct. With slowly progressive lesions (e.g. a hemisphere glioma), a characteristic pattern of weakness emerges: a hemiparesis.

In the upper limb, flexors remain stronger than extensors, whereas in the lower limb, extensors remain stronger than flexors. In the upper arm, weaker movements are thus shoulder abduction and elbow extension; in the forearm and hand, wrist and finger extensors and abductors are weaker than their antagonists. In the lower limb, weaker movements are hip flexion, knee flexion, ankle dorsiflexion and eversion. There is also loss of skilled movement; fine finger and toe control diminishes. Wasting (except from disuse) is not a feature. When a UMN lesion is below the decussation of the pyramids – in the cervical cord, for example – hemiparesis is on the same side as the lesion; this is an unusual situation.

Changes in tone and tendon reflexes

An acute lesion of one pyramidal tract (e.g. internal capsule stroke) causes initially flaccid paralysis with loss of tendon reflexes. Increase in tone follows, usually within several days, due to loss of inhibitory effects of the corticospinal pathways and an increase in spinal reflex activity. This increase in tone (spasticity) is most easily detectable in stronger muscles. Spasticity is characterized by sudden changing resistance to rapid passive movement – the
clasp-knife effect. Relevant tendon reflexes become exaggerated; clonus may emerge.

Changes in superficial reflexes

The normal flexor plantar response becomes extensor. In a severe acute lesion, this extensor response can be elicited from a wide area of the foot. As recovery progresses, the receptive area diminishes until the lateral posterior third of the sole remains receptive to an orange-stick stimulus (the appropriate instrument). An extensor plantar response is certain when great toe dorsiflexion is accompanied by abduction of adjacent toes. Abdominal reflexes are abolished on the affected side.

Patterns of UMN disorders

There are three main patterns:

• **Hemiparesis** means weakness of the limbs on one side; it is usually caused by a lesion in the brain and occasionally in the cord.

• **Paraparesis** means weakness of both lower limbs and is usually diagnostic of a cord lesion; bilateral medial brain lesions (e.g. parasagittal meningioma) occasionally cause paraparesis.

• **Tetraparesis** (also called **quadriparesis**) means weakness of four limbs.

Hemiparesis, paraplegia and tetraplegia (strictly) indicate total paralysis but are often used to describe severe weakness.

Hemiparesis

The level within the corticospinal system is recognized from particular features.

**Motor cortex.** Weakness and/or loss of skilled movement confined to one contralateral limb (an arm or a leg – monoparesis) or part of a limb (e.g. a clumsy hand) is typical of an isolated motor cortex lesion (e.g. an infarct or secondary neoplasm). A defect in cognitive function (e.g. aphasia) and focal epilepsy may occur.

**Internal capsule.** Corticospinal fibres are tightly packed in the internal capsule (about 1 cm²); thus a small lesion causes a large deficit. A middle cerebral artery branch infarction (see p. 833) produces a sudden, dense, contralateral hemiplegia.

**Pons.** A pontine lesion (e.g. an MS plaque) is rarely confined to the corticospinal tract. Adjacent structures, e.g. VIth and VIIth nuclei, MLF and PPRF (see p. 805) are involved. Diplopia, facial weakness, internuclear ophthalmoplegia (INO) and/or a lateral gaze palsy occur with contralateral hemiparesis.

**Spinal cord.** An isolated lesion of one lateral corticospinal tract (e.g. a cervical cord injury) causes an ipsilateral UMN lesion, the level being indicated by changes in reflexes (e.g. absent biceps, C5/6), features of a Brown–Séquard syndrome (see p. 817) and muscle wasting at the level of the lesion (p. 818).
Paraparesis indicates bilateral damage to corticospinal pathways, causing weakness and spasticity (or flaccid weakness in the initial phase of spinal shock after an acute cord insult). Cord compression (see pp. 872–873) or cord diseases are the usual causes; cerebral lesions occasionally produce paraparesis. Paraparesis is a feature of many neurological conditions; finding the cause is crucial (see p. 872).

**Extrapyramidal system**

The extrapyramidal system is a general term for basal ganglia motor systems: that is, corpus striatum (caudate nucleus + globus pallidus + putamen), subthalamic nucleus, substantia nigra and parts of the thalamus. In basal ganglia/extrapyramidal disorders, two features (either or both) become apparent, in limbs and axial muscles:

- reduction in speed of movement (**bradykinesia**) or akinesia (no movement), with muscle rigidity
- involuntary **hyperkinetic** movements (tremor, chorea, dystonia, tics, myoclonus).

Extrapyramidal disorders are classified broadly into **akineti–rigid syndromes** (see p. 855) where poverty of movement predominates, and **hyperkinetic** movement disorders where there are abnormal involuntary movements (see pp. 855–857).

The most common extrapyramidal disorder is Parkinson's disease.

**Essential anatomy**

The corpus striatum lies close to the substantia nigra, thalami and sub-thalamic nuclei, lateral to the internal capsule (**Fig. 21.11**; see **Fig. 21.10**).
Function and dysfunction

Overall function of this system is modulation of cortical motor activity by a series of loops between cortex and basal ganglia (Fig. 21.11). In involuntary movement disorders, there are specific changes in neurotransmitters (Box 21.16) rather than focal lesions seen on imaging or at postmortem.

Box 21.16

Changes in neurotransmitters in Parkinson's and Huntington's diseases
Proposed model of principal pathways

1. Direct pathway from striatum to medial globus pallidus (GPm) and substantia nigra pars reticulata (SNr). Inhibitory synapse F, GABA and substance P.
2. Indirect pathway from striatum to globus pallidus, via lateral globus pallidus (GPl; inhibitory synapse C, GABA, enkephalin) and subthalamic nucleus (inhibitory synapse D, GABA). Terminates in GPm-SNr (in excitatory synapse E, glutamate).
3. Direct pathways, both inhibitory and excitatory, from substantia nigra pars compacta (SNc) to striatum. Synapse A, dopamine, D₁, excitatory; and synapse B, D₂, inhibitory.
4. GPm and SNr to thalamus. Inhibitory synapse G, GABA.
5. Thalamus to cortex. Excitatory, synapse H.

The model helps explain how basal ganglia disease can either reduce excitatory thalamocortical activity at synapse H – that is, movement – causing bradykinesia, or increase it, causing hyperkinetic disorders.

**Parkinson's disease (PD).** This is characterized by slowness, stiffness and rest tremor (see p. 853). Degeneration in SNc causes loss of dopamine activity in the striatum. Dopamine is excitatory for synapse A and inhibitory for synapse B. Through the direct pathway there is reduced activity at synapse F, leading to increased inhibitory output (G) and decreased cortical activity (H).

Also in PD, in the indirect pathway, dopamine deficiency results in disinhibition of neurones synapsing at C. This leads to reduced activity at D, and to increased activity of neurones in the subthalamic nucleus. There is excess stimulation at synapse E, enhancing further inhibitory output of GPm–SNr.

The net effect via both pathways is to inhibit the ventral anterior (VA) and ventrolateral (VL) nuclei of the thalamus at synapse G. Cortical (motor) activity at H is thus reduced.

Levodopa helps slowness and tremor in PD (see p. 854) but induces unwanted dyskinesias.
by increasing dopamine activity at synapses A and B; it is thought to do this by reversing sequences in both direct and indirect pathways.

**Hemiballismus** (see p. 856). Wild, flinging (ballistic) limb movements are caused by a lesion in the subthalamic nucleus, typically an infarct. This reduces excitatory activity at synapse E, reduces inhibition at G, with increased thalamo-cortical neuronal activity, and increases activity at H.

**Cerebellum**

The third system of motor control modulates coordination and learned movement patterns, rather than speed. Ataxia, i.e. unsteadiness, is characteristic.

The cerebellum receives afferents from:

- proprioceptive receptors (joints and muscles)
- vestibular nuclei
- basal ganglia
- the corticospinal system
- olivary nuclei.

Efferents pass from the cerebellum to:

- each red nucleus
- vestibular nuclei
- basal ganglia
- the corticospinal system.

Each lateral cerebellar lobe coordinates movement of the ipsilateral limbs. The vermis (a midline structure) is concerned with maintenance of axial (midline) posture and balance.

---

**Cerebellar lesions**

*Box 21.17* summarizes the main causes of cerebellar disease. Expanding lesions obstruct the aqueduct to cause hydrocephalus, with severe pressure headaches, vomiting and papilloedema. Coning of the cerebellar tonsils (see p. 869) through the foramen magnum leads to respiratory arrest, sometimes within minutes/hours. Rarely, tonic seizures (attacks of limb stiffness) occur.

---

**Box 21.17**

**Principal causes of cerebellar syndromes**

**Tumours**

- Haemangioblastoma
- Medulloblastoma
- Secondary neoplasm
- Compression by acoustic neuroma

**Vascular**
- Haemorrhage
- Infarction
- Arteriovenous malformation

**Infection**
- Abscess
- HIV
- Prion diseases
- Encephalitis

**Developmental**
- Arnold–Chiari malformation
- Cerebral palsy

**Toxic and metabolic**
- Antiepileptic drugs
- Chronic alcohol use
- Carbon monoxide poisoning
- Lead poisoning
- Solvent misuse

**Inherited**
- Friedreich's and other spinocerebellar ataxias
- Ataxia telangiectasia

**Miscellaneous**
- Multiple sclerosis (common in MS)
- Hydrocephalus
- Hypothyroidism
- Paraneoplastic syndromes (rapidly progressive)
- Multiple system atrophy
- Superficial siderosis

**Lateral cerebellar hemisphere lesions**
A lesion within one cerebellar lobe (e.g. tumour or infarction) causes disruption of the normal
sequence of movements (dyssynergia) on the same side.

**Posture and gait.** The outstretched arm is held still in the early stages of a cerebellar lobar lesion (cf. the drift of pyramidal lesions) but there is rebound upward overshoot when the limb is pressed downwards and released. Gait becomes broad and ataxic, faltering towards the side of the lesion.

**Tremor and ataxia.** Movement is imprecise in direction, force and distance (dysmetria). Rapid alternating movements (tapping, clapping or rotary hand movements) become disorganized (dysdiadochokinesia). Intention tremor (action tremor with past-pointing) is seen, but speed of fine movement is preserved (cf. extrapyramidal and pyramidal lesions).

**Nystagmus.** Coarse horizontal nystagmus (see p. 806) develops with a lateral cerebellar lobe lesion. The fast component is always towards the side of the lesion.

**Dysarthria.** Halting, jerking speech (scanning speech) develops.

**Other signs.** Titubation – rhythmic head tremor as either forward and back (yes–yes) movements or rotary (no–no) movements – can occur, mainly when cerebellar connections are involved (e.g. in essential tremor and MS; see pp. 856 and 858–862). Hypotonia (floppy limbs) and depression of reflexes (with slow, pendular reflexes) are also sometimes seen.

### Midline cerebellar lesions

Cerebellar vermis lesions have dramatic effects on trunk and axial muscles. There is difficulty standing and sitting unsupported (truncal ataxia), with a broad-based, ataxic gait. Lesions of the flocculonodular region cause vertigo and vomiting with gait ataxia if they extend to the roof of the IVth ventricle.

### Tremor

Tremor means a regular and sinusoidal oscillation of the limbs, head or trunk.

**Postural tremor**

Everyone has a physiological tremor (often barely perceptible) of the outstretched hands at 8–12 Hz. This is increased with anxiety, caffeine, hyperthyroidism and drugs (e.g. sympathomimetics, sodium valproate, lamotrigine, lithium) and occurs in mercury poisoning. A higher-amplitude, postural tremor is seen in benign essential tremor (usually quite fast at 5–12 Hz).

**Intention tremor**

Tremor exacerbated by action, with past-pointing and accompanying incoordination of rapid alternating movement (dysdiadochokinesia), occurs in cerebellar lobe disease and with lesions of cerebellar connections. Titubation (head tremor) and nystagmus may be present.
### Rest tremor

Seen typically in Parkinson's disease, this tremor is noticeably worse at rest, usually 4–7 Hz (often pill-rolling, between thumb and forefinger). Unlike essential tremor, Parkinsonian tremor is generally unilateral for the first few years.

### Other tremors

Dystonic tremor occurs after the age of 50 and is a manifestation of dystonia that is often seen without dystonic posturing. It is generally unilateral (or asymmetric), affecting hand/arm or head, and worse with posture and certain tasks such as drinking, pouring liquids, or using cutlery or a pen. It is often mistaken for parkinsonian tremor. Holmes tremor (present at rest, action and posture) is seen following lesions of the red nucleus (e.g. infarction, multiple sclerosis).

### Lower Motor Neurone Lesions

The lower motor neurone (LMN) is the pathway from anterior horn cell (or cranial nerve nucleus) via a peripheral nerve to muscle motor end-plates. The motor unit consists of one anterior horn cell, its single fast-conducting axon that leaves the cord via the anterior root, and the group of muscle fibres (100–2000) supplied via the nerve. Anterior horn cell activity is modulated by impulses from:

- corticospinal tracts
- the extrapyramidal system
- the cerebellum
- afferents via posterior roots.

### Clinical features of lower motor neurone lesions

These are seen in voluntary muscles that depend on an intact nerve supply for both contraction and metabolic integrity. Signs follow rapidly if the LMN is interrupted (Box 21.18).

#### Box 21.18

**Features of lower motor neurone lesions**

- Weakness
- Wasting
- Hypotonia
- Reflex loss
- Fasciculation
- Fibrillation potentials (electromyography)
- Muscle contractures
- Trophic changes in skin and nails

### Aetiology

Examples of LMN lesions at various levels include:
- cranial nerve nuclei (Bell's palsy) and anterior horn cell (motor neurone disease)
- spinal root – **radiculopathy**, e.g. cervical and lumbar disc protrusion (see p. 887)
- peripheral (or cranial) nerve – trauma, entrapment (see pp. 882–883) and polyneuropathy (pp. 883–886).

### Spinal reflex arc

Components are illustrated in **Figure 21.12**. The stretch reflex is the physiological basis for all tendon reflexes. In the knee jerk, a tap on the patellar tendon activates stretch receptors in the quadriceps. Impulses in first-order sensory neurones pass directly to LMNs (L3 and L4) that contract quadriceps. Loss of a tendon reflex is caused by a lesion anywhere along the spinal reflex path. The reflex lost indicates its level (**Box 21.19**).

![Figure 21.12](image-url)  
**Knee jerk: a spinal reflex arc.** Sudden patellar tendon stretching generates sensory action potentials in 1α-muscle spindle afferents that synapse with γ-motor fibres to spindles and α-motor fibres. Motor action potentials cause brisk extensor muscle contraction; there is also inhibition of knee flexors.
