**Reinforcement.** Distraction of the patient's attention, clenching teeth or pulling interlocked fingers enhances reflex activity (Jendrassik manœuvre). Such reinforcement manoeuvres should be done before a reflex is recorded as absent.

**Sensory Pathways and Pain**

**Peripheral nerves and spinal roots**

Peripheral nerves carry all modalities of sensation from either free or specialized nerve endings to dorsal roots and thence to the cord. Sensory distribution of spinal roots (dermatomes) is shown in *Figure 21.13*. 
Spinal cord

**Posterior columns**

Axons in the posterior columns whose cell bodies are in the ipsilateral gracile and cuneate nuclei in the medulla carry sensory modalities of vibration, joint position (proprioception), light touch and two-point discrimination. Axons from second-order neurones then cross in the brainstem to form the medial lemniscus, passing to the thalamus (Fig. 21.14).
Spinothalamic tracts
Axons carrying pain and temperature sensation synapse in the dorsal horn of the cord, cross within the cord, and pass in the spinothalamic tracts to the thalamus and reticular formation.

Sensory cortex
Fibres from the thalamus pass to the parietal region sensory cortex \((\text{Fig. 21.14})\). Connections exist between the thalamus, sensory cortex and motor cortex.

Lesions of the sensory pathways
Altered sensation, tingling (paraesthesia), clumsiness, numbness and pain are the principal symptoms of sensory lesions. The pattern and distribution point to the site of pathology \((\text{Fig. 21.15})\).

Peripheral nerve lesions

Symptoms are felt within the distribution of a peripheral nerve (see pp. 881–888). Section of a sensory nerve is followed by complete sensory loss. Nerve entrapment (see pp. 882–883) causes numbness, pain and tingling. Tapping the site of compression sometimes causes a sharp, electric shock-like pain in the distribution of the nerve, known as Tinel’s sign, such as in carpal tunnel syndrome (see p. 882).

Neuralgia

Neuralgia refers to pain, usually of great severity, in the distribution of a damaged nerve. Examples are:

• trigeminal neuralgia (see p. 845)
- postherpetic neuralgia (see p. 866)
- complex regional pain syndrome type II (causalgia) – chronic burning pain that occasionally follows peripheral nerve damage.

### Spinal root lesions

**Root pain**

Pain of root compression is felt in the myotome supplied by the root, and there is also a tingling discomfort in the dermatome. The pain is worsened by manoeuvres that either stretch the root (e.g., straight leg raising in lumbar disc prolapse) or increase pressure in the spinal subarachnoid space (coughing and straining). Cervical and lumbar disc protrusions (see p. 887) are common causes of root lesions.

**Dorsal spinal root lesions**

Section of a dorsal root causes loss of all modalities of sensation within a dermatome (*Fig. 21.13*). However, overlap between adjacent dermatomes makes it difficult to detect anaesthesia when a single root is destroyed.

### Spinal cord lesions

**Posterior column lesions**

These cause:
- tingling
- electric shock-like sensations
- clumsiness
- numbness
- tight band-like sensations.

These symptoms, though lateralized, are often felt vaguely without a clear sensory level. Position sense, vibration sense, light touch and two-point discrimination are diminished below the lesion. Position sense loss produces a stamping gait (sensory ataxia; see p. 797).

**Lhermitte's phenomenon**

Electric shock-like sensations radiate down the trunk and limbs on neck flexion. This points to a cervical cord lesion. Lhermitte's is common in acute exacerbations of MS (see p. 859), and also occurs in cervical myelopathy (pp. 887–888), subacute combined degeneration of the cord (p. 886), radiation myelopathy (p. 888) and cord compression.

**Spinothalamic tract lesions**
Pure spinothalamic spinal lesions cause contralateral loss of pain and temperature sensation with a clear level below the lesion. This is called **dissociated** sensory loss – pain and temperature are dissociated from light touch, which remains preserved. This is seen typically in syringomyelia where a cavity occupies the central cord (see p. 874).

The spinal level is modified by lamination of fibres within the spinothalamic tracts. Fibres from lower spinal roots lie superficially and are damaged first by compressive lesions from outside the cord. As an external compressive lesion (e.g. a mid-thoracic extradural meningioma; **Fig. 21.16**) enlarges, the spinal sensory level ascends as deeper fibres become involved. Conversely, a central cord lesion (e.g. a syrinx; see p. 874) affects deeper fibres first. Spinothalamic tract lesions cause loss of pain and temperature perception (e.g. painless burns). Perforating ulcers and neuropathic (Charcot) joints develop.

---

**Spinal cord compression**

Cord compression (**Fig. 21.16**) causes progressive spastic paraparesis (or tetraparesis/quadriparesis) with sensory loss below the level of compression. Sphincter disturbance is common. Root pain is frequent but not invariable, felt characteristically at the level of compression. With thoracic cord compression (e.g. an extradural meningioma), pain radiates around the chest and is exacerbated by coughing and straining, as meningeal root sheaths are stretched.

Damage to one spinothalamic tract (contralateral loss of pain and temperature) with the
ipsilateral corticospinal tract is known as the **Brown–Séquard syndrome** (originally, cord hemisection). The patient complains of numbness on one side and weakness on the other. Paraparesis/spinal cord lesions are discussed on page 859.

### Pontine lesions

Since lesions (e.g. an MS plaque) lie above the decussation of the posterior columns, and both medial lemniscus and spinothalamic tracts are close together, there is loss of all forms of sensation on the side opposite the lesion. Combinations of IIIrd, IVth, Vth, VIth and VIIth cranial nerve nuclei are seen, and may indicate a level (**Fig. 21.14**).

### Thalamic lesions

Thalamic pain (also called **central post-stroke pain** or **thalamic syndrome**) follows a small thalamic infarct. The patient has a stroke (hemiparesis and sensory loss). Weakness improves but deep-seated constant pain in the paretic limbs develops. Choreo-athetotic movements occur. Secondary depression may lead to self-harm. Thalamic lesions can also cause diminished sensation alone, on the opposite side; this is less usual.

### Parietal cortex lesions

Sensory loss, neglect of one side, apraxia (see p. 798) and subtle disorders of sensation occur. Pain is not a feature of destructive cortical lesions. Irritative phenomena (e.g. focal sensory seizures from a parietal cortex glioma) cause tingling sensations in a limb or elsewhere.

### Pain

Pain is an unpleasant, complex sensory and emotional experience. Acute pain serves a biological purpose (e.g. withdrawal) and is typically self-limiting, ceasing as healing ensues. Some forms of chronic pain (e.g. causalgia) outlast the period required for healing and may be permanent.

### Essential physiology of pain

Pain perception is mediated by small-diameter myelinated A-delta and non-myelinated C fibres. Chemicals released following injury produce pain either by direct stimulation or by sensitization of nerve endings. A-delta fibres give rise to perception of sharp, immediate pain; slower-onset, more diffuse and prolonged pain is mediated by slower-conducting C fibres.

Nociceptive (pain) impulses enter the cord via dorsal spinal roots forming synapses in the spinal cord dorsal horn (substance P and glutamate neurotransmitters). Second-order neurones then decussate to the contralateral side and ascend in the spinal cord via two main pathways: the spinothalamic tract (for pain localization) and the spinoreticular tract (mediation of the
emotional component of pain; **Fig. 21.17**). Both pathways project via synapses in the thalamus to the sensory cortex and limbic system. There are projections to brainstem structures: the reticular formation (spinoreticular tract) and periaqueductal grey matter (spinothalamic tract), which modulates pain transmission via descending monoaminergic pathways to the spinal cord dorsal horn. The emotional and affective components of pain, mediated through cortical and limbic networks, are now recognized to be fundamental to pain perception.
Gate theory of pain

Gate theory proposes that transmission of afferent nociceptive (pain) impulses is regulated ('gated') in the spinal cord dorsal horn synapses by afferent impulses from non-nociceptive, large-diameter sensory fibres and descending pathways from the periaqueductal grey (PAG) and other brainstem structures. It explains the phenomenon of rubbing a painful area to ease the pain and is also the basis of transcutaneous electrical nerve stimulation (TENS) therapy.
Similar gating and modulation of afferent pain signals occur in the brainstem under the influence of connections from the thalamus and limbic system.

Peripheral and central sensitization

Sensitization is an increase in the excitability of peripheral nociceptors and central pain pathways, causing normal sensory inputs such as light touch to produce abnormal responses: that is, pain (termed *allodynia*). For example, warm water in a shower feels painfully burning on sunburnt skin and touching the scalp is painful during a migraine. This is an adaptive protective response to ensure that contact with an injured area is minimized. However, maladaptive responses to pain via this mechanism at the central or peripheral level may be the basis for chronic pain when it becomes permanent and out of proportion to the initial painful stimulus.

Plasticity and receptor changes

Pain results in neural plasticity changes and reorganization in pain pathways at spinal cord and cortical/brainstem level. These modulate pain and may be maladaptive in some cases, leading to maintenance of chronic pain. Molecular changes also occur in response to painful stimuli, including upregulation of sodium channels and receptor changes.

Neuropathic pain

Pain results directly from damage to, or dysfunction of, the pain/sensory pathways, such as in peripheral nerve damage, radiculopathy, post-stroke pain and post-herpetic neuralgia (*Box 21.20*). It is common, affecting 6–8% of people. Clinically, the pain usually has an unpleasant burning, electrical or stabbing quality, with allodynia being a frequent feature. It often becomes chronic due to peripheral and central sensitization processes.

---

**Box 21.20**

**Causes of neuropathic pain**

**Peripheral nerve injury**

- Peripheral neuropathy – especially if small (pain) fibres are affected, e.g. diabetes, AL amyloid, HIV, chemotherapy (e.g. carboplatin neuropathy), vitamin deficiency, alcohol, Fabry's
- Vasculitic nerve lesions – e.g. diabetic femoral neuropathy (neuralgic amyotrophy)
- Nerve compression – carpal tunnel syndrome, meralgia paraesthetica
- Post-herpetic neuralgia
- Nerve trauma or section – e.g. phantom limb pain
- Trigeminal neuralgia
Nerve root and plexus

- Radiculopathy due to intervertebral disc prolapse
- Plexopathy – e.g. inflammatory (brachial neuritis) or neoplastic infiltrative (e.g. breast cancer)

Central nervous system disorders

- Multiple sclerosis (pain is common in progressive forms)
- Post-stroke pain – e.g. thalamic strokes
- Spinal cord lesions – intrinsic cord lesions, inflammatory or vascular (infarcts) especially Parkinson's disease

Neurotransmitters and receptors involved in pain

These are involved in pain processing, explaining why a wide range of drug classes are helpful in treating pain.

- **Excitatory neurotransmitters** include substance P, glutamate and calcitonin gene-related peptide (CGRP) in the dorsal horn of the spinal cord and peripherally.
- **Gamma-aminobutyric acid (GABA)** is a key inhibitory neurotransmitter.
- **Opioid receptors**, activated by endogenous endorphins or opiate medications, are widely distributed in pain pathways, including in the spinal cord, PAG and other brainstem structures.
- **Noradrenaline (norepinephrine)** and 5-HT (serotonin) are distributed in descending regulatory pathways.
- **The vanilloid receptor** (TRPV1 – transient receptor potential cation channel VI) on peripheral nociceptors is activated by capsaicin, the active constituent of chilli peppers.

Management of chronic pain

Chronic pain is gravely disabling, distressing and difficult to treat (see pp. 663–665). Multidisciplinary pain clinics provide the best setting for long-term management.

Management plans for intractable pain have seven components.

Diagnostic

Rigorous attention must be paid to the diagnosis, reviewing the entire history and investigations. A specific surgical approach may become apparent (e.g. nerve root or peripheral nerve compression or trigeminal neuralgia).

Psychological

Chronic pain influences quality of life. Depression (see pp. 907–908) is commonly associated with pain; antidepressants can help. Psychology-based pain management programmes and
cognitive behavioural therapy are now a cornerstone of chronic pain management, helping people to control symptoms and the response to pain.

**Analgesics**

These include aspirin, paracetamol, non-steroidal anti-inflammatory drugs (NSAIDs) and opiates. Some opiates, such as tramadol and tapentadol, also have a monoamine reuptake inhibition mechanism of action. The World Health Organization (WHO) analgesic ladder (see pp. 32–33) is useful.

**Co-analgesics**

Co-analgesics have a primary use other than for pain, and help when used alone or added to analgesics. They may have a synergistic effect when used in combination. Examples are:

- **tricyclic antidepressants**, e.g. amitriptyline
- **duloxetine** — a serotonin (5-HT)–noradrenaline (norepinephrine) reuptake blocker (SNRI)
- **anticonvulsants**, e.g. carbamazepine, gabapentin, pregabalin and lamotrigine (see Box 3.3)
- **calcium-channel blockers**, e.g. ziconotide used intrathecally
- **muscle relaxants**, e.g. baclofen
- **capsaicin** topical preparations — extracts from capsicum plants (chilli peppers), which bind to vanilloid receptors (see above)
- **N-methyl-D-aspartate (NMDA) antagonists**, e.g. ketamine
- **cannabinoids** — administered via oral spray in MS and resistant cancer pain
- **botulinum toxin** — licensed for chronic migraine; increasing evidence supports a role in modulating pain neurotransmitters.

**Stimulation**

Acupuncture, ice, heat, ultrasound, massage, TENS and spinal cord stimulation all achieve analgesia by gating effects on large myelinated nerve fibres.

**Nerve blocks**

Pain pathways can be blocked, either temporarily by local anaesthetic (by injection or with topical patches) or permanently with phenol or with radiofrequency lesions:

- **somatic blocks**:
  - peripheral nerve and plexus injections
  - epidural and spinal analgesia
- **sympathetic blocks**:
  - sympathetic ganglia injections
  - central epidural and spinal sympathetic blockade.
Neurosurgery
Highly specialized techniques have a place alongside drugs. Examples are dorsal rhizotomy, sympathectomy, cordotomy and neurostimulation.

Further reading

Bladder Control and Sexual Dysfunction
Changes in micturition and failure of normal sexual activity due to neurological conditions are seen in sacral, spinal cord and cortical disease.
Essential functions and anatomy

The bladder has two functions: storage and voiding. Afferent pathways (T12–S4) respond to pressure within the bladder and sensation from the genitalia. As the bladder distends, continence is maintained by suppression of parasympathetic outflow and reciprocal activation of sympathetic outflow. Both are under some voluntary control. Voiding takes place by parasympathetic activation of the detrusor, and relaxation of the internal sphincter (Box 21.21).

Cortical awareness of bladder fullness is located in the post-central gyrus, parasagittally, while initiation of micturition is in the pre-central gyrus. Voluntary control of micturition is located in the frontal cortex, parasagittally.

Neurological disorders of micturition

Urogenital tract disease is dealt with largely by urologists. Incontinence is common and easy to recognize; neurological causes are sometimes not obvious. These are:

Cortical:

• Post-central lesions cause loss of the sense of bladder fullness.
• Pre-central lesions cause difficulty in initiating micturition.
• Frontal lesions cause socially inappropriate micturition.

Spinal cord. Bilateral UMN lesions (pyramidal tracts) cause urinary frequency and incontinence. The bladder is small and hypertonic: that is, sensitive to small changes in intravesical pressure. Frontal lesions can also cause a hypertonic bladder.

LMN. Sacral lesions (conus medullaris, sacral root and pelvic nerve – bilateral) cause a flaccid, atonic bladder that overflows (cauda equina; see p. 888), often unexpectedly.

Management. Assessment of both urological causes (e.g. calculi, prostatism, gynaecological problems) and potential neurological causes of incontinence is necessary.
Intermittent self-catheterization is used by many patients who have, for example, spinal cord lesions.

**Male erectile dysfunction**

Failure of penile erection often has mixed organic and psychological causes. Depression is common. Erectile dysfunction is described on page 1217.

**Investigation of Neurological Disease**

Neurological investigations, such as brain scans, should not be a substitute for clinical evaluation through history-taking and examination. An experienced clinician will be able to make an accurate diagnosis in most patients without recourse to investigations: for example, in most individuals presenting with headache. However, cross-sectional imaging will allow confirmation of the anatomical localization of lesions and may reveal the presence of other clinically ‘silent’ lesions. Imaging does not always indicate the pathological nature of a visualized lesion (careful history-taking is essential in this regard) and therefore needs to be carefully interpreted in the clinical context. Neurophysiological investigations provide information about nervous system function and are more diagnostically helpful than imaging in some situations: for example, in patients with primary generalized epilepsies or peripheral nerve disorders.

Unnecessary or inappropriate use of investigations, particularly brain imaging, exposes patients to risk, such as radiation, is an inefficient use of resources, and may lead to identification of incidental findings that cause considerable anxiety (3% incidental abnormality rate for brain MRI scans). Clinicians should also be familiar with the range of normal in the population: for example the high prevalence of white-matter hyperintensities on brain MRI in older people and the range of common non-specific electroencephalogram (EEG) changes.

**Neuroimaging**

**Skull and spinal X-rays**

*Skull X-rays* have now been largely superseded by computed tomography (CT) and MRI. They show fractures, bone metastases, osteomyelitis, Paget's disease, sinus disease and intracranial calcification.

*Spinal X-rays* show fractures, congenital and destructive lesions (bone cysts, infection, metastases), and degenerative spondylosis.

**Brain computed tomography**

In brain CT, an X-ray beam and detectors revolve rapidly as the patient is moved slowly through the scanner, producing a spiral set of ‘slices’. The digital data are converted to cross-sectional images.
Differences in attenuation (density, expressed as Hounsfield units) between different tissues allow accurate recognition of, for example, fresh blood, bone or calcification (Fig. 21.18). Enhancement with intravenous iodinated contrast delineates areas of vascular leak, such as with tumours and inflammation (Box 21.22).

**FIGURE 21.18** Extradural haematoma.

---

**Box 21.22**

Comparison of magnetic resonance imaging and computed tomography

**Advantages of CT over MRI**

- Speed – brain imaging takes seconds, an advantage in restless or critically ill patients; CT is also less sensitive to artefact due to patient motion
- Patient access – critically ill patients can be monitored more easily than in an MRI scanner
- Method of choice to detect acute haemorrhage
- Detailed evaluation of bone, e.g. spinal vertebrae and fractures
- Easier identification of calcification and metal foreign bodies
- Toleration by claustrophobic patients
- Safety with implanted devices, e.g. pacemakers
- Wider availability than MRI
- Imaging modality of choice in trauma and acute stroke for these reasons

**Advantages of MRI over CT**

- Superior spatial resolution and soft tissue contrast for imaging of brain parenchyma, spinal cord and nerve roots, e.g. white-matter disease such as multiple sclerosis plaques and spinal cord, which are not visible on CT
No bone artefact, so superior visualization of posterior fossa and spinal cord
Availability of numerous special sequences, e.g. diffusion-weighted sequence sensitive to early infarction; multiple sequences increase diagnostic utility
No ionizing radiation
MR angiography may be performed without contrast
Viewing of images in axial, sagittal and coronal planes

**CT angiography**
Spiral CT after intravenous injection of contrast produces high-quality arterial angiograms (or venograms), which are now considered the gold standard for non-invasive angiography.

**Spinal CT and CT myelography**
Spinal CT is useful for assessing the bone architecture of the spine but provides little information about soft tissues, such as nerve roots and spinal cord (MRI is required). CT myelography (spinal CT after intrathecal injection of contrast) is used for identification of spinal fluid leaks/blockage or for situations where MRI is contraindicated.

**Magnetic resonance imaging**
A hydrogen nucleus is a proton whose electrical charge creates a local electrical field. In MRI, protons are aligned by sudden, strong magnetic impulses and then imaged with radiofrequency waves at right angles to their alignment. The protons resonate and spin, then revert to their normal alignment. As they do so, images are made at different phases of relaxation, known as $T_1$, $T_2$, $T_2^{*}$, STIR, FLAIR, diffusion-weighted imaging (DWI) and other sequences. The combination of these sequences increases the diagnostic sensitivity and specificity of MRI. Gadolinium is used as intravenous contrast to show areas of increased vascularity.

The superior spatial resolution and soft tissue contrast of MRI, as compared to CT, makes MRI of the brain and spine generally preferable in the non-emergency situation. It can image pathology not easily visualized on CT, such as small lesions, white-matter disease such as MS plaques and spinal cord lesions or compression, and demonstrate anatomy more accurately.

**Doppler studies**
Ultrasound is a safe, low-cost and rapid method for detecting and quantifying carotid stenosis and assessing carotid plaque burden. It is operator-dependent and less reproducible than other imaging modalities.

**Catheter angiography**
Contrast is injected intra-arterially in selected vessels via a catheter inserted in the femoral artery. Angiography carries a mortality and stroke risk (<1%). Images of aorta, carotid, vertebral and brain arteries demonstrate occlusion, stenoses, aneurysms and arteriovenous malformations (AVMs). Spinal angiography is complex and is used to identify spinal AVMs...
and dural fistulas. Aneurysms and AVMs may be treated by endovascular means (embolization with glue or platinum coils) during the procedure.

**Positron emission tomography, single proton emission computed tomography, dopamine transporter imaging and functional MRI**

These functional imaging techniques track uptake of radioisotopes and/or metabolites. Fluorodeoxyglucose positron emission tomography (FDG-PET) is used principally to detect occult neoplasms or tumour recurrence, outside the central nervous system (CNS), or to identify large-vessel vasculitis. Dopamine transporter imaging (DAT) is used to identify reduced nigrostriatal dopaminergic terminals in parkinsonian disorders, mainly in patients with atypical tremor where the clinical diagnosis is uncertain. Functional MRI (fMRI) is largely a research tool for mapping brain function, in health and disease. New techniques using radionuclide tracers to image brain amyloid deposits in Alzheimer's disease are in development and will soon be available for clinical use.

**Isotope bone scanning**

The radioisotope $[^{99m}Tc]$-pertechnetate is given intravenously. The technique is used principally in detection of vertebral, skull and bone metastases.

**Neurophysiological investigations**

**Electroencephalography**

Brain electrical activity *(Fig. 21.19)* is recorded from scalp electrodes (20 channels simultaneously). Its main use is to characterize epilepsy syndromes. Recordings are usually made between seizures (inter-ictal). Sleep-deprived EEG and 24-hour ambulatory EEG increase diagnostic sensitivity. Videotelemetry (VT) combines continuous EEG with video over several days to record the semiology and electrical characteristics of seizures. VT is invaluable diagnostically to identify seizure type where there is clinical uncertainty, and to pinpoint the seizure focus in focal epilepsies.
Epilepsy
Spikes, or spike-and-wave abnormalities, are hallmarks of epilepsy, but it is important to emphasize that patients with epilepsy often have a normal EEG between seizures (see p. 849).

Diffuse brain disorders
Slow-wave EEG abnormalities appear in encephalopathy (e.g. hepatic coma), encephalitis and prion (Creutzfeldt–Jakob) diseases.

Brain death
The EEG is isoelectric (flat); EEG is not necessary to confirm brain death in many countries (see p. 1172).

Electromyography and nerve conduction studies
Electromyography (EMG) and nerve conduction studies (NCS) are skilled investigations of nerve function that are essential for investigation of peripheral nerve, anterior horn cell, neuromuscular junction (NMJ) and, to a lesser extent, muscle disorders. NCS are highly sensitive in identification of peripheral neuropathy, and assessment of the nerves affected and the type of pathology (axonal loss versus demyelinating). In mononeuropathies, the anatomical site of the lesion may be identified with considerable accuracy and prognostic information obtained.

Electromyography
A concentric needle electrode is inserted into voluntary muscle. Amplified recordings, on an
oscilloscope, are also heard through a speaker. The main EMG features include:
• normal interference pattern
• denervation and re-innervation changes
• myopathic and myotonic features (see p. 889).

Single-fibre EMG is used for disorders of NMJ transmission.

**Peripheral nerve conduction**

Electrical stimulation of a peripheral nerve generates a nerve impulse that may be recorded (**Fig. 21.20**). Four measurements are of principal value in neuropathies and nerve entrapment:
• nerve conduction velocity
• distal motor latency
• sensory action potentials (SAPs)
• compound muscle action potentials (CMAPs).

![FIGURE 21.20 Measurement of motor conduction velocity (MCV) in ulnar nerve. The recording electrode on abductor pollicis brevis measures the muscle action potential (M) from ulnar nerve stimulation at the elbow (stimulus 1) and wrist (stimulus 2). MCV calculation:
M1 = muscle action potential (MAP) from stimulus 1
M2 = MAP from stimulus 2
T1 = time from elbow to recording electrode
T2 = time from wrist to recording electrode

Small action potential size (SAP and CMAP) indicates loss of axons. Conduction block and slowing of conduction velocity indicate demyelinating neuropathy, as salutatory conduction is lost with damage to the myelin sheath. Repetitive nerve stimulation is used to identify NMJ conduction disorders (myasthenia).
Cerebral-evoked potentials

Visual-evoked potentials (VEPs) record the interval visual stimuli take to reach the occipital cortex, and the amplitude of response. VEPs are used to confirm previous optic neuritis (see p. 803); this leaves a delayed latency despite clinical recovery.

Similar techniques for auditory and somatosensory potentials (from a limb) are also used.

Lumbar puncture and cerebrospinal fluid examination

See Boxes 21.23 and 21.24. Indications for lumbar puncture (LP) include:

• diagnosis of meningitis and encephalitis
• diagnosis of subarachnoid haemorrhage (in a patient with a normal CT)
• measurement of CSF pressure, e.g. idiopathic intracranial hypertension (see p. 845)
• removal of CSF therapeutically, e.g. idiopathic intracranial hypertension
• diagnosis of various conditions, e.g. MS, neurosyphilis, sarcoidosis, Behçet's, malignant meningitis, polyneuropathies
• intrathecal injection/drugs.

Box 21.24

Lumbar puncture (LP)

Explain the procedure to the patient and obtain consent. LP should not be performed in the presence of raised intracranial pressure or when an intracranial mass lesion is a possibility.

Technique

• Place the patient on the edge of the bed in the left lateral position, with knees and chin as close together as possible.
• Mark the third and fourth lumbar spines. The fourth lumbar spine usually lies on a line joining the iliac crests.
• Using sterile precautions, inject 2% lidocaine into the dermis by raising a bleb in either the third or fourth lumbar interspace.
• Push the LP needle through the skin in the midline, steadily forwards and slightly towards the head, with the head and spine bolstered horizontally with pillows.
• When you feel the needle penetrate the dura, withdraw the stylet and allow a few drops of CSF to escape.
• You can then measure CSF pressure with a manometer connected to the needle. The patient's head must be on the same level as the sacrum. Normal CSF pressure is 60–150 mm of CSF. The level rises and falls with respiration and heartbeat, and rises on coughing.
• Collect CSF specimens in three sterile bottles and take a sample for CSF glucose, together with a simultaneous blood glucose sample.
• Record CSF naked-eye appearance: clear, cloudy, yellow (xanthochromic) or red.
• Ask the patient to lie flat after the procedure to avoid subsequent headaches; this manoeuvre is probably of little value, however.
• Analgesics may be required for post-LP headaches.

**Contraindications**

• Suspicion of a mass lesion in the brain or cord. Caudal herniation of the cerebellar tonsils (coning) may occur if an intracranial mass is present and the pressure below is reduced by removal of CSF
• Any cause of raised intracranial pressure
• Local infection near the LP site
• Congenital lesions in the lumbosacral region (e.g. meningomyelocele)
• Platelet count <40 × 10⁹/L and other clotting abnormalities, including anticoagulant drugs
• Unconscious patients and those with papilloedema must have a CT scan before LP.

**Notes**

• Contraindications are relative; there are circumstances when LP is carried out despite them.
• Composition of normal CSF is shown in Box 21.23.

In suspected CNS infection, close liaison between clinician and microbiologist is essential. Specific techniques (e.g. polymerase chain reaction to identify specific pathogens) are invaluable. Repeated CSF examination is often necessary in chronic infection such as tuberculosis. Post-LP headaches, worse on standing, are a common complaint for several days (or more). Prolonged headaches can be treated by an ‘autologous intrathecal blood patch’: injection of 20 mL of the patient's venous blood into the lumbar epidural space.
Biopsy
Interpretation of brain, tonsillar, muscle and nerve histology requires specialist neuropathology services.

Brain and meninges
Brain biopsy (e.g. of a non-dominant frontal lobe) is rarely used to diagnose inflammatory and degenerative brain diseases. CT and MR stereotactic biopsies of intracranial lesions are standard procedures.

Muscle
Muscle biopsy (usually quadriceps), with light/electron microscopy and immunohistochemical analysis, is performed routinely for diagnosis of inflammatory, metabolic and dystrophic disorders (see p. 889).

Peripheral nerve
Nerve biopsy, usually of the (sensory) sural nerve or superficial sensory branch of the radial nerve, can be of value in the diagnosis of peripheral neuropathy: for example, if vasculitis, amyloid deposition or malignant infiltration is suspected. There may be significant complications (wound healing and pain), so it should be undertaken only where all other investigations are non-diagnostic and where there is clinical evidence of a severe or progressive neuropathy.

Psychometric assessment
Psychometric testing, performed by neuropsychologists, assesses cognitive function in more detail than bedside testing during clinical examination. Decline in intellectual function, as compared to estimated pre-morbid IQ, is seen following brain injury or in dementia, for example. Individual cognitive domains, such as various types of memory, language, visuospatial function and frontal executive function, are tested separately, as they may be differentially involved in different disorders, the pattern of involvement often being of considerable diagnostic value. Serial testing at intervals of 6–12 months may be needed to show clear evidence of progression in neurodegenerative disorders such as dementias.

Routine tests
Standard blood tests, such as full blood count, erythrocyte sedimentation rate (ESR), biochemistry, glucose/HbA$_{1c}$, C-reactive protein, creatine kinase and protein electrophoresis, are helpful to identify underlying disorders such as diabetes, metabolic disorders and other systemic disorders that may underlie neurological presentations (e.g. coma or peripheral neuropathy). Relevant tests are covered in disease-specific sub-sections.
Specialized tests in specific diseases

An increasing number of highly specialized tests are employed to diagnose individual (sometimes rare) diseases (*Box 21.25*).

*b* May be paraneoplastic.

Genetic tests

Several hundred neurogenetic disorders are now recognized and, for many of these, specific molecular genetic investigations are available for diagnostic and predictive testing (see pp. 880–881). As genetic testing is complex and expensive, it should only be undertaken after senior specialist advice. It is likely that there will be gene chip-based testing of panels of disease genes (e.g. for dementias or muscular dystrophies) in the near future. Informed patient consent is required, as a positive test may have implications for other family members. Predictive testing in non-affected, at-risk individuals should only be undertaken after detailed genetic counselling by a specialist.

Immunological tests

An increasing number of autoimmune neurological disorders are recognized, many of which are associated with specific antibody tests (*Box 21.25*). Many of these are paraneoplastic syndromes but an increasing number of non-cancer-related autoimmune syndromes have been identified, such as forms of encephalitis or myasthenia gravis. In addition, monoclonal
paraproteins associated with plasma cell dyscrasias may cause immune-mediated peripheral neuropathy.

Further reading

Unconsciousness and Coma

Consciousness is dependent on the functioning of two separate anatomical and physiological systems:
• The ascending reticular activating system (ARAS), projecting from brainstem to thalamus. This determines arousal (the level of consciousness).
• The cerebral cortex, which determines the content of consciousness.
  Impaired functioning of either anatomical system may cause coma.

Disturbed consciousness: definitions
• Coma: a state of unrousable unresponsiveness. Level of consciousness represents a continuum between being alert and deeply comatose. It may be quantified using the Glasgow Coma Scale (GCS) with a score between 3 and 15 (Box 21.26). Coma may be conveniently defined as a GCS score of 8 or lower. Terms such as stupor and obtundation have been superseded by the GCS score and are no longer used.

*GCS score = E + M + V (GCS minimum = 3; maximum = 15).

**Delirium**: a confusional state in which reduced attention is a cardinal feature, usually with altered behaviour, cognition, orientation and a fluctuating level of consciousness (from agitation to hypoarousal; see pp. 926–927).

### Mechanisms and causes of coma

Altered consciousness is produced by four mechanisms affecting the ARAS in the brainstem or thalamus, and/or widespread impairment of cortical function (*Box 21.27* and *Fig. 21.21*).

- **Brainstem lesion.** A discrete brainstem or thalamic lesion, e.g. stroke, may damage the ARAS.
- **Brainstem compression.** A supratentorial mass lesion within the brain compresses the brainstem, inhibiting the ARAS, e.g. ‘coning’ from a brain tumour or haemorrhage. Mass lesions within the posterior fossa are particularly prone to causing brainstem compression and hydrocephalus.
- **Diffuse brain dysfunction.** Generalized severe metabolic or toxic disorders (e.g. alcohol, sedatives, uraemia, hypercapnia) depress cortical and ARAS function.
- **Massive cortical damage.** Unlike brainstem lesions, extensive damage of the cerebral cortex and cortical connections is required to cause coma, e.g. meningitis or hypoxic–ischaemic damage after cardiac arrest (*Fig. 21.22*).
Principal causes of coma: examples of mechanisms

**Diffuse brain dysfunction**
- Drug overdose (accidental or deliberate), including alcohol
- CO poisoning
- Traumatic brain injury
- Hypoglycaemia, hyperglycaemia
- Severe uraemia (see p. 772)
- Hepatic encephalopathy (see p. 474)
- Respiratory failure with CO\(_2\) retention (see p. 1081)
- Hypercalcaemia, hypocalcaemia
- Hypoadrenalism, hypopituitarism and hypothyroidism
- Hyponatraemia, hypernatraemia
- Metabolic acidosis
- Hypothermia, hyperpyrexia
- Seizures – post-ictal state and non-convulsive status
- Metabolic rarities, e.g. porphyria
- Extensive cortical damage
- Hypoxic–ischaemic brain injury, e.g. cardiac arrest
- Encephalitis, meningitis, cerebral malaria
- Subarachnoid haemorrhage

**Direct effect within brainstem**
- Brainstem haemorrhage, infarction or demyelination
- Brainstem neoplasm, e.g. glioma
- Wernicke–Korsakoff syndrome

**Pressure effect on brainstem**
- Tumour, massive hemisphere infarction with oedema, haematoma, abscess
- Cerebellar mass
A single focal hemisphere (or cerebellar) lesion does not produce coma, unless it compresses the brainstem. Cerebral oedema frequently surrounds masses, increasing their pressure effects.

The most common causes of coma are:
- metabolic disorders – 35%
- drugs and toxins – 25%
- mass lesions – 20%
• other – including trauma, stroke and CNS infections.

## The unconscious patient

### Immediate assessment and management

• Check the airway, breathing, circulation, disability and exposure/examination.
• Use Stix to measure blood glucose; if the patient is hypoglycaemic, give glucose (25 mL 50%).
• Treat seizures with buccal midazolam; if not terminated, use intravenous phenytoin.
• If there is fever and meningism, give intravenous antibiotics.
• Give intravenous naloxone or flumazenil (for overdose) and thiamine (in Wernicke's encephalopathy) in people who use excess alcohol.

Obtain as much history as possible. A limited history is one of the problems in assessing the unconscious patient. What were the circumstances? Ask paramedics, police and witnesses. Contact the patient's relatives, friends and GP, and obtain past hospital notes. Look for drug details/bottles and identification data.

### General and neurological examination

#### General examination

(See Fig. 21.23.)

• Measure the patient's temperature (with a low-reading rectal thermometer if hypothermic). Check for meningism.
• Sniff the patient's breath for ketones, alcohol and hepatic fetor.
• Survey the skin for signs of trauma or spinal injury, rash (meningococcal sepsis), jaundice or stigmata of chronic liver disease, cyanosis and injection marks.
• Assess the respiratory pattern, e.g. Cheyne–Stokes (alternating hyperpnoea and periods of apnoea indicating bilateral cerebral or upper brainstem dysfunction) or acidotic (Kussmaul) respiration (deep, sighing hyperventilation seen in diabetic ketoacidosis and uraemia).
Neurological examination

Neurological examination aims to determine:

- depth of coma (GCS)
- brainstem function
- lateralization of pathology.

Depth of coma

**GCS.** Assessment of the GCS score is repeated regularly to determine whether the patient's level of consciousness is progressively declining. Use a painful stimulus (e.g. nail-bed pressure) to each limb and central area (sternal rub or pressure over the supraorbital nerve), and record the best response. Shout commands.

**Fundi.** Look for papilloedema and subhyaloid retinal haemorrhage (seen in subarachnoid haemorrhage).

Brainstem function

Pupils

Record their size and reaction to light (**Fig. 21.24**):

- **Dilatation of one pupil** that then becomes fixed to light indicates compression of the IIIrd nerve. This is a potential neurosurgical emergency (**Fig. 21.25**).
- **Bilateral mid-point reactive pupils** (i.e. normal pupils) are characteristic of metabolic comas and follow coma due to sedative drugs (except opiates).
• **Bilateral light-fixed, dilated pupils** are one cardinal sign of brain death. They can occur in deep coma of any cause, but particularly in barbiturate intoxication and hypothermia.

• **Bilateral pinpoint, light-fixed pupils** occur with pontine lesions (e.g. haemorrhage) and with opiates.

![Examination of the pupils](image)

**FIGURE 21.24** Examination of the pupils.

![Medial temporal lobe (uncal) herniation causing compression](image)

**FIGURE 21.25** Medial temporal lobe (uncal) herniation causing compression.

Mydriatic drugs and previous pupillary surgery can cause diagnostic difficulty.
Eye movements and position

• Disconjugate eyes (divergent ocular axes) indicate a brainstem lesion, e.g. *skew deviation* (one eye up, one eye down; *Fig. 21.26*).

\[\text{FIGURE 21.26} \quad \text{Disconjugate eye position. This usually indicates brainstem lesion (the eyes may be mildly disconjugate in metabolic coma).}\]

• Conjugate gaze deviation means the eyes deviate towards the lesion in the frontal lobe and the normal limbs (unopposed activity of the intact frontal eye fields drives eyes to the opposite side); and away from the lesion in the brainstem and towards the weak limbs (the PPRF in the pons controls lateral gaze to the ipsilateral side; see p. 805) (*Fig. 21.27*).

\[\text{FIGURE 21.27} \quad \text{Conjugate gaze deviation. A. Frontal lesion. B. Brainstem lesion.}\]

• Vestibulo-ocular reflex means that passive head-turning produces conjugate ocular deviation away from the direction of rotation (doll's eye reflex). This reflex disappears in deep coma, brainstem lesions and brain death (*Fig. 21.28*).
In light coma, slow, side-to-side eye movements are seen (‘windscreen wiper’ eyes; Fig. 21.29). This is also seen with extensive cortical damage in deep coma.

**Other brainstem reflexes**
- Corneal reflex.
- Gag/cough reflex (via endotracheal tube if intubated).
Lateralizing signs
Coma makes it difficult to recognize lateralizing signs. These are helpful:

- **Asymmetry of response to visual threat** in a stuporose patient: suggests hemianopia.
- **Asymmetry of face**: drooping or dribbling on one side; blowing in and out of mouth when the paralysed cheek does not move.
- **Asymmetry of tone**: unilateral flaccidity or spasticity – may be the only sign of hemiparesis.
- **Asymmetry of decerebrate and decorticate posturing**.
- **Asymmetrical response** to painful stimuli.
- **Asymmetry of tendon reflexes and plantar responses**: both plantars are often extensor in deep coma.

Coma ‘look-alikes’

- Psychogenic coma.
- ‘Locked-in’ syndrome – complete paralysis, except for vertical eye movements/blinking in ventral pontine infarction. Patients have a functioning cerebral cortex and are fully aware but unable to communicate, except through eye movements (*Box 21.28*).

EEG, electroencephalography; MCS, minimally conscious state; PET, positron emission tomography; vegetative state.

- Severe paralysis, e.g. myaesthenic crisis or severe Guillain–Barré syndrome.

### Diagnosis and investigations in coma

Often, the cause is evident (e.g. head injury, metabolic disorder, overdose). Where lateralizing signs or brainstem pathology are found on examination, a mass lesion or infarction/haemorrhage is likely (note that hypoglycaemia may also cause focal signs). If no cause is obvious after clinical assessment, further investigations are essential.

### Blood and urine

- **Drug screen** – blood alcohol and salicylates, urine toxicology including screening for benzodiazepines, narcotics, amphetamines.
Biochemistry – urea, electrolytes, glucose, calcium, liver biochemistry.

Metabolic and endocrine studies – thyroid stimulating hormone, cortisol.

Arterial blood gases – for acidosis or high CO₂ levels.

Other – e.g. cerebral malaria (request thick blood film; see pp. 299–300) and porphyria (pp. 1289–1291).

Brain imaging

CT brain imaging is the most readily available and safest modality in the unconscious patient (MRI is useful where CT is normal but presents greater monitoring challenges in the unconscious patient). CT is quick and effective in demonstrating all types of brain haemorrhage and most mass lesions; infarcts may be missed in the early stages and where only the brainstem is affected.

CSF examination

LP should be performed in coma only after careful risk assessment. It is contraindicated when an intracranial mass lesion is a possibility; CT is essential to exclude this. CSF examination is likely to alter therapy only if undiagnosed meningoencephalitis or other infection is present, or in subarachnoid haemorrhage where CT may give a false negative result, particularly after 24 hours.

Electroencephalography

EEG is of some value in the diagnosis of metabolic coma, encephalitis and non-convulsive status epilepticus.

General management

Comatose patients need careful nursing, meticulous attention to the airway, and frequent monitoring of vital functions.

   Longer-term essentials are:

   • skin care – turning (to avoid pressure ulcers and pressure palsies)
   • oral hygiene – mouthwashes, suction
   • eye care – prevention of corneal damage (lid taping, irrigation)
   • fluids – nasogastric or intravenous
   • feeding – via a fine-bore nasogastric tube or via PEG
   • sphincters – catheterization when essential (use a penile urinary sheath if possible in men); rectal evacuation.

Prognosis in coma and the vegetative state

Prognosis depends on the cause of coma and the extent of brain damage sustained. Metabolic
and toxic causes of coma have the best prognosis when the underlying problem can be corrected. Following hypoxic–ischaemic brain injury, such as after cardiac arrest, only 11% make a good recovery; after stroke, the prognosis is worse still, with only 7% recovering. Of those patients who do not recover consciousness, a substantial proportion will remain in a vegetative or minimally responsive state.

- **The vegetative state** (VS) is usually a consequence of extensive cortical damage. Brainstem function is intact and so breathing is normal without the need for mechanical ventilation, and the patient appears awake with eye-opening and sleep–wake cycles. However, there is no sign of awareness or response to environmental stimuli, except reflex movements. Feeding is via gastrostomy. Patients may remain in this state for years. It is considered permanent (PVS) if there is no recovery after 12 months where trauma is the cause, and after 6 months for all other causes. Prolonged support of patients after this time presents a number of ethical issues; families may apply to the courts for withdrawal of feeding in PVS.

- **Minimally conscious state** (MCS) describes patients with some, often fluctuating, limited awareness, with inconsistent but reproducible responses, e.g. movements in response to voice; crying or laughing in response to emotional stimuli; and vocalization in response to questions. A patient may emerge from VS into MCS. Distinguishing VS from MCS requires careful specialist assessment over a long period. Functional brain imaging has recently been used for this purpose.

- **Brainstem death** is discussed on pages 1172–1173.

  Distinction between these states is essential before addressing issues of prognosis and cessation of supportive care.

---

**Further reading**

---

**Stroke**

Stroke is the third most common cause of death in high-income countries (11% of all deaths in the UK) and the leading cause of adult disability worldwide. Approximately two-thirds of the global burden of stroke is in middle- and low-income countries. Stroke rates are higher in Asian and black African populations than in Caucasians. Stroke risk increases with age but one-quarter of all strokes occur before the age of 65. The death rate following stroke is 20–25%, and 40% of surviving patients are dependent at 6 months.

**Definitions**

- **Stroke.** To the public, stroke means weakness, usually permanent on one side, often with loss of speech. Stroke is defined as a syndrome of rapid onset of neurological deficit caused by focal, cerebral, spinal or retinal infarction. Tissue injury is confirmed by neuroimaging.
Hemiplegia following middle cerebral arterial thromboembolism is the typical example.

• **Transient ischaemic attack (TIA)** means a brief episode of neurological dysfunction due to temporary focal cerebral or retinal ischaemia without infarction, e.g. a weak limb, aphasia or loss of vision, usually lasting seconds or minutes with complete recovery. TIA may herald a stroke. The arbitrary time of <24 hours is no longer used.

‘Cerebrovascular accident’ is a vague term and should be avoided.

---

**Pathophysiology**

The underlying pathology responsible for stroke is either infarction or haemorrhage. Stroke mechanism and pathophysiology depend on the population studied but are broadly as follows (**Fig. 21.30**):

- ischaemic stroke/infarction (85%)
  - thrombotic
  - large-artery stenosis
  - small-vessel disease
  - cardio-embolic
  - hypoperfusion
- haemorrhagic stroke (10%) (see pp. 838–839)
  - intracerebral haemorrhage (12%) (see pp. 838–839)
  - subarachnoid haemorrhage (5%) (see pp. 839–841)
- other (5%), e.g. arterial dissection, venous sinus thrombosis, vasculitis (see p. 699).
Ischaemic stroke

Arterial disease and atherosclerosis are the main pathological processes causing stroke. Arterial branch points, such as the origin of the great vessels arising from the aorta, the proximal internal carotid artery and its distal intracranial branches, are particularly affected (Fig. 21.31). Non-Caucasian populations tend to have more intracranial narrowing and white populations more extracranial disease (which is strongly correlated with co-morbid coronary artery and peripheral vascular disease).
Thrombosis. Thrombosis at the site of ruptured mural plaque leads to artery-to-artery embolism or vessel occlusion.

Large-artery stenosis. This usually causes stroke by acting as an embolic source rather than by occluding the vessel (which may not in itself cause stroke if it occurs gradually and collateral circulation is adequate).

Small-vessel disease. Small penetrating arterial branches supply the deep brain parenchyma and are affected by a different pathological process: an occlusive vasculopathy – lipohyalinosis – that is a consequence of hypertension. This leads to small infarcts called ‘lacunes’ and/or gradual accumulation of diffuse ischaemic change in deep white matter.

Cardio-embolic stroke. The heart is a common source of embolic material. Atrial fibrillation (and other arrhythmias) leading to thrombosis in a dilated left atrium is the most common cause. Cardiac valve disease, including congenital valve disorders, infective vegetations, and rheumatic and degenerative calcific changes, may cause embolization. Mural thrombosis may occur in a damaged or akinetic segment of the ventricle. A patent foramen ovale (PFO), which is a common variant, may occasionally allow passage of fragments of thrombus (e.g. from a lower limb deep vein thrombosis) from the right atrium to the left when Valsalva causes shunting of blood across the PFO. Pulmonary arteriovenous fistulas may also act as a conduit for paradoxical embolization. Rarer causes include fat emboli after long bone fracture, atrial myxomas and iatrogenic causes, such as cardiac bypass and air embolism. Simultaneous infarcts in different vascular territories are very suggestive of a proximal source of emboli in the heart or aorta.
**Hypoperfusion.** Severe hypotension, such as in cardiac arrest, may lead to border-zone infarction in the watershed areas between vascular territories, particularly if there is severe stenosis of proximal carotid vessels. The parieto-occipital area between the middle and posterior cerebral artery territories is particularly vulnerable.

**Carotid and vertebral artery dissection**

Dissection accounts for around 1 in 5 strokes below the age of 40 and is sometimes a sequel of trivial neck trauma or hyperextension: for example, after whiplash, osteopathic manipulation, hairwashing in a salon or exercise. Subtle collagen disorders, such as partial forms of Marfan syndrome, may be a predisposing factor.

Most dissections are in large extracranial neck vessels. Blood penetrates the subintimal vessel wall, forming a false lumen, but it is thrombosis within the true lumen due to tissue thromboplastin release that leads to embolization from the site of dissection and stroke, sometimes days after the initial event.

Pain in the neck or face is often the clue leading to diagnosis. Horner syndrome or lower cranial nerve palsies may occur with carotid dissection, as these structures are intimately associated with the carotid artery in the neck.

**Venous stroke**

Only 1% of strokes are venous. Thrombosis within intracranial venous sinuses, such as the superior sagittal sinus, or in cortical veins, may occur in pregnancy, hypercoagulable states and thrombotic disorders, or with dehydration or malignancy. Cortical infarction, seizures and raised intracranial pressure result.

**Haemorrhagic stroke**

See page 838.

**Transient ischaemic attacks**

TIAs are usually the result of microemboli but different mechanisms produce similar clinical events. For example, TIAs may be caused by a fall in cerebral perfusion (e.g. a cardiac dysrhythmia, postural hypotension or decreased flow through atheromatous arteries). Infarction is usually averted by autoregulation. Rarely, tumours and subdural haematomas cause episodes that are indistinguishable from thromboembolic TIAs. Principal sources of emboli to the brain are cardiac thrombus and atheromatous plaques/thrombus within the aortic arch and carotid and vertebral systems. Cardiac thrombus often results from atrial fibrillation (which can be paroxysmal) or myocardial infarction. Cardiac valve disease may be a source of emboli: for example, calcific material or vegetations in infective endocarditis. Polycythaemia is also a cause.

**Risk factors for stroke**
The principal risk factors are those for atherosclerosis: age, smoking, dyslipidaemia, diabetes, obesity, inactivity and genetic/ethnic factors.

Hypertension is overall the most modifiable stroke risk factor in the population; stroke is decreasing in the 40–60 age group partly because hypertension is now more effectively identified and treated (Box 21.29). There is a linear relationship between blood pressure and stroke risk.

---

++, major correlation with reduced stroke risk; +, moderate correlation; SAH, subarachnoid haemorrhage.

On an individual rather than population basis, anticoagulation for atrial fibrillation is the intervention resulting in the greatest stroke risk reduction.

Other risk factors and rarer causes of stroke

- Thrombocythaemia, polycythaemia and hyperviscosity states – thrombophilia (e.g. protein C deficiency, factor V Leiden) is weakly associated with arterial stroke but predisposes to cerebral venous thrombosis.
- Anti-cardiolipin and lupus anticoagulant antibodies (anti-phospholipid syndrome; see p. 695) predispose to arterial thrombotic strokes in young patients.
- Low-dose, oestrogen-containing oral contraceptives do not increase stroke risk significantly in healthy women but probably do so in combination with other risk factors, e.g. uncontrolled hypertension or smoking.
• Migraine is a rare cause of cerebral infarction.
• Vasculitis (systemic lupus erythematosus (SLE), polyarteritis, giant cell arteritis, granulomatous CNS angiitis) is a rare cause of stroke.
• Amyloidosis can present as recurrent cerebral haemorrhage (see p. 1288).
• Hyperhomocysteinaemia predisposes to thrombotic strokes. Folic acid therapy does not reduce the incidence.
• Neurosyphilis, mitochondrial disease, Fabry's disease (see pp. 1287–1288).
• Sympathomimetic drugs such as cocaine, and possibly over-the-counter cold remedies containing vasoconstrictors; neuroleptics in older patients.
• CADASIL (cerebral dominant arteriopathy with subcortical infarcts and leucoencephalopathy) is a rare inherited cause of stroke/vascular dementia.

### Vascular anatomy

Knowledge of normal arterial anatomy and likely sites of atheromatous plaques and stenoses helps understanding of the main stroke syndromes.

The circle of Willis is supplied by the two internal carotid arteries (the anterior cerebral circulation) and by the vertebro-basilar posterior cerebral circulation. The distribution of the anterior, middle and posterior cerebral arteries that supply the cerebrum is shown in **Figures 21.32** and **21.33** (see also **Figs 21.30** and **21.31**).
Clinical syndromes

Transient ischaemic attacks

Clinical features

TIAs cause sudden loss of function, usually lasting for minutes only, with complete recovery and no evidence of infarction on imaging. The previous classical definition of a duration of <24 hours is no longer used. Clinical features of the principal forms of TIA are given in Box 21.30. Hemiparesis and aphasia are the most common.

Box 21.30

Features of transient ischaemic attacks
Anterior circulation

Carotid system
- Amaurosis fugax
- Aphasia
- Hemiparesis
- Hemisensory loss
- Hemianopic visual loss

Posterior circulation

Vertebrobasilar system
- Diplopia, vertigo, vomiting
- Choking and dysarthria
- Ataxia
- Hemisensory loss
- Hemianopic visual loss
- Bilateral visual loss
- Tetraparesis
- Loss of consciousness (rare)
- Transient global amnesia (possibly)

Amaurosis fugax

This is a sudden transient loss of vision in one eye. When it is due to the passage of emboli through the retinal arteries, the embolus is sometimes visible through an ophthalmoscope during an attack (Hollenhorst plaque). A TIA causing an episode of amaurosis fugax is often the first clinical evidence of internal carotid artery (ICA) stenosis – a warning sign of incipient ICA territory stroke.

Diagnosis

Diagnosis of TIA is often based solely on its description. It is unusual to witness an attack, as it is so brief. Consciousness is usually preserved in TIA. There may be clinical evidence of a source of embolus, such as:
- carotid arterial bruit (stenosis)
- atrial fibrillation or other dysrhythmia
- valvular heart disease/endocarditis
- recent myocardial infarction.

An underlying condition may be evident:
• atheroma
• hypertension
• postural hypotension
• bradycardia or low cardiac output
• diabetes mellitus
• rarely, arteritis, polycythaemia, neurosyphilis, HIV
• antiphospholipid syndrome (see p. 695).

### Differential diagnosis

TIAs can be distinguished, usually on clinical grounds, from other transient episodes (see p. 851). Occasionally, events identical to TIAs are produced by mass lesions. Focal epilepsy is usually recognized by its positive features (e.g. limb jerking and loss of consciousness) and progression over minutes. In a TIA, involuntary limb movements do occur occasionally – **limb-shaking TIA** – and are pathognomonic of severe carotid stenosis causing transient focal cerebral hypoperfusion. Cerebral amyloid angiopathy can cause TIA-like events; identification on imaging is necessary, as antiplatelet therapy is contraindicated.

Migraine aura causing visual loss or dysphasia, particularly when it occurs without subsequent headache in elderly people, often causes diagnostic difficulty. Headache, common but not invariable in migraine, is rare in TIA. Positive visual phenomena such as shimmering, which are typical of migraine, are not seen in TIA. The onset and evolution of symptoms is usually slower with migraine aura than TIA (minutes rather than seconds). Limb weakness is rarely due to migraine.

### Prognosis

Prospective studies show that 5 years after a single thromboembolic TIA:
• 30% have had a stroke, a third of these in the first year
• 15% have suffered a myocardial infarct.

TIAs in the anterior cerebral circulation carry a more serious prognosis than those in the posterior circulation (see **Box 21.30**).

The **ABCD² score (Box 21.31)** can help to stratify stroke risk in the first 2 days. If patients are considered to have had a high-risk TIA – that is, ABCD² score of >4, or have had two recent TIAs, especially within the same vascular territory, then they should have urgent investigation and commencement of secondary prevention. All patients should be referred to a TIA clinic and ideally should be seen within 24 hours. Investigation and treatment should be regarded as urgent and completed within 2 weeks.

A score of <4 is associated with a minimal risk whereas >6 is high-risk for a stroke within 7 days of a TIA.

**Investigations** should include Doppler of the internal carotid arteries, cardiac echo, ECG and 24-hour tape, MRI brain and MR or CT angiography. Treat with medical therapy (see pp. 836–837) and surgery if appropriate (pp. 837–838). Surgery or stenting of high-grade symptomatic carotid stenosis should take place within 1 week of TIA (pp. 837–838).

### Cerebral infarction

Major thromboembolic cerebral infarction usually causes an obvious stroke. The clinical picture is thus very variable, depending on the infarct site and extent.

Following vessel occlusion, brain ischaemia occurs, with electrical neuronal failure causing symptoms, followed by infarction and cell death. The infarcted region is surrounded by a swollen ischaemic area that does not function but is structurally intact. This is the **ischaemic penumbra**, which is detected on MRI and can regain function following revascularization.

Within the ischaemic area, hypoxia leads to neuronal damage. There is a fall in ATP with release of glutamate, which opens calcium channels with release of free radicals. These alterations lead to inflammatory damage, necrosis and apoptotic cell death.

### Clinical features

An acute onset (over minutes) of ‘negative’ symptoms indicating focal deficits in brain function, such as weakness, sensory loss, dysphasia and visual loss, are the characteristic defining features of ischaemic stroke. The exact clinical picture depends on the vascular
Anterior circulation infarcts

This includes infarcts in the territory of the internal carotid, middle cerebral (MCA), anterior cerebral (ACA) and ophthalmic arteries. Complete MCA occlusion results in devastating stroke with contralateral hemiplegia and facial weakness, hemisensory loss and neglect syndromes (parietal lobe – severe if the non-dominant side is affected), eye deviation towards the affected side (frontal eye fields), aphasia (dominant hemisphere lesions) and hemianopia. Brain swelling of infarcted tissue leads to a high risk of death due to coning – malignant MCA infarction. Decompressive craniectomy (Fig. 21.34) within the first 48 hours has been shown to reduce mortality and slightly improve the long-term severe disability.

A similar picture to MCA stroke is caused by internal carotid occlusion, although collateral circulation may reduce the infarct size (see Fig. 21.31). MCA branch occlusions produce fragments of the picture described above, such as hemiparesis, monoparesis and aphasia. Occlusion of lenticulostriate perforating arteries (or MCA occlusion with collateral circulation protecting the cortex) causes infarction of deep sub-cortical structures such as the internal capsule, resulting in hemiplegia and hemisensory deficits. ACA infarcts are significantly less common than MCA infarcts and typically produce hemiparesis affecting the leg more than arm, and frontal lobe deficits such as apathy or apraxia.

Posterior circulation infarcts

• Brainstem infarction causes complex signs, depending on the relationship of the infarct to cranial nerve nuclei, long tracts and brainstem connections (Box 21.32).

• **The lateral medullary syndrome** (Wallenberg syndrome) is a common brainstem vascular syndrome presenting as acute vertigo with cerebellar and other signs, including Horner syndrome (**Box 21.33** and **Fig. 21.35**). It follows thromboembolism in the posterior inferior cerebellar artery (PICA) or its branches, vertebral artery thromboembolism or dissection.

**FIGURE 21.35** Medulla (cross-section). Structures at risk after brainstem infarction.

- **Cerebellar infarcts** occur in isolation or as part of a more extensive brainstem syndrome. Swelling of the cerebellum may cause brainstem compression and coma or obstructive hydrocephalus necessitating decompressive surgery.
- **Basilar artery thrombosis** is more common than embolism. The clinical picture depends on
the level of the occlusion and the branch vessels affected. High lesions cause midbrain infarction, including coma and **locked-in syndrome** (see p. 828) or **top of the basilar syndrome**, when the posterior cerebral artery (PCA) is also affected, causing devastating midbrain, occipital lobe and thalamic infarction.

*Posterior cerebral artery infarcts* are typically embolic. Homonymous hemianopia results from unilateral lesions, cortical blindness (**Anton syndrome**) from bilateral lesions (see **Fig. 21.33** and p. 804). Neglect syndromes and visual agnosias are associated with involvement of more anterior visual association areas. The PCA supplies the thalamus, and postero-medial temporal lobe and infarction of these structures causes confusion or memory impairment.

**Lacunar infarction**

Lacunes are small (<1.5 cm³) infarcts seen on MRI or at postmortem. Hypertension is the major risk factor. Strokes without cortical features, such as pure motor stroke, pure sensory stroke, sudden unilateral ataxia and sudden dysarthria with a clumsy hand, are typical lacunar syndromes. Lacunar infarction is often symptomless.

**Multi-infarct dementia (vascular dementia)**

Multiple lacunes or larger infarcts cause generalized intellectual loss seen with advanced cerebrovascular disease. In the late stages, there is dementia (see pp. 874–879), pseudobulbar palsy and a shuffling gait – **marche à petits pas** (small steps), sometimes called atherosclerotic parkinsonism. **Binswanger's disease** is a term for widespread low attenuation in cerebral white matter, usually with dementia, TIAs and stroke episodes in hypertensive patients (the changes being seen on imaging/autopsy).

**Watershed (border-zone) infarction**

Severe cerebral hypoperfusion, such as hypotension after cardiac arrest or bypass surgery, causes ischaemia in the border zones between areas supplied by the anterior, middle and posterior cerebral arteries (affecting the occipito-parietal cortex, hippocampi and motor pathways). Complex patterns of visual loss (e.g. **Balint syndrome**), memory loss, intellectual impairment and sometimes motor deficits are typical. A vegetative state or minimally conscious state may result from severe hypoxic–ischaemic encephalopathy after prolonged cerebral hypoperfusion (see p. 829).

**Investigations in stroke**

The purpose of investigations in stroke is to:

• confirm the clinical diagnosis, distinguish between haemorrhage and thromboembolic infarction, and exclude stroke mimics, e.g. tumour

• identify an underlying cause for the purposes of secondary prevention and identification of stroke mimics.
Investigations in thromboembolic stroke and TIA are listed in **Box 21.34**.

**Box 21.34**

**Stroke investigations**

**Immediate urgent investigations**
*(Within 1 h if considering thrombolysis or patient is on anticoagulants or has reduced conscious level; otherwise within 24 h)*

- CT brain scan
- Blood count and glucose (and clotting studies if anticoagulated)

**Further investigations**
*(Within 24 h)*

- Routine blood tests – blood count, erythrocyte sedimentation rate, glucose, clotting studies, lipids
- Electrocardiography (ECG) and later 24-h ECG for atrial fibrillation
- Carotid Doppler studies (in patients with anterior circulation stroke fit for surgery)

**In addition**

*In selected patients, e.g. young stroke or no cause identified*

- CT or MR angiography
- MRI brain scan with dissection protocol
- Echocardiogram (consider transoesophageal echocardiography)
- Prolonged cardiac monitoring for paroxysmal atrial fibrillation in cryptogenic stroke, e.g. implantable loop recorder
- Vasculitis screen
- Antiphospholipid antibodies
- Thrombophilia screen
- Other: genetics for CADASIL and mitochondrial disorders; alpha-galactosidase for Fabry's disease; drugs of abuse screen, e.g. cocaine
  - CADASIL, cerebral dominant arteriopathy with subcortical infarcts and leucoencephalopathy.

**Neuroimaging**

- **CT** will demonstrate haemorrhage immediately but cerebral infarction is often not detected in the acute phase or only subtle changes are seen *(Fig. 21.36A)*. Repeat CT at 24–48 h may be helpful.
• MRI is more sensitive than CT for early changes of infarction (diffusion-weighted sequences, DWI; Fig. 21.36B) and for small infarcts (Fig. 21.37). MRI also clearly demonstrates the extent and anatomy of an infarct and shows evidence of clinically silent simultaneous infarcts that indicate an embolic cause. MRI can also help identify the underlying cause, e.g. arterial dissection using specific sequences to show the false lumen (crescent sign) or venous cortical infarcts. Many stroke mimics, such as demyelination, are shown with MRI but not CT. For these reasons, MRI is increasingly used in routine assessment of stroke and is essential in younger patients or in those where the cause is uncertain.
Vascular imaging by carotid Doppler within 24 h is essential to identify high-grade symptomatic carotid stenosis requiring surgery. CT or MR angiography is now widely used to corroborate the results of Doppler, to identify arterial stenosis in the posterior circulation or intracranial vessels that are not visible on Doppler, and also to identify arterial dissection and venous sinus thrombosis. Catheter angiography is rarely needed following ischaemic stroke.

Cardiac investigations

Identification of a cardioembolic source of stroke, principally atrial fibrillation, is achieved with electrocardiography (ECG) or 24-hour ECG. Other causes, such as valve disease, patent foramen ovale or mural thrombus, require transthoracic echocardiography, or transoesophageal echo in selected patients. Recent research has shown that prolonged cardiac monitoring (e.g. with an implantable loop recorder) demonstrates paroxysmal atrial fibrillation in a significant
minority of people with stroke of unknown cause.

Other investigations

In young patients with stroke or in those individuals where there is no evidence of atherosclerosis or an embolic source, more specialist investigations may be required to look for an underlying vasculitic, inflammatory, infective, metabolic or genetic cause (see Box 21.34 and p. 831).

Acute stroke: immediate care and thrombolysis

(See Box 21.35.) Stroke is a medical emergency. Paramedics and members of the public are encouraged to make the diagnosis of stroke on a simple history and examination – FAST:

- **Face** – sudden weakness of the face
- **Arm** – sudden weakness of one or both arms
- **Speech** – difficulty speaking, slurred speech
- **Time** – the sooner treatment can be started, the better.

---

**Box 21.35**

**Stroke management outline**

1. Immediate general medical measures:
   - Airway: confirm patency and monitor
   - Continue care of the unconscious or stuporose patient
   - Give oxygen by mask
   - Monitor blood pressure
2. Is thrombolysis appropriate?
   - If so (see Box 21.36), immediate brain imaging is essential
3. Brain imaging:
   - CT should always be available; this will indicate haemorrhage, other pathology and sometimes infarction
4. Cerebral infarction
   - If CT excludes haemorrhage, give immediate thrombolytic therapy. Give aspirin 300 mg/day if thrombolytic therapy is contraindicated
5. Cerebral haemorrhage:
   - If CT shows haemorrhage, give no drugs that could interfere with clotting; neurosurgery may occasionally be needed
6. Admit to multidisciplinary stroke unit:
   - Assess swallowing
   - Start thromboembolism prophylaxis
   - Treat medical complications, e.g. infection, hyperglycaemia, atrial fibrillation and so
7. Rehabilitation – specialized unit or community

During initial assessment, immediate, continued and meticulous attention to the airway, blood pressure and swallowing is essential. Management of unconscious or stuporose patients is outlined on page 826.

Thrombolysis
Thrombolysis significantly increases the chances of having no disability or minimal disability after stroke, by reducing infarct size (Figs 21.38 and 21.39; Box 21.36). Earlier treatment within the 4.5-hour time window significantly improves outcome, so every minute counts. Approximately 10% of patients are potential candidates for thrombolysis, most being excluded due to late presentation outside the time window for treatment. Two recent studies have shown benefit, with a low complication rate, from endovascular therapy (usually performed with retrievable stents) following alteplase therapy. In both studies, patients with proximal vessel occlusion and salvageable brain tissue were selected, with improved function and reduced mortality after treatment.

![CT perfusion scans. A. Pre-thrombolysis; B. Post-thrombolysis showing reperfusion of the ischaemic site. (Courtesy of Professor Adrian Dixon, Cambridge Radiology Department, UK.)](image-url)
**Box 21.36**

**Thrombolysis in acute ischaemic stroke**

**Eligibility**

- Clinical diagnosis of acute ischaemic stroke
- Assessment by experienced team
- Persisting neurological deficit
- Imaging excludes haemorrhage
- Timing of onset well established
- Thrombolysis should commence as soon as possible and up to 4.5 h after acute stroke

**Exclusion criteria**

**Historical**

- Stroke or head trauma within the prior 3 months
- Any prior history of intracranial haemorrhage
- Major surgery within 14 days
- Gastrointestinal or genitourinary bleeding within the previous 21 days
- Arterial puncture at a non-compressible site within 7 days
- Lumbar puncture within 7 days

**Clinical**

- Rapidly improving stroke syndrome
• Minor and isolated neurological signs
• Seizure at the onset of stroke if the residual impairments are due to post-ictal phenomena
• Symptoms suggestive of subarachnoid haemorrhage, even if the CT is normal
• Persistent systolic blood pressure (BP) >185, diastolic BP >110 mmHg, or requiring aggressive therapy to control BP
• Pregnancy
• Active bleeding or acute trauma (fracture)

**Laboratory**

• Platelets <100 000/mm³
• Serum glucose <2.8 mmol/L or >21.2 mmol/L
• International Normalized Ratio (INR) >1.7 if on warfarin
• Elevated partial thromboplastin time if on heparin

**Dose of i.v. alteplase (tissue plasminogen activator)**

• Total dose 0.9 mg/kg (max. 90 mg)
• 10% of total dose by initial i.v. bolus over 1 min
• Remainder infused intravenously over 60 min

---

*a*See Figure 21.38.

In a recent meta-analysis of five trials, endovascular thrombectomy has been shown to benefit most patients with an acute stroke caused by occlusion of the proximal anterior circulation. This treatment may become the accepted standard of care.

**Antiplatelet therapy and anticoagulation**

High-dose aspirin (300 mg) is started 24 hours after thrombolysis, or immediately haemorrhage is excluded if thrombolysis is contraindicated, and continued for 2 weeks before switching to clopidogrel. The number needed to treat (NNT) to prevent one stroke is 100.

Anticoagulants are started for atrial fibrillation-associated cardioembolic stroke only after 2 weeks to reduce the risk of acute haemorrhagic transformation of infarcts (NNT = 12). However, for arterial dissection, the risk of recurrent embolic stroke from the site of dissection is considered to be high enough to justify immediate anticoagulation, although controlled trial evidence is lacking. Venous sinus or cortical vein thrombosis causing stroke is also treated with anticoagulation. In addition to warfarin for oral anticoagulation, other oral anticoagulants (OACs; see p. 972) that inhibit factor Xa or thrombin are now available. They have the advantage over warfarin of a wider therapeutic index with a lower rate of haemorrhage, no need for monitoring and few drug interactions. Idarucizumab has FDA approval for intravenous use, fully reversing dabigatran in 4 hours.
Decompressive craniectomy
This should be performed within 48 hours in MCA strokes causing infarction of more than 50% of the MCA territory to prevent coning and improve long-term outcome (see p. 833).

Stroke units
Direct admission to a stroke unit has been demonstrated to be one of the most effective interventions in acute stroke, saving lives and reducing long-term disability. Specialized multidisciplinary teams and clear protocols for aspects of care, such as swallowing assessment, thromboembolism prevention, treatment of infections, management of hyperglycaemia and other medical complications, improve quality and consistency of care, and thus outcomes. Early mobilization and access to physiotherapy, occupational therapy and speech therapy, as well as initiation of secondary prevention and patient education, are equally necessary. Early supported discharge and assessment of rehabilitation needs are also better coordinated on a stroke unit than a general ward.

Secondary prevention interventions

Antihypertensive therapy
Recognition and good control of high blood pressure are the major factors in primary and secondary stroke prevention. Transient hypertension, often seen following stroke, usually does not require treatment, provided diastolic pressure does not rise above 100 mmHg. Sustained severe hypertension needs treatment after 72 hours (see p. 1048); blood pressure should be lowered slowly to avoid any sudden fall in perfusion.

Lipid-lowering therapy
Statins, typically simvastatin 40 mg, should be offered to all patients unless there is a contraindication, aiming for a target total cholesterol <4 mmol/L (low-density lipoprotein <2 mmol/L).

Lifestyle modification and education
Education of patient and family is an essential aspect of secondary prevention. Smoking cessation and advice about diet, exercise, weight reduction and alcohol consumption should be started on the stroke unit and continued after discharge.

Surgery and stenting for carotid stenosis
High-grade symptomatic carotid stenosis is associated with a significant risk of recurrent stroke during the weeks after TIA or stroke. Carotid endarterectomy should be performed within 2 weeks in patients with 70–99% stenosis on the affected side, provided the initial stroke was not severely disabling. A second imaging modality, such as CT angiography, should be performed to confirm the results of Doppler studies. For patients with moderate
symptomatic stenosis (50–69%), there is a modest benefit with intervention over the 3% stroke risk associated with the procedure itself. Carotid stenting is an alternative to surgery in some patients (major stroke risk is the same for surgery and stenting but the chance of minor non-disabling stroke is higher for stenting).

The case for intervention in asymptomatic stenosis is debatable. Patients with 70–99% stenosis may have a modest stroke risk reduction at 5 years, but moderate stenosis should be treated conservatively. Screening asymptomatic individuals for carotid stenosis is not helpful. Carotid occlusion is always treated conservatively (there is no risk of distal embolization).

**Stroke in the elderly**

Thrombolysis is not contraindicated. Age is no barrier to recovery; elderly patients benefit from good rehabilitation. Consider social isolation, pre-existing cognitive impairment, nutrition, and skin and sphincter care, and reassess swallowing. Carotid endarterectomy over 75 years of age confers greater risk reduction than in younger patients.

**Rehabilitation: multidisciplinary approach**

Physiotherapy has particular value in the first few weeks after stroke to relieve spasticity, prevent contractures and teach patients to use walking aids. The benefits of physiotherapy for longer-term outcome are still inadequately researched. Baclofen and/or botulinum toxin are sometimes helpful in the management of severe spasticity.

Speech and language therapists have a vital understanding of aphasic patients' problems and frustration. Return of speech is hastened by conversation generally. If swallowing is unsafe because of the risk of aspiration, either nasogastric feeding or percutaneous gastrostomy will be needed. Video-fluoroscopy while attempting to swallow is helpful.

Physiotherapy, occupational and speech therapy have a vital role in assessing and facilitating the future care pathway. Stroke is frequently devastating and, particularly during working life, radically alters the patient's remaining years. Many become unemployable, lose independence and are financially embarrassed. Loss of self-esteem makes depression common.

At home, aids and alterations may be needed: stair and bath rails, portable lavatories, hoists, sliding boards, wheelchairs, tripods, stair lifts, electric blinds and modified sleeping arrangements, kitchen, steps, flooring and doorways. Liaison between hospital-based and community care teams, and primary care physician, is essential.

**Prognosis**

About 25% of patients die within 2 years of a stroke, nearly 10% within the first month (Fig. 21.39). This early mortality is higher following intracranial haemorrhage than ischaemic stroke. Poor outcome is likely when there is coma, a defect in conjugate gaze and hemiplegia. Many complications, such as aspiration or pressure ulcers, are preventable, particularly in the elderly. Coordinated care reduces deaths.

Recurrent strokes are, however, common (10% in the first year) and many patients die
subsequently from myocardial infarction. Of initial stroke survivors, some 30–40% remain alive at 3 years.

Gradual improvement usually follows stroke, with recovery plateauing after 12 months. One-third of survivors return to independent mobility and one-third have disability requiring institutional care.

**Further reading**

**Intracranial haemorrhage**

This comprises:

- intracerebral and cerebellar haemorrhage
- subarachnoid haemorrhage
- subdural and extradural haemorrhage/haematoma.
Intracerebral haemorrhage

Aetiology

Intracerebral haemorrhage causes approximately 10% of strokes. It is associated with a higher mortality than ischaemic stroke (up to 50%). A large haematoma may act as a space-occupying lesion, causing raised intracranial pressure with brain displacement and herniation.

- **Hypertensive.** Rupture of microaneurysms (Charcot–Bouchard aneurysms, 0.8–1.0 mm in diameter) and degeneration of small, deep, penetrating arteries are the principal pathologies. Such haemorrhage is usually massive, often fatal, and occurs in chronic hypertension and at well-defined sites: basal ganglia, pons, cerebellum and sub-cortical white matter. Vasopressor drugs, such as cocaine, may cause haemorrhage. Alcohol is also a risk factor (probably as a result of impaired coagulation/platelet function).

- **Cerebral amyloid angiopathy (CAA).** Deposition of amyloid-β in the walls of small and medium-sized arteries in normotensive patients, particularly over 60 years, causes lobar intracerebral haemorrhage (especially posterior, i.e. occipital/parietal lobes), which is often recurrent. CAA is associated with particular apolipoprotein E genotypes (E2) and is more common in patients with Alzheimer's disease. Cerebral microbleeds are usually seen on MRI sequences sensitive to haemosiderin deposition. CAA may occasionally cause TIA-like, transient neurological symptoms.

- **Secondary.** Arteriovenous malformations, cavernomas, aneurysms and dural venous thrombosis cause around 20% of intracerebral haemorrhages. Coagulopathies, anticoagulants and thrombolysis may cause haemorrhage. Haemorrhagic transformation of a large ischaemic infarct may sometimes present as a haemorrhage.

Clinical features and investigations

At the bedside, there is no entirely reliable way of distinguishing between haemorrhage and ischaemic infarcts. Intracerebral haemorrhage is more often associated with severe headache or coma. Patients on oral anticoagulants should be assumed to have had a haemorrhage unless it is proved otherwise.

Brain haemorrhage is seen on CT imaging immediately (compare infarction; see pp. 821–822) as intraparenchymal, intraventricular or subarachnoid blood. Routine MRI may not identify an acute small haemorrhage reliably in the first few hours. MRI and MR angiography are necessary to identify underlying vascular malformations such as AVMs or aneurysms. Catheter angiography may be required in selected patients with no obvious risk factors or no underlying cause identified on imaging.

Management of haemorrhagic stroke
Medical
Treatment should be on a stroke unit or a neuroscience intensive care unit. Frequent monitoring of GCS and neurological signs is essential, as neurosurgery may be required. Antiplatelet drugs are, of course, contraindicated. Anticoagulation should be rapidly reversed where possible (for patients on warfarin give intravenous vitamin K and clotting factor concentrates). Control of hypertension is vital with intravenous drugs in an intensive care unit setting for systolic blood pressure >160–180 mmHg. Measures to reduce intracranial pressure may be required, including mechanical ventilation and mannitol. Recombinant activated factor VII administration may prevent haematoma expansion but has not yet been shown to improve outcome.

Surgical
Cerebellar haematomas may cause obstructive hydrocephalus or coma due to brainstem compression; urgent neurosurgical clot evacuation is life-saving (and is required where the haematoma is >3 cm or the patient is drowsy or deteriorating). The role of surgical decompression for non-cerebellar bleeds is less clear-cut and liaison with neurosurgeons is vital. Use of minimally invasive surgical techniques to evacuate haematomas is an area of active research. Placement of an external ventricular drain is needed if obstructive hydrocephalus develops: for example, with extension of the haemorrhage into the ventricular system.

Subarachnoid haemorrhage
Subarachnoid haemorrhage (SAH) means spontaneous arterial bleeding into the subarachnoid space, and is usually clearly recognizable clinically from its dramatic onset. SAH accounts for some 5% of strokes and has an annual incidence of 6 per 100 000.

Aetiology
The causes of SAH are shown in Box 21.37; it is unusual to find any contributing disease.

Box 21.37
Underlying causes of subarachnoid haemorrhage
<table>
<thead>
<tr>
<th></th>
<th>(%)</th>

**Rare associations**
- Bleeding disorders
- Mycotic aneurysms – endocarditis
- Acute bacterial meningitis
- Tumours, e.g. metastatic melanoma, oligodendroglioma
- Arteritis (e.g. systemic lupus erythematosus)
- Spinal AVM → spinal SAH
- Coarctation of the aorta
- Marfan, Ehlers–Danlos syndrome
- Polycystic kidneys
- <5%

**Saccular (berry) aneurysms**

Saccular aneurysms (*Fig. 21.40*) develop within the circle of Willis and adjacent arteries. Common sites are at arterial junctions:

- between posterior communicating and internal carotid artery – posterior communicating artery aneurysm
- between anterior communicating and anterior cerebral artery – anterior communicating and anterior cerebral artery aneurysm
- at the trifurcation or a bifurcation of the middle cerebral artery – middle cerebral artery aneurysm

*FIGURE 21.40* Digital subtraction angiogram: posterior communicating artery aneurysm.

Other aneurysm sites are on the basilar, posterior inferior cerebellar, intracavernous internal carotid and ophthalmic arteries. Saccular aneurysms are an incidental finding in 1% of autopsies and can be multiple.
Aneurysms cause symptoms either by spontaneous rupture, when there is usually no preceding history, or by direct pressure on surrounding structures; for example, an enlarging unruptured posterior communicating artery aneurysm is the most common cause of a painful IIIrd nerve palsy (see p. 806).

**Arteriovenous malformation**

Arteriovenous malformation (AVM) is a vascular developmental malformation, often with a fistula between arterial and venous systems, causing high flow through the AVM and high-pressure arterialization of draining veins. An AVM usually presents following a spontaneous intracerebral haemorrhage or with a seizure, often focal in onset. The risk of a first haemorrhage in unruptured AVMs (20% fatal and 30% resulting in permanent disability) is approximately 2–3% per year. Once an AVM has caused a haemorrhage, the risk of rebleeds is increased to approximately 10% per year. AVMs may be ablated with endovascular treatment (catheter injection of glue into the nidus, usually), microsurgery or stereotactic radiotherapy. A multidisciplinary team approach with neurologist, interventional neuroradiologist and neurosurgeon is required in deciding on treatment options. There is no clear consensus on the best treatment modality or, indeed, whether the considerable risk of intervention is lower than with a conservative approach.

Cavernous haemangiomas (cavernomas) are common (0.1–0.5% prevalence) and consist of a tangle of low-pressure dilated vessels without a major feeding artery; they are frequently symptomless (*Fig. 21.41*) and seen incidentally on imaging. Multiple cavernomas often have a genetic basis. Cavernomas may cause seizures. Small haemorrhages may occur but are usually low-pressure bleeds and rarely cause severe deficits. Surgical resection is rarely needed, except where the cavernoma is gradually enlarging or causing significant neurological symptoms.
Clinical features of subarachnoid haemorrhage

There is a sudden, very severe headache, often occipital (mean time to peak headache 3 min). Headache is usually followed by vomiting and often by coma and death. Survivors of SAH may remain comatose or drowsy for hours, days or longer. SAH is a possible diagnosis in any sudden headache.

Following major SAH, there is neck stiffness and a positive Kernig's sign. Papilloedema is sometimes present, with retinal and/or subhyaloid haemorrhage (tracking beneath the retinal hyaloid membrane). Minor bleeds cause few signs but almost invariably do cause headache (approximately 17% of patients have small ‘sentinel bleeds’ in the weeks before presenting with SAH).

Investigations

CT imaging is the immediate investigation (Fig. 21.42). Subarachnoid and/or intraventricular blood is usually seen (sensitivity of CT to detect subarachnoid blood is 95% within 24 hours of onset but much lower over subsequent days). Lumbar puncture is not necessary if SAH is confirmed by CT, but should be performed if doubt remains. CSF becomes yellow (xanthochromic) within 12 hours of SAH and remains detectable for 2 weeks. Visual inspection of supernatant CSF is usually sufficiently reliable for diagnosis. Spectrophotometry to estimate bilirubin in the CSF released from lysed cells is used to define SAH with certainty. CT angiography or catheter angiography to identify the aneurysm or other source of bleeding is performed in patients potentially fit for surgery. In some, no aneurysm or source of bleeding is found, despite a definite SAH.
**Differential diagnosis**

SAH must be differentiated from migraine. This is sometimes difficult but a short time to maximal headache intensity and the presence of neck stiffness usually indicate SAH. *Thunderclap headache* is used (confusingly) to describe either SAH or a sudden (benign) headache for which no cause is ever found. The syndrome of reversible cerebral vasoconstriction (Call–Fleming syndrome) presents with thunderclap headache. Acute bacterial meningitis occasionally causes a very abrupt headache, when a meningeal microabscess ruptures; SAH also occasionally occurs at the onset of acute bacterial meningitis. Cervical arterial dissection can present with a sudden headache.

**Complications**

Blood in the subarachnoid space can lead to obstructive hydrocephalus, seen on CT. Hydrocephalus can be asymptomatic but may cause deteriorating consciousness following SAH. Shunting may be necessary. Arterial spasm (visible on angiography and a cause of coma or hemiparesis) is a serious complication of SAH and a poor prognostic feature.

**Management**

Immediate treatment of SAH involves bed rest and supportive measures. Hypertension should be controlled. Nimodipine, a calcium-channel blocker given for 3 weeks, reduces mortality.

All SAH cases should be discussed urgently with a neurosurgical centre. Nearly half of SAH cases are either dead or moribund before reaching hospital. Of the remainder, a further 10–20% rebleed and die within weeks. Failure to diagnose SAH – for example, mistaking SAH for migraine – contributes to this mortality.
Where angiography demonstrates an aneurysm (the cause of the vast majority of SAHs), endovascular treatment by placing platinum coils via a catheter in the aneurysm sac, to promote thrombosis and ablation of the aneurysm, is now the first-line treatment. Endovascular coiling has a lower complication rate than surgery but direct surgical clipping of the aneurysm neck is still required in some selected cases. For asymptomatic (unruptured) aneurysms over 8 mm in diameter, the risk of treatment is less than the risk of haemorrhage if not treated. Patients who remain comatose or who have persistent severe deficits after SAH have a poor outlook.

### Subdural and extradural bleeding

These conditions can cause death following head injuries unless treated promptly.

#### Subdural haematoma

Subdural haematoma (SDH) means accumulation of blood in the subdural space following rupture of a vein. This usually follows a head injury, sometimes a trivial one. The interval between injury and symptoms can be days, or may extend to weeks or months. Chronic, apparently spontaneous, SDH is common in the elderly, and also occurs with anticoagulants.

Headache, drowsiness and confusion are common; symptoms are indolent and can fluctuate. Focal deficits, such as hemiparesis or sensory loss, develop. Epilepsy occasionally occurs. Stupor, coma and coning may follow.

#### Extradural haemorrhage

Extradural haemorrhage (EDH) typically follows a linear skull vault fracture tearing a branch of the middle meningeal artery. Extradural blood accumulates rapidly over minutes or hours. A characteristic picture is that of a head injury with a brief duration of unconsciousness, followed by improvement (the lucid interval). The patient then becomes stuporose; there is an ipsilateral dilated pupil and contralateral hemiparesis, with rapid transtentorial coning. Bilateral fixed, dilated pupils, tetraplegia and respiratory arrest follow. An acute progressive SDH presents similarly.

### Management

Possible extradural or subdural bleeding needs immediate imaging. CT (Fig. 21.43A) is the most widely used investigation because of its immediate availability. MRI is more sensitive for the detection of small haematomas. T1-weighted MRI (Fig. 21.43B) shows bright images due to the presence of methaemoglobin.
**EDHs require urgent neurosurgery;** if it is performed early, the outlook is excellent. When the patient is far from a neurosurgeon, such as in wartime or at sea, drainage through skull burr-holes has been life-saving when an EDH has been diagnosed clinically.

**Subdural bleeding** usually needs less immediate attention but close neurosurgical liaison is necessary. Even large collections can resolve spontaneously without drainage. Serial imaging is required to assess progress.

---

### Cortical venous thrombosis and dural venous sinus thrombosis

Intracranial venous thromboses are usually (>50%) associated with a pro-thrombotic risk factor, such as oral contraceptives, pregnancy, genetic or acquired pro-thrombotic states, and dehydration. Head injury is also a cause. Infection, such as from a paranasal sinus, may be present. Venous thromboses can also arise spontaneously.

#### Cortical venous thrombosis

The venous infarct leads to headache, focal signs (e.g. hemiparesis) and/or seizures. Cortical haemorrhagic infarction is shown on MRI.

#### Dural venous sinus thromboses

Cavernous sinus thrombosis causes eye pain, fever, proptosis and chemosis. External and internal ophthalmoplegia with papilloedema develops.

Thrombosis of the dural venous sinuses, such as when the sagittal sinus causes raised intracranial pressure with headache, papilloedema and frequently seizures, may progress to coma.

---

### Management

MRI and MR venography (MRV) show occluded sinuses and/or veins. Treatment is with heparin initially, followed by warfarin or other oral anticoagulants for 6 months.
Anticonvulsants are given if necessary.

**Headache, Migraine and Facial Pain**

Headache is an almost universal experience and one of the most common symptoms in medical practice. It varies from an infrequent and trivial nuisance to a pointer to serious disease. Headache symptoms are unpleasant, disabling and common worldwide, and have a substantial economic impact because of time lost from work.

**Mechanisms**

Pain receptors are located at the base of the brain in arteries and veins, and throughout meninges, extracranial vessels, scalp, neck and facial muscles, paranasal sinuses, eyes and teeth. Curiously, brain substance is almost devoid of pain receptors. Head pain is mediated by the Vth and IXth cranial nerves and upper cervical sensory roots.

**A clinical approach to the patient with headache**

In assessing patients with headache, the aim should be to make a confident diagnosis based on the history. Examination is helpful in excluding underlying medical disorders as a cause of headache but will not distinguish between different types of primary headache.

There is an internationally agreed classification for headaches that defines all headache patterns. Headache is divided into primary headache disorders such as migraine, and secondary headaches due to underlying pathology such as raised intracranial pressure or meningitis (*Box 21.38*). It is also useful to distinguish between episodic (recurrent) headache, single first headache episodes and patients with chronic headache.

---

*Box 21.38*
Some causes of secondary headache

- Raised intracranial pressure, e.g. idiopathic intracranial hypertension
- Infections, e.g. meningitis, sinusitis
- Giant cell arteritis
- Intracranial haemorrhage, esp. subarachnoid haemorrhage or subdural haematoma
- Low cerebrospinal fluid volume (low-pressure) headache
- Post-traumatic headache
- Cervicogenic headache
- Acute glaucoma

In an outpatient clinic setting, most headaches will be benign. Fewer than 1% of outpatients with non-acute headache have a serious underlying cause but in the Emergency Department there will be a much higher prevalence of serious underlying pathology presenting with headache. New-onset severe headache in those without a previous headache history, especially in older patients (>50), requires exclusion of underlying pathology causing secondary headache.

There are some widely believed ‘headache myths’. Headaches are not caused by hypertension, except rarely with malignant hypertension (see p. 1048). Eye strain from refractive error does not cause headache and sinusitis is rarely the explanation for recurrent or chronic headache.

Taking a history for ‘headaches’

Ask about:

- Headache location (e.g. hemicranial), severity and character (e.g. throbbing versus non-throbbing).
- Associated symptoms, e.g. nausea, photophobia, phonophobia and motion sensitivity.
- Presence of autonomic symptoms, e.g. tearing or ptosis.
- Relieving or exacerbating features, e.g. effect of posture.
- Headache pattern: Is headache episodic and part of a pattern of previous similar headaches? Age at onset and headache frequency.
- Duration of headache episodes (helpful in distinguishing between different primary headache types).
- Triggers.
- Pattern of analgesic use.
- Family history of headache.
- ‘Red flag’ symptoms: fever (meningitis, sinusitis).
- Sudden onset in less than 1 minute (SAH).
• Features of raised intracranial pressure.
• Jaw claudication (giant cell arteritis).

Examination
Examination should include fundoscopy to look for papilloedema. In older patients, temporal arteries should be palpated for loss of pulsatility and tenderness that may be features of giant cell arteritis (GCA). Fever and neck stiffness suggest meningitis. Examination is generally normal in patients with primary headache disorders.

Investigations
Investigations, including brain imaging, do not contribute to the diagnosis of primary headache disorders. Neuroimaging is indicated only where history or examination suggests an underlying secondary cause. Older patients with new-onset headache and those with ‘red flag’ symptoms should have brain CT. In patients over 50 with new headache, the ESR should be checked to exclude GCA.

Primary headache disorders

Migraine
Migraine is the most common cause of episodic headache (15–20% of women and 5–10% of men); in 90%, onset is before 40 years of age. Episodes of headache are associated with sensory sensitivity such as to light, sound or movement, and sometimes with nausea and vomiting. There is a spectrum of severity between individuals and from one attack to another. Migraine is usually high-impact, with inability to function normally during episodes. Headache frequency in migraine varies from an occasional inconvenience to frequent headaches severely impacting on quality of life, and may transform into chronic daily headache.

Mechanisms
Genetic factors play a part in causing the neuronal hyper-excitability that is probably the biological basis of migraine. Migraine is polygenic but a rare form of familial migraine is associated with mutations in the α-1 subunit of the P/Q-type voltage-gated calcium channel or neuronal sodium channel (SCN1A), and a dominant loss-of-function mutation in a potassium channel gene (TRESK) has been identified in some patients with migraine with aura.

The pathophysiology of migraine is now thought to have a primarily neurogenic rather than vascular basis. Spreading cortical depression – a wave of neuronal depolarization followed by depressed activity slowly spreading anteriorly across the cerebral cortex from the occipital region – is thought to be the basis of the migraine aura. Activation of trigeminal pain neurones is the basis of the headache. The innervation of the large intracranial vessels and dura by the first division of the trigeminal nerve is known as the trigeminovascular system. Release of
calcitonin gene-related peptide (CGRP), substance P and other vasoactive peptides, including 5-HT, by activated trigeminovascular neurones causes painful meningeal inflammation and vasodilatation. Peripheral and central sensitization of trigeminal neurones and brainstem pain pathways makes otherwise innocuous sensory stimuli (such as CSF pulsation and head movement) painful, and light and sound are perceived as uncomfortable.

Clinical features

Migraine without aura

Migraine typically starts around puberty with increasing prevalence into the fourth decade. There is a spectrum of severity and associated features, but attacks have recognizable core features (Box 21.39). Most migraine attacks are usually of sufficient severity to prevent sufferers continuing with normal activities; sleep usually helps. A washed-out feeling follows the attack. The scalp may be tender to touch during episodes (allodynia) and the preference is to be still in a dark, quiet environment.

Box 21.39

Migraine: simplified diagnostic criteria

Headache lasting 4 hours to 3 days (untreated)

At least two of:
  • Unilateral pain (may become holocranial later in attack)
  • Throbbing-type pain
  • Moderate to severe intensity
  • Motion sensitivity (headache made worse with head movement or physical activity)

At least one of:
  • Nausea/vomiting
  • Photophobia/phonophobia
  • Normal examination and no other cause of headache

Some patients recognize changes in routine as trigger factors:
  • Sleep (too little or too much).
  • Stress (including letdown after a period of stress).
  • Hormonal factors for women – changes in oestrogen levels, e.g. menstrual migraine (usually just before menses) and worsening with the oral contraceptive pill and menopause.
  • Eating – skipping meals and alcohol. Contrary to popular belief, individual foods are rarely a
trigger.
• Other – sensory stimuli, such as bright lights or loud sounds; physical exertion; and changes in weather patterns, e.g. stormy weather. Minor head injuries may trigger a worsening of migraine frequency and severity.

Migraine with aura
Approximately 25% of migraine sufferers experience focal neurological symptoms immediately preceding the headache phase in some or all attacks; this is termed migraine aura. Most never experience aura, and the presence of aura is therefore not required for a diagnosis of migraine. Aura usually evolves over 5–20 minutes, with symptoms changing as the wave of spreading neuronal depression moves across the surface of the cortex. It rarely lasts longer than 60 minutes and is followed immediately by the headache phase.

Visual aura is the most common type, with positive visual symptoms such as shimmering, teichopsia (zigzag lines, also called fortification spectra) and fragmentation of the image (like looking through a pane of broken glass) often accompanied by patches of loss of vision, which may move across the visual field (scotomas) and even evolve into hemianopia or tunnel vision. Positive sensory symptoms (mainly tingling), dysphasia and, rarely, loss of motor function may also occur, and may occur successively within the same episode of aura following the visual symptoms.

Migraine aura usually presents no diagnostic difficulty, but problems with diagnosis may sometimes arise in men over the age of 50 who develop migraine aura for the first time without subsequent headache (sometimes referred to as accephalic migrainous aura). This is frequently misdiagnosed as a TIA (see p. 833). Distinguishing the two conditions is often difficult and relies on the characteristic evolution of symptoms over minutes and the presence of positive symptoms in aura, in contrast to TIA where symptom onset is acute and negative symptoms (visual loss as opposed to visual distortion and teichopsia) are the norm. There may also be a history of previous typical migraine aura in early adult life to help distinguish the conditions.

Migraine-related dizziness
Vertigo is now recognized as being a migrainous symptom in some individuals, with attacks lasting for hours in the context of migraine attacks. There is an overlap with what is sometimes described as basilar migraine, a poorly defined migraine subtype associated with brainstem aura-type symptoms before or during attacks, including perioral paraesthesiae, diplopia, unsteadiness and, rarely, reduced level of consciousness.

Hemiplegic migraine
This rare autosomal dominant disorder causes a hemiparesis and/or coma and headache, with recovery within 24 hours. Some patients have permanent cerebellar signs, as it is allelic with episodic ataxia. It is distinct from more common forms of migraine.
Management

General measures include:

• explanation
• avoidance of trigger factors and lifestyle modification where possible.

Acute treatment of attacks

Analgesics, such as high-dose dispersible aspirin (900 mg), paracetamol 1 g or an NSAID (e.g. naproxen 250–500 mg), are often effective, with an antiemetic such as metoclopramide if necessary. Acute treatment should be taken as soon as possible after onset of headache. Patients should be aware that repeated use of analgesics leads to further headaches (see medication overuse headache, p. 844).

Triptans (5-HT\textsubscript{1B/1D} agonists) are specific for migraine and may be effective where simple analgesics are insufficient. Sumatriptan was the first marketed; almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan and zolmitriptan are now available, with various routes of administration. Subcutaneous sumatriptan injection may be effective where vomiting prevents absorption of oral medication (note that nasal triptan sprays rely on gastrointestinal rather than nasal absorption). Triptans should be avoided when there is vascular disease, and like analgesics, they should not be overused. CGRP antagonists, e.g. telcagepant, are proving to be very effective for acute treatment of migraine.

Migraine suppression medication

When migraine episodes are frequent – >1–2 per month, for example – and impacting on quality of life, migraine suppression medication should be offered. The key principles are that a period of 3–6 months' treatment is usually sufficient to reduce headache frequency and severity by approximately 50%, with the effect of ‘resetting’ migraine frequency beyond the treatment period. However, these medications will not be effective where ongoing analgesic overuse is an issue. Treatment options include:

• **Anticonvulsants.** Valproate (800 mg) or topiramate (100–200 mg daily) is generally the most effective option.
• **Beta-blockers,** e.g. propranolol slow-release 80–160 mg daily.
• **Tricyclics,** e.g. amitriptyline 10 mg, increasing weekly in 10 mg steps to 50–60 mg.
• **Botulinum toxin.** This was recommended as a treatment for chronic migraine (see p. 844). The technique involves 31 injections over the scalp and neck repeated every 3 months. Its effect is inconsistent.
• **Pizotifen.** This is rarely used. Flunarizine (a calcium antagonist) and methysergide are used in refractory patients.

Tension-type headache
The exact pathogenesis of tension-type headache (TTH) remains unclear. There is overlap with migraine, and many headaches traditionally subsumed under this category probably, in fact, represent mild migraine. Since there are no diagnostic tests to separate TTH from mild migraine it is difficult to know if the conditions are biologically distinct. In contrast to migraine, pain is usually of mild to moderate severity, bilateral and relatively featureless, with tight band sensations, pressure behind the eyes, and bursting sensations being described.

Depression is also a frequent co-morbid feature. TTH is often attributed to cervical spondylosis, refractive errors or high blood pressure; evidence for such associations is poor.

Simple analgesics are often effective but overuse should be avoided. Physical treatments, such as massage, ice packs and relaxation, are often recommended. Frequent or chronic TTH may respond to migraine suppression medications as above, with tricyclics often being used first-line.

### Trigeminal autonomic cephalalgias

The trigeminal autonomic cephalalgias are a group of primary headache disorders characterized by unilateral trigeminal distribution pain (usually in the ophthalmic division of the nerve) and prominent ipsilateral autonomic features.

### Cluster headache

Cluster headache is distinct from migraine and much rarer (1 per 1000). It affects adults, mostly males aged between 20 and 40. Patients describe recurrent bouts (clusters) of excruciating unilateral retro-orbital pain with parasympathetic autonomic activation in the same eye, causing redness or tearing of the eye, nasal congestion or even a transient Horner syndrome. The pain is reputed to be the worst known to humans, and patients often contemplate, and sometimes commit, suicide, such is the severity of the pain. Unlike with migraine attacks, patients prefer to move about or rock rather than remain still.

Attacks are shorter than migraine, usually 30–90 minutes, and may occur several times per day, especially during sleep. Clusters last 1–2 months, with attacks most nights, before stopping completely and typically recurring a year or more later, often at the same time of year. Although the cause is not known, hypothalamic activation is seen on functional imaging studies during an attack.

**Management.** Analgesics are unhelpful. Subcutaneous sumatriptan is the drug of choice for acute treatment, as no other drug works quickly enough. High-flow oxygen is also used. Most prophylactic migraine drugs are unhelpful. Verapamil, lithium and/or a short course of steroids help terminate a bout of cluster headaches.

### Paroxysmal hemicrania and SUNCT

*Paroxysmal hemicrania* is a rare condition with similarities to cluster headache, differing mainly in that attacks are briefer (10–30 min) and more frequent (>5 per day, at any time of
day) and do not occur in clusters. Women are more often affected than men. There is a rapid and complete response to indometacin.

Short-lasting unilateral neuralgiform headache with conjunctival injection and tearing (SUNCT) is very rare. Attacks are short, 5 seconds to 2 minutes, and very frequently occur in bouts. Distinguishing SUNCT from trigeminal neuralgia can be difficult.

Other primary headache disorders

- **Primary stabbing headache** (‘ice pick headache’) involves momentary jabs or stabs of localized pain occurring either in the same spot or moving about the head. Symptoms wax and wane, and are more common in patients with other primary headache disorders, particularly migraine. Treatment is usually not needed but this type of headache responds well to indometacin.

- **Primary cough headache** is a sudden, sharp head pain on coughing. No underlying cause is found but intracranial pathology should be excluded. The problem often resolves spontaneously. Indometacin is the treatment of choice; LP with removal of CSF can help.

- **Primary sex headache** is characterized by explosive headache at or before orgasm. It often resolves spontaneously after several attacks. Investigation to exclude SAH is required after the first episode.

- **Other varieties** of primary headache include hemicrania continua, primary exertional headache, hypnic headache (headache triggered by sleep), and primary thunderclap headache.

Chronic daily headache

This is defined as headache on \( \geq 15 \) days per month for at least 3 months. Up to 4% of the population are affected by daily or near-daily headache. Although there are many possible causes, including secondary headache disorders, in practice, primary headache disorders, particularly migraine, are responsible for the majority. Where migraine is the cause, the term chronic migraine is now preferred.

Overuse of analgesic medication or triptans (termed *medication overuse headache*) is often a major factor leading to and maintaining chronicity, particularly in those with migrainous biology. Use of \( \geq 10 \) doses per month of any analgesic or triptan, particularly codeine or opiate-containing drugs such as co-codamol, or numerous over-the-counter analgesics, may eventually lead to transformation of episodic headache into chronic daily headache.

Explanation that medication overuse is part of the problem is essential to help patients withdraw from or substantially reduce analgesic intake. This is a difficult process for many patients, especially as there may be a period of transient rebound worsening of headache after withdrawal. Concurrent introduction of migraine suppression medication (see above) may help withdrawal but will not be effective if patients cannot withdraw from frequent analgesic use. Occasionally, hospital admission for analgesic withdrawal with parenteral administration of dihydroergotamine is required.
Secondary headache disorders

Raised intracranial pressure headache

Any headache present on waking and made worse by coughing, straining or sneezing may be due to raised intracranial pressure (ICP) caused by a mass lesion. Vomiting often accompanies pressure headaches. Visual obscurations (momentary bilateral visual loss with bending or coughing) are characteristic and seen in the presence of papilloedema. Occasionally, where ICP rises quickly, papilloedema may not be present.

Neuroimaging is mandatory if raised ICP is suspected. Where no mass lesion, venous sinus thrombosis or hydrocephalus is detected on imaging in the presence of papilloedema, idiopathic intracranial hypertension may be the cause and LP is performed to measure CSF opening pressure.

Idiopathic intracranial hypertension

Idiopathic intracranial hypertension (IIH) probably results from reduced CSF resorption. IIH typically develops in younger, overweight female patients, many of whom have polycystic ovaries. Headaches and transient visual obscurations due to the florid papilloedema are the presenting features. A VIth nerve palsy may develop – a false localizing sign (see p. 806). CSF pressure is very elevated, with normal constituents. Brain imaging is normal, although ventricles may be small and appear ‘slit-like’.

Various drugs, such as tetracyclines, and vitamin A supplements have been implicated. Other causes of papilloedema should be excluded. Sagittal sinus thrombosis can cause a similar picture and should always be looked for on MR venography.

IIH is usually self-limiting. However, optic nerve damage can result from longstanding severe papilloedema with progressive loss of peripheral visual fields. Regular monitoring of visual fields with perimetry is essential. Repeated LP, acetazolamide and thiazide diuretics are used to reduce CSF production. Weight reduction is helpful. Ventriculoperitoneal shunt insertion or optic nerve sheath fenestration to protect vision is sometimes necessary.

Low-CSF-volume (low-pressure) headache

Although most often seen following LP, CSF leaks may occur spontaneously, leading to postural headache, worse on standing or sitting and relieved completely by lying flat. The patient may give a history of vigorous Valsalva, straining or coughing just prior to onset. Leptomeningeal enhancement may be seen on MRI but is not reliably present. LP is generally avoided for obvious reasons but may reveal low opening pressure. The site of the leak is usually within the spine; thus treatment consists of injection of autologous blood into the spinal epidural space to seal the leak (a ‘blood patch’), or occasionally surgical repair of the dural tear. Intravenous caffeine infusion and bed rest are sometimes effective.
### Post-traumatic headache

Pre-existing migraine may worsen following head injury. *De novo* headache sometimes follows a minor head injury but post-traumatic headache is an ill-defined entity. Improvement over a few weeks is the norm, but where litigation is ongoing, symptoms can persist for long periods. Subdural haematoma and low-pressure headache need to be considered as a possible cause.

### Facial pain

The face has many pain-sensitive structures: teeth, gums, sinuses, temporomandibular joints, jaw and eyes. Dental causes are common and should always be considered. Facial pain is also caused by specific neurological conditions.

### Trigeminal neuralgia

Trigeminal neuralgia typically starts in the sixth and seventh decades; hypertension is the main risk factor. Compression of the trigeminal nerve at or near the pons by an ectatic vascular loop is the usual cause. High-resolution MRI studies may demonstrate the vascular loop in contact with the nerve in a high proportion of cases. In younger patients, multiple sclerosis or a cerebellopontine angle tumour (acoustic schwannomas, meningiomas, epidermoids) is more likely to be the cause.

### Clinical features

Paroxysms of knife-like or electric shock-like pain, lasting seconds, occur in the distribution of the Vth nerve. Pain tends to commence in the mandibular division (V₃) but may spread over time to involve the maxillary (V₂) and, occasionally, the ophthalmic divisions (V₁). Bilateral trigeminal neuralgia is rare (3%) and usually due to intrinsic brainstem pathology, such as demyelination. Episodes occur many times a day with a refractory period after each. They may be brought on by stimulation of one or more trigger zones in the face. Washing, shaving, a cold wind and chewing are examples of trivial stimuli that provoke pain. The face may be screwed up in agony. Spontaneous remissions last months or years before (almost invariable) recurrence. There are no signs of Vth nerve dysfunction on examination.

### Management

Carbamazepine (600–1200 mg daily) reduces the severity of attacks in the majority. Oxcarbazepine, lamotrigine and gabapentin are also used. If drugs fail or are not tolerated, a number of surgical options are available that, in general, are more effective than medical treatments. Percutaneous radiofrequency selective ablation of the trigeminal ganglion is performed as a day-case procedure; recurrence may occur after an average of 2 years.
Microvascular decompression of the nerve in the posterior fossa has a high long-term success rate (approximately 90%).

**Atypical facial pain**

Facial pain differs from trigeminal neuralgia in quality and distribution, and trigger points are absent. The condition is probably heterogeneous in aetiology but is believed by some (on little evidence) to be a somatic manifestation of depression. Tricyclic antidepressants and drugs used in neuropathic pain are sometimes helpful.

**Other causes of facial pain**

Facial pain occurs in the trigeminal autonomic cephalgias (see above), occasionally in migraine and in carotid dissection.

**Giant cell arteritis (temporal arteritis)**

A granulomatous large-vessel arteritis is seen almost exclusively in people over 50 (see p. 842).

**Clinical features**

- **Headache.** This is almost invariable in giant cell arteritis (GCA). Pain develops over inflamed superficial temporal and/or occipital arteries. Touching the skin over an inflamed vessel (e.g. when combing the hair) causes pain. Arterial pulsation is soon lost; the artery becomes hard, tortuous and thickened. The scalp over inflamed vessels may become red. Rarely, gangrenous patches appear.

- **Facial pain.** Pain in the face, jaw and mouth is caused by inflammation of facial, maxillary and lingual branches of the external carotid artery in GCA. Pain is characteristically worse on eating (jaw claudication). Mouth opening and protruding the tongue become difficult. A painful, ischaemic tongue occurs rarely.

- **Visual problems.** Visual loss from arterial inflammation and occlusion occurs in 25% of untreated cases. Posterior ciliary artery occlusion causes anterior ischaemic optic neuropathy in three-quarters of these. Other mechanisms are central retinal artery occlusion, cilioretinal artery occlusion and posterior ischaemic optic neuropathy. There is sudden monocular visual loss (partial or complete), usually painless. Amaurosis fugax (see p. 832) may precede permanent blindness.

  When the posterior ciliary vessels are affected, ischaemic optic neuropathy causes the disc to become swollen and pale; retinal branch vessels usually remain normal. When the central retinal artery is occluded, there is sudden permanent unilateral blindness, disc pallor and visible retinal ischaemia. Bilateral blindness may develop, with the second eye being affected
1–2 weeks after the first.

**Diagnosis and management**

See page 701.

Epilepsy and Loss of Consciousness

Epilepsy

An epileptic seizure can be defined as a sudden synchronous discharge of cerebral neurones causing symptoms or signs that are apparent either to the patient or to an observer. For example, a limited discharge affecting only part of the cortex may cause a subjective aura apparent only to the patient, or a generalized seizure may cause a convulsion witnessed by an observer of which the patient may be unaware. This definition excludes disorders such as migrainous aura that are more gradual in onset and usually more prolonged, and EEG discharges that do not have a clinical correlate. Epilepsy is an ongoing liability to recurrent epileptic seizures.

Epidemiology

Epilepsy is common. Its population prevalence is 0.7–0.8% (higher in developing countries). Approximately 440,000 people in the UK have epilepsy. The incidence of epilepsy is age-dependent; it is highest at the extremes of life, most cases starting before the age of 20 or after the age of 60. The cumulative incidence (lifetime risk) of epilepsy is over 3% and the lifetime risk of having a single seizure is 5%. The fact that the prevalence is much lower than the cumulative incidence in part reflects the fact that epilepsy often goes into remission.

Classification

Seizures are divided by clinical pattern into two main groups (Box 21.40 and Fig. 21.44): focal seizures and generalized seizures.

- A focal seizure is caused by electrical discharge restricted to a limited part of the cortex of one cerebral hemisphere. Partial seizures are further characterized according to whether or not there is:
  - aura, e.g. smell or auditory hallucination, déjà vu, fear, visual distortion, sensory symptoms such as tingling, abdominal rising sensation
  - motor features, e.g. one limb jerking (a Jacksonian seizure)
– loss of awareness or responsiveness, e.g. in many temporal lobe seizures.

• **In a generalized seizure**, there is simultaneous involvement of both hemispheres, always associated with loss of consciousness or awareness.

---

### Box 21.40

**Classification of seizures**

1. **Generalized seizures**
   - A. Tonic–clonic seizures (grand mal)
   - B. Absence seizures with 3 Hz spike-and-wave discharge (petit mal)
   - C. Myoclonic seizures
   - D. Tonic, clonic and atonic seizures

2. **Focal seizures** (originating within one hemisphere)
   - Characterized according to one or more features:
     - A. Aura
     - B. Motor (without impaired awareness, e.g. Jacksonian seizures)
     - C. Awareness and responsiveness altered or retained (e.g. with impaired awareness, in temporal lobe seizures)

   A focal seizure can evolve into bilateral convulsive seizure – secondary generalization

3. **Unknown** (insufficient evidence to characterize as focal, generalized or both)

---

Focal seizures with electrical activity confined to one part of the brain may spread after a few seconds, due to failure of inhibitory mechanisms, to involve the whole of both hemispheres, causing a **secondary generalized seizure**. The patient may remember the initial focal seizure before losing consciousness, in which case this is called an **aura**; sometimes, however, the spread of electrical activity is so rapid that the patient does not experience any warning before a secondary generalized seizure.

**Generalized seizure types**

**Typical absence seizures (petit mal)**
This generalized epilepsy almost invariably begins in childhood. Each attack is accompanied by 3 Hz spike-and-wave EEG activity (see Fig. 21.19). There is loss of awareness and a vacant expression for <10 seconds before returning abruptly to normal and continuing as though nothing had happened. Apart from slight fluttering of the eyelids, there are no motor manifestations. Patients often do not realize they have had an attack but may have many per day. Typical absence attacks are never due to acquired lesions such as tumours; they are a manifestation of primary generalized epilepsy. Children with absence seizures may go on to develop generalized convulsive seizures. Absence seizures are often confused with temporal lobe seizures causing transient alteration of awareness.
**Generalized tonic–clonic seizures (grand mal seizures)**

*Prodrome.* There is often no warning before generalized tonic–clonic seizures (GTCS), or there may be an aura prior to a secondary generalized seizure.

*Tonic–clonic phase.* An initial tonic stiffening is followed by the clonic phase with synchronous jerking of the limbs, reducing in frequency over about 2 minutes until the convulsion stops. The patient may utter an initial cry and then falls, sometimes suffering serious injury. The eyes remain open and the tongue is often bitten. There may be incontinence of urine or faeces.

*Post-ictal phase.* A period of flaccid unresponsiveness is followed by gradual return of awareness with confusion and drowsiness lasting 15 minutes to an hour or longer. Headache is common after a GTCS.

**Myoclonic, tonic and atonic seizures**

*Myoclonic seizures* or ‘jerks’ take the form of momentary brief contractions of a muscle or muscle groups: for example, causing a sudden involuntary twitch of a finger or hand. They are common in primary generalized epilepsies. *Tonic seizures* consist of stiffening of the body, not followed by jerking. *Atonic seizures* involve a sudden collapse with loss of muscle tone and consciousness.

**Focal seizure types**

**Focal seizures with aura**

The nature of the aura helps to localize the seizure focus. Temporal lobe auras include déjà vu or jamais vu; fear (may be mistaken for panic attacks); olfactory, gustatory or auditory hallucinations; altered perception, such as macropsia or micropsia; an abdominal rising sensation; nausea; and vertigo. With some frontal seizures, conjugate gaze (see p. 827) deviates away from the epileptic focus and the head turns; this is known as an adversive seizure. Occipital lobe auras include visual phenomena such as zigzag lines and coloured scotomas. Some auras are vague or hard for patients to describe but they are generally stereotyped: that is, the same on each occasion.

**Focal motor seizures**

These originate within the motor cortex. Jerking typically begins on one side of the mouth or in one hand, sometimes spreading to involve the entire side. This visible spread of activity is called the *Jacksonian march* of a seizure. Local temporary paralysis of the limbs affected sometimes follows: Todd's paralysis.

**Focal seizures with altered awareness or responsiveness**

These usually arise from the temporal lobe (60%) or the frontal lobe. There is often a preceding aura followed by a period of complete or partial loss of awareness of surroundings, lasting for 1–2 minutes on average (as opposed to 10 seconds in absence seizures), which the
patient generally does not remember subsequently. This stage is accompanied by speech arrest and often by **automatisms**: semi-purposeful stereotyped motions such as lip smacking or dystonic limb posturing, or more complex motor behaviours such as walking in a circle or undressing. The attacks may be followed by a short period of post-ictal confusion or may develop into a secondary generalized convulsive seizure.

---

**Epilepsy syndromes and aetiology of epilepsy**

The range of causes of epilepsy (**Box 21.41**) is different at different ages and in different countries.

- **Children and teenagers**: genetic, perinatal and congenital disorders predominate.
- **Younger adults**: trauma, drugs and alcohol are common.
- **Older ages (>60 years)**: vascular disease and mass lesions such as neoplasms are important.

---

**Box 21.41**

**Causes of epilepsy**

- Primary generalized epilepsy, e.g. juvenile myoclonic epilepsy
- Developmental, e.g. neuronal migration abnormalities, cortical dysplasia
- Hippocampal sclerosis
- Brain trauma and surgery
- Intracranial mass lesions, e.g. tumour
- Vascular, e.g. cerebral infarction, arteriovenous malformation, venous sinus thrombosis
- Infectious, e.g. viral encephalitis, meningitis, cerebral tuberculosis, HIV, cerebral toxoplasmosis, neurocysticercosis
- Immune, e.g. NMDA receptor antibody and potassium channel antibody encephalitis
- Genetic, e.g. channelopathies
- Metabolic abnormalities, e.g. hyponatraemia, hypocalcaemia
- Neurodegenerative disorders, e.g. Alzheimer's
- Drugs, e.g. ciclosporin, lidocaine, quinolones, tricyclic antidepressants, antipsychotics, lithium, stimulant drugs such as cocaine
- Alcohol withdrawal

---

**Primary generalized epilepsies**

Presenting in childhood and early adult life, primary generalized epilepsies (PGEs) account for up to 20% of all patients with epilepsy. The cause is thought to be polygenic with complex inheritance. The brain is structurally normal but abnormalities of ion channels influencing neuronal firing, abnormalities of neurotransmitter release and synaptic connections are
probably the underlying molecular pathological substrates. They include:

- **Childhood absence epilepsy**: absence seizures. Spontaneous remission by age 18 is usual.
- **Juvenile myoclonic epilepsy** (JME; Box 21.42): this accounts for 10% of all epilepsy patients. Typically, myoclonic jerks start in the teenage years (and are usually ignored by the patient; ask about jerks when taking an epilepsy history – Box 21.42), followed by generalized tonic–clonic seizures that bring the patient to medical attention. One-third of patients also have absences. Seizures and jerks often occur in the morning after waking. Lack of sleep, alcohol and strobe or flickering lights are seizure triggers in JME. JME usually responds well to treatment, is usually associated with EEG abnormalities and requires life-long treatment.

### Box 21.42

**Juvenile myoclonic epilepsy**

- 10% of all epilepsy patients
- Starts in teenage years
- Clinical features:
  - Myoclonic jerks
  - Generalized tonic–clonic seizures
  - Absence in one-third
  - Triggers: sleep deprivation, alcohol, strobe lighting
- Abnormal EEG
- Good response to treatment
- Requires life-long treatment

- **Monogenic disorders**: research has identified a number of single-gene epilepsy disorders, e.g. autosomal dominant nocturnal frontal lobe epilepsy (caused by mutations in the nicotinic acetylcholine receptor gene). Many are due to mutations of neuronal voltage-gated channels, e.g. potassium and sodium channels, or ligand-gated channels and receptors (channelopathies).

**Focal epilepsy**

Almost any process disrupting the cortical grey matter can cause epilepsy. Seizures arise from the affected area of cortex, with or without secondary generalized seizures (these may obscure the focal onset). A focal seizure onset often indicates a structural cause and detailed imaging is required to identify this. In general, the response to treatment is less good than with PGE.

**Hippocampal sclerosis**

This is a major cause of epilepsy. Hippocampal sclerosis (damage with scarring and atrophy
of the hippocampus and surrounding cortex) is the main pathological substrate causing temporal lobe epilepsy and the leading cause of localization-related epilepsy. Childhood febrile convulsions are the main risk factor. Hippocampal sclerosis is usually visible on MRI. It is one of the more common causes of refractory epilepsy, in which case it may be amenable to surgical resection of the damaged temporal lobe.

**Genetic and developmental disorders**

Over 200 genetic disorders, such as tuberous sclerosis, include epilepsy among their features. These account for less than 2% of epilepsy cases. Neuronal migration defects during brain development, dysplastic areas of cerebral cortex and hamartomas contribute to seizures in both infancy and adult life.

**Trauma, hypoxia and neurosurgery**

*Traumatic brain injury*. This may cause epilepsy, sometimes years after the event. The risk is not increased after mild injury (loss of consciousness or post-traumatic amnesia <30 min). Depressed skull fracture, penetrating injury and intracranial haemorrhage increase risk significantly.

*Perinatal brain injury and cerebral palsy*. Periventricular leukomalacia and brain haemorrhage associated with prematurity and fetal hypoxia, may cause early-onset epilepsy. One-third of children with cerebral palsy have epilepsy.

*Brain surgery*. This is followed by seizures in up to 17% of cases. Prophylactic anticonvulsant use after surgery is not recommended.

**Brain tumours and other mass lesions**

Mass lesions involving the cortex cause epilepsy. Seizures are one of the most common presenting features of brain tumours. Brain tumours cause 6% of cases of adult-onset epilepsy.

**Vascular disorders**

*Stroke and small-vessel cerebrovascular disease* is the most common cause of epilepsy after the age of 60.

**Cortical venous thrombosis or venous sinus thrombosis**

Arteriovenous malformations commonly cause epilepsy.

*Cavernous haemangiomas (cavernomas)* usually present with epilepsy (see *Fig. 21.41*).

**Neurodegenerative disorders**

Neurodegenerative disorders involving the cerebral cortex, such as Alzheimer's disease, are associated with an increased risk of epilepsy.

**Infection**

Seizures are often the presenting feature of encephalitis, cerebral abscess and tuberculomas.
They also occur in chronic meningitis (e.g. tuberculosis) and may rarely be the first sign of acute bacterial meningitis. Neurocysticercosis is a major cause of seizures in countries where the pork tapeworm is endemic, such as India and South America. HIV and complications of immunosuppression, such as cerebral toxoplasmosis, may also lead to seizures.

**Immunological disorders**

Autoimmune antibody-mediated encephalitis, such as that due to antibodies against potassium channels or NMDA or glycine receptors, typically present with seizures, as may autoimmune limbic encephalitis.

**Alcohol and drugs**

Chronic alcohol use is a common cause of seizures. These occur either during heavy drinking bouts or during periods of withdrawal. Alcohol-induced hypoglycaemia and head injury also lead to seizures.

Several drugs, including antipsychotics, tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), lithium, class Ib anti-arrhythmics such as lidocaine, ciclosporin and mefloquine, sometimes provoke fits, either in overdose or at therapeutic doses in individuals with a low seizure threshold. Stimulant drugs such as cocaine also cause seizures.

Withdrawal of antiepileptic drugs (especially barbiturates) and benzodiazepines may provoke seizures.

**Metabolic abnormalities**

Seizures can be caused by:

- hypocalcaemia, hypoglycaemia, hyponatraemia
- acute hypoxia
- uraemia, hepatic encephalopathy
- porphyria.

**Diagnosis of the first fit and investigations**

The diagnosis of a seizure is essentially a clinical one, based on taking a history from the patient and any witnesses (Boxes 21.43 and 21.44). Investigations have a limited role in distinguishing between a seizure and other causes of a blackout or attack (see p. 851).

**Box 21.43**

**Diagnosis of a seizure: taking a history after an episode of loss of consciousness**

Witness account is crucial
- What happened:
– Before: aura versus pre-syncopal prodrome
– During: convulsion, automatisms versus brief syncopal blackout and pallor
– After: post-ictal confusion and headache versus rapid recovery in syncope

• Circumstances:
  – Seizure triggers? Sleep deprivation, alcohol binge or drugs
  – Syncope triggers? Pain, heat, prolonged standing and so on

• Epilepsy risk factors?
  – Childhood febrile convulsions
  – Significant head injury
  – Meningitis or encephalitis
  – Family history of epilepsy

• Previous unrecognized seizures?
  – Myoclonic jerks
  – Absences
  – Auras (focal seizures)

• Alcohol excess?

• Medication lowering seizure threshold?

• Hold a driving licence?

---

**Box 21.44**

Useful points when diagnosing epilepsy

**Diagnosis is a clinical one.** Tests such as EEG have little role in distinguishing between epilepsy and other attack types:

• Poor clinical discriminators between types of blackout:
  – Urinary incontinence – may occur in both seizure and syncope
  – Presence of injury

• Good discriminators between types of blackout:
  – Prolonged recovery period (seizure)
  – Bitten tongue – side usually (seizure)
  – Colour change – pallor (syncope), cyanosis (seizure)

• Stereotyped attacks are usually due to epilepsy

• If in doubt, do not diagnose epilepsy – best to wait and see rather than label and treat as epilepsy

• There is no role for a ‘trial of anticonvulsant treatment’ in uncertain cases

The majority of patients referred to a first fit clinic have not had a seizure. The most common error is to misdiagnose a syncopal blackout for a seizure.
Which investigations are needed?

Blood tests, including serum calcium, and an ECG (rhythm, conduction abnormalities, QT interval) are necessary in most patients following an episode of loss of consciousness (Box 21.45).

**Box 21.45**

**Checklist after a first seizure**

- Perform tests:
  - Blood tests and ECG
  - EEG
  - MRI brain (most patients – see text)
- Avoid or remove precipitants: drugs, alcohol, sleep deprivation
- Give advice on safety: e.g. avoid swimming, baths, working at heights
- Stop driving and ask the patient to inform the Driver and Vehicle Licensing Authority (DVLA; in the UK)
- Discuss recurrence risk and treatment

**Electroencephalography**

EEG is most useful to categorize epilepsy and understand its cause, rather than as a means of confirming a doubtful diagnosis of epilepsy. EEG has a high false-negative rate in epilepsy (>&20% even with awake and sleep recordings) and a low false-positive rate (1% of people without epilepsy have epileptiform changes on EEG).

- **EEG abnormalities in epilepsy**: focal cortical spikes (e.g. over a temporal lobe) or generalized spike-and-wave activity (in PGE). Epileptic activity is continuous in status epilepticus.
- **Sleep recordings or 24 h ambulatory EEG** increase sensitivity when routine EEG is normal.
- **Inpatient EEG videotelemetry** is helpful for diagnosis in attacks of uncertain cause.

**Brain imaging**

MRI is indicated in most patients after a first seizure, particularly in focal-onset seizures and in older patients where the chance of a focal brain lesion is greatest. In patients below the age of 30 with a definite electroclinical diagnosis of PGE, brain imaging is not essential.

**Recurrence risk after a first fit**

Some 70–80% of people will have a second seizure, the risk being highest in the first 6 months after the initial seizure. The vast majority of those who have a second seizure will have further seizures if not started on treatment. The risk of seizure recurrence is significantly increased by
features of PGE on EEG, focal seizures and the presence of structural brain lesions.

Management

Emergency measures
Most seizures last only minutes and end spontaneously. A prolonged seizure (>5 min) or repeated seizures may be terminated with rectal diazepam, intravenous lorazepam or buccal midazolam. Oxygen should be given and the airway monitored in the post-ictal phase.

Status epilepticus
This medical emergency (Box 21.46) means continuous seizures for 30 minutes or longer (or two or more seizures without recovery of consciousness between them over a similar period). Status epilepticus has a mortality of 10–15%. The longer the duration of status, the greater the risk of permanent cerebral damage. Rhabdomyolysis may lead to acute kidney injury in convulsive status epilepticus.

Box 21.46

Status epilepticus

Management

Early status (up to 30 min)
• Administer oxygen, monitor ECG and blood pressure, perform routine blood tests (include glucose, calcium, drug screen, anticonvulsant levels urgently)
• Give lorazepam i.v. 4 mg bolus. Repeat once if necessary. Buccal midazolam is an alternative

Established status (30–90 min)
• Phenytoin: give 15 mg/kg i.v. diluted to 10 mg/mL in saline into a large vein at 50 mg/min (ECG monitoring required)
  or
• Fosphenytoin: this is a prodrug of phenytoin and can be given faster than phenytoin. Doses are expressed in phenytoin equivalents (PE): fosphenytoin 1.5 mg = 1 mg phenytoin. Give 15 mg/kg (PE) fosphenytoin (15 mg × 1.5 = 21.5 mg) diluted to 10 mg/mL in saline at 50–100 mg (PE)/min

If ongoing seizures
• Phenobarbital 10 mg/kg i.v. diluted 1 in 10 in water for injection at <100 mg/min
• Valproate i.v. (25 mg/kg) is an alternative
Refractory status (>90 min) – general anaesthesia

• Only in intensive care setting; intubation and ventilation usually required
• Propofol bolus 2 mg/kg, repeat, followed by continuous infusion of 5–10 mg/kg per hour
• Thiopental and midazolam infusions may also be used
• Use continuous EEG monitoring to assess efficacy of treatment – aim for EEG burst suppression pattern
• Reinstate previous AED medication via nasogastric tube
• Establish diagnosis: CT or MRI may reveal an underlying cause
• Remember: 25% of apparent status cases turn out to be pseudostatus

Over 50% of cases occur without a previous history of epilepsy. Some 25% with apparent refractory status have pseudostatus (non-epileptic attack disorder).

Not all status is convulsive. In absence status, for example, status is non-convulsive; the patient is in a continuous, distant, stuporose state. Focal status also occurs. Epilepsia partialis continua is continuous seizure activity in one part of the body, such as a finger or a limb, without loss of consciousness. This is often due to a cortical neoplasm or, in the elderly, a cortical infarct.

Antiepileptic drugs

Antiepileptic drugs (AEDs; Box 21.47) are indicated when there is a firm clinical diagnosis of epilepsy and a substantial risk of recurrent seizures. Some general principles apply:
• Introduce AEDs at low dose and slowly titrate upwards until the seizures are controlled or side-effects become unacceptable.
• Aim for monotherapy; 70% of patients will have good seizure control with a single AED.
• If seizures are not controlled with the first AED, gradually introduce a second agent and then slowly withdraw the first AED. If the patient is still not seizure-free, then combination therapy is required.
• Epilepsy is one of the few disorders where non-generic (‘brand name’) prescribing is justified to ensure consistent drug levels.
• Routine monitoring of AED levels is not needed and should be reserved for assessing compliance and toxicity. Measuring sodium valproate levels is rarely useful, as levels fluctuate widely.
• There are interactions between AEDs (and with other medications), e.g. between sodium valproate and lamotrigine. New-generation AEDs have fewer interactions.
• Phenytoin is no longer considered a first-line AED; it is now principally used in emergency control of seizures (see status epilepticus above). Levetiracetam is increasingly used in most types of epilepsy.

### Unwanted effects of drugs

Intoxication with most AEDs causes unsteadiness, nystagmus and drowsiness. Side-effects are more common with multiple AED usage. Skin rashes are seen particularly with lamotrigine, carbamazepine and phenytoin. A wide variety of idiosyncratic drug reactions may occur, such as blood dyscrasias with carbamazepine.

### Epilepsy in women

See page 1306.

### Epilepsy and driving

Patients should be asked to stop driving after a seizure and to inform the regulatory authorities if they hold a driving licence. After a seizure, a temporary driving ban until seizure-free is usual but regulations vary from country to country. Many driving regulatory bodies also suggest refraining from driving while withdrawing from AEDs.

### Lifestyle and safety

People with epilepsy (the term ‘epileptic’ is no longer used) should be encouraged to lead lives as unrestricted as reasonably possible, though observing simple safety measures such as avoiding swimming and dangerous sports like rock-climbing. Advice at home includes leaving bathroom and lavatory doors unlocked and taking showers rather than baths. Epilepsy triggers, such as sleep deprivation, excess alcohol and drugs, should be avoided, as should strobe lighting where there is EEG evidence of a photo-paroxysmal response.
Drug withdrawal
Withdrawal of AEDs should be considered after a seizure-free period of at least 2–3 years. There is a 50% seizure recurrence rate after withdrawal so detailed discussion and explanation are essential.

Refractory epilepsy
• Seizures may persist despite treatment, especially with temporal lobe epilepsy.
• Re-evaluate the diagnosis.
• Consider concordance (compliance).
• Combine AEDs and use the maximum tolerated dose.
• Refer to a specialist unit for consideration of epilepsy surgery.
• Other non-pharmacological treatments, such as vagal nerve stimulation and the ketogenic low-carbohydrate diet, may sometimes be useful.

Epilepsy surgery
Temporal lobectomy will result in seizure freedom in 50–70% of selected patients with uncontrolled seizures caused by hippocampal sclerosis (defined by imaging and confirmed by EEG).

Other causes of blackouts
The distinction between a fit (seizure), a faint (syncope) or another type of attack is primarily a clinical one, dependent on the history and an eyewitness account (Box 21.48). Mistaking a syncopal loss of consciousness for a seizure is the most frequent error made in differential diagnosis.

Box 21.48
Causes of blackouts and ‘funny turns’
• Epilepsy
• Syncope:
  – Neurocardiogenic syncope (vasovagal)
  – Cardiac syncope (Stokes–Adams attacks)
  – Micturition syncope
  – Cough syncope
  – Postural hypotension
  – Carotid sinus syncope
• Non-epileptic attacks (pseudoseizures)
• Panic attacks and hyperventilation
The simple faint that over half the population experiences at some time (particularly in childhood, youth or pregnancy) is due to sudden reflex bradycardia with vasodilatation of both peripheral and splanchnic vasculature (*neurocardiogenic or vasovagal syncope*).

**Precipitants**: a common response to prolonged standing, fear, venesection or pain. Syncope almost never occurs in the recumbent posture.

**Prodrome**: usually brief. There is dizziness and a light-headed feeling, often with nausea, sweating, a feeling of heat and visual grey-out.

**Blackout** (see p. 798): patients usually lie still but jerking and twitching movements can occur and are sometimes mistaken for a convulsion. Their appearance is pale. Incontinence of urine or faeces can occur and is not a good discriminator between seizure and syncope.

**Recovery**: rapid, usually taking place over seconds, but may be followed by a feeling of general fatigue (as opposed to post-ictal drowsiness and confusion following a seizure).

### Other types of syncope

**Cardiac syncope** (Stokes–Adams attacks) is potentially serious and often treatable. Typically, there is little or no warning. Cardiac arrhythmias, such as those due to heart block, or left ventricular outflow tract obstruction may be the cause. Syncope during exercise is often cardiac in origin.

- **Micturition syncope** occurs during micturition in men, particularly at night.
- **Cough syncope** occurs when venous return to the heart is obstructed by bouts of severe coughing; it is also seen with laughter occasionally.
- **Postural hypotension** (see p. 939) can cause syncope and occurs in the elderly, in autonomic neuropathy, and with some drugs, such as antihypertensives.
- **Carotid sinus syncope** (see p. 940) is due to a vagal response caused by pressure over the carotid sinus baroreceptors in the neck: for example, due to a tight collar.
- **Convulsive syncope** is when collapsing in a propped-up position following a syncope results in delayed restoration of cerebral blood flow and may lead to a secondary anoxic seizure following syncope.
Investigations

A 12-lead ECG should always be performed after a syncope to identify heart block, pre-excitation or long QT syndrome. Cardiac ECG holter monitoring and echocardiography are required where cardiac syncope is suspected. An implantable loop recorder is occasionally needed for infrequent events with a possible cardiac origin. Tilt-table testing (see p. 948) is sometimes diagnostic but has low sensitivity.

Other conditions

**Non-epileptic attack disorder** *(pseudoseizures)* regularly causes difficulty in diagnosis. Attacks may look like grand mal fits. Usually, there are bizarre thrashing, non-synchronous limb movements, but there can be extreme difficulty in separating these attacks from seizures. EEG videotelemetry is valuable. Apparent status epilepticus can occur. The serum prolactin level is of some value; this rises during a grand mal seizure but not during a pseudoseizure (or a partial seizure).

**Panic attacks** (see p. 916) trigger sudden sympathetic activation and often hyperventilation, leading to respiratory alkalosis. They cause some or all of the following symptoms: dizziness, chest pains or tightness, a feeling of choking or shortness of breath, tingling in face and extremities, palpitations, trembling and a feeling of dissociation or of impending doom. Consciousness is usually preserved and attacks are easily recognized. Blood gases should be measured.

**Hypoglycaemia** (see p. 1258) causes confusion followed by loss of consciousness, sometimes with a convulsion, dysphasia or hemiparesis. There is often a warning, with hunger, malaise, shaking and sweating. Prompt recovery occurs with intravenous (or oral) glucose. Prolonged hypoglycaemia causes widespread cerebral damage. Hypoglycaemic attacks unrelated to diabetes are rare (see pp. 1275–1276). Feeling faint after fasting does not indicate anything serious.

**Vertigo**, when acute, can be sufficiently severe as to cause prostration; a few seconds’ unresponsiveness sometimes follows.

**Migraine**, in the form of severe basilar migraine and familial hemiplegic migraine, may occasionally lead to loss of consciousness.

**Drop attacks** are instant, unexpected episodes of lower limb weakness with falling, largely in women over 60 years. Awareness is preserved. They are due to sudden change in lower limb tone, presumably of brainstem origin. Sudden attacks of leg weakness also occur in hydrocephalus.

**TIAs** are almost never a cause of loss of consciousness.

Sleep disorders

Sleep architecture and insomnia are discussed on pages 904–905. Myoclonic jerks when
falling asleep are a normal phenomenon (see p. 856). Seizures may occur predominantly or solely during sleep.

### Narcolepsy and cataplexy

Narcolepsy is caused by abnormalities of the brain neurotransmitter hypocretin (orexin), which is a regulator of sleep. CSF levels are usually low, thought in most cases to be due to autoimmune damage to the hypothalamic cells secreting the neurotransmitter. Narcolepsy is strongly associated with human leucocyte antigen (HLA)-DR2 and HLA-DQBl*0602 antigens. The prevalence is estimated at 30–50/100 000.

There are four main clinical features but not all patients have the full tetrad:

• **Excessive daytime sleepiness (EDS)**. This is the usual presenting symptom and the main cause of disability. Patients have frequent irresistible sleep attacks during the day, often in inappropriate circumstances, e.g. during meals or conversations or while driving. EDS may be quantified with the Epworth Sleepiness Scale. Night-time sleep may be disrupted and, paradoxically, insomnia may occur.

• **Cataplexy**. This is sudden loss of muscle tone leading to head droop or even falling with intact awareness. Attacks are often set off by sudden surprise or emotion, e.g. laughter.

• **Hypnagogic/hypnopompic hallucinations**. These terms refer to dream-like hallucinations occurring while falling asleep or waking from sleep; these are often frightening.

• **Sleep paralysis**. A brief paralysis on waking or while falling asleep is due to intrusion of rapid eye movement (REM) atonia into wakefulness. This occasionally occurs in people without narcolepsy.

### Diagnosis and management

Multiple sleep latency testing demonstrating a rapid transition from wakefulness to sleep and a short time to onset of REM sleep confirms the diagnosis. HLA testing may also be useful.

Good sleep hygiene advice is necessary. Modafinil dexamfetamine and methylphenidate are used to treat EDS, often with only partial response. Tricyclic antidepressants, particularly clomipramine, or SSRIs can improve cataplexy. Sodium oxybate is also used.

### Parasonias

**Disruptive motor or verbal behaviours occurring during sleep** are divided into REM and non-REM parasonias, depending on which stage of sleep they arise in. They include sleepwalking, night terrors, confusional arousals and REM sleep behaviour disorder (which may be an early feature of Parkinson's disease).

### Obstructive sleep apnoea
Restless leg syndrome (Willis–Ekbom disease)

This affects about 10% of adults, both women and men, and is also seen in children. Most people do not seek medical advice but it can be quite severe in 2–3%. The syndrome is characterized by an unpleasant sensation of ‘wanting to move’ the legs with throbbing or pulling, and usually occurs when the person is resting, sitting or lying; it can be totally or partially relieved by stretching or walking. It often occurs in the evenings or night-time and appears to be more frequent in the elderly. The condition is usually idiopathic and there is a familial tendency. It has been associated with pregnancy, Parkinson's disease, uraemia or a haematinic deficiency. Some drugs have been implicated.

There is no specific treatment. Dopamine agonist drugs and benzodiazepines may help. Some suggest a decreased use of alcohol or caffeine.

Movement Disorders

Disorders of movement divide broadly into two categories:

• hypokinesias – characterized by slowed movements with increased tone (parkinsonism)
• hyperkinesias – excessive involuntary movements.

Both types may coexist: for example, in Parkinson's disease, where there are both slowed movements and tremor. Many of these disorders (not all) relate to dysfunction of the basal ganglia.

Parkinsonian disorders

Idiopathic Parkinson's disease
In 1817, James Parkinson, a physician in Hoxton, London, published *The Shaking Palsy*, describing this common worldwide condition that has a prevalence of 150/100,000. Parkinson's disease (PD) is clinically and pathologically distinct from other parkinsonian syndromes.

### Aetiology

The causes of idiopathic PD are still not fully understood. The relatively uniform worldwide prevalence suggests that a single environmental agent is not responsible. There may be multiple interacting risk factors, including genetic susceptibility.

### Age and gender

Prevalence increases sharply with age, particularly over 70 years, with prevalence of 1 in 200 over age 80. Ageing changes are likely to be a factor in causation. Prevalence is higher in men (1.5:1 male to female).

### Environmental factors

Epidemiological studies consistently show a small increased risk with rural living and drinking well water. Pesticide exposure has been implicated and pesticide-induced rodent models of PD exist, which increases biological plausibility of a link. The chemical compound methyl-phenyl tetrahydropyridine (MPTP), a potent mitochondrial toxin, causes severe parkinsonism, leading to suggestions that oxidative stress may be a factor leading to neuronal cell death in idiopathic PD. Studies consistently show that non-smokers have a higher risk of PD than smokers (even after controlling for shorter life expectancy in smokers), an observation that is difficult to explain.

### Genetic factors

Idiopathic PD is not usually familial but twin studies show there is a significant genetic component in early-onset PD (onset before 40). Several genetic loci for Mendelian inherited monogenic forms of PD have now been identified (*Box 21.49*), designated PARK 1–11. Most of these are rare but together they account for a large proportion of early-onset and familial PD, and a small proportion (perhaps 1–2%), of sporadic late-onset cases. The main significance of the PARK genes is that they provide insights into the pathophysiological mechanisms underlying PD that may be relevant to sporadic cases. Polymorphisms in these and other genes may, in combination, constitute a susceptibility to PD that can be triggered by environmental factors or the ageing process.

AD, autosomal dominant; AR, autosomal recessive.

Pathology

The pathological hallmarks of PD are the presence of neuronal inclusions called Lewy bodies (see pp. 877–878) and loss of the dopaminergic neurones from the pars compacta of the substantia nigra in the midbrain that project to the striatum of the basal ganglia (see Fig. 21.11). Lewy bodies contain tangles of α-synuclein and ubiquitin, and become gradually more widespread as the condition progresses, spreading from the lower brainstem to the midbrain and then into the cortex. Degeneration also occurs in other basal ganglia nuclei. The extent of nigrostriatal dopaminergic cell loss correlates with the degree of akinesia.

Clinical features

PD almost always presents with the typical motor symptoms of tremor and slowness of movement but it is likely that the pathological process starts many years before these symptoms develop. By the time of first presentation, on average 70% of dopaminergic nigrostriatal cells have already been lost.

Prodromal pre-motor symptoms

Patients develop a variety of non-specific non-motor symptoms during the approximately 7 years, sometimes longer, before the motor symptoms become manifest. These include:

• anosmia (present in 90%) – the olfactory bulb is one of the first structures to be affected
• depression/anxiety (50%)
• aches and pains
• REM sleep behaviour disorder
• autonomic features – urinary urgency, hypotension
• constipation
• restless legs syndrome.

**Motor symptoms**
These develop slowly and insidiously, and are often initially attributed to ‘old age’ by patients. The core motor features of PD are:
• akinesia
• tremor
• rigidity
• postural and gait disturbance.

    Slowness causes difficulty rising from a chair or getting into or out of bed. Writing becomes small (micrographia) and spidery, tending to tail off. Relatives often notice other features: slowness and an impassive face. Idiopathic PD is almost always more prominent initially on one side. The diagnosis is usually evident from the overall appearance.

**Akinesia**
Poverty/slowing of movement (also called bradykinesia) is the cardinal clinical feature of Parkinsonism and the main cause of disability. What distinguishes it from slowness of movement from other causes is a progressive *fatiguing and decrement* in amplitude and speed of repetitive movements, such as opening and closing the hand or finger tapping.

    There is difficulty initiating movement. The upper limb is usually affected first and is almost always unilateral for the first years. Rapid dexterous movements are impaired, causing difficulty writing (micrographia) and doing up buttons and zips, for example. Facial immobility gives a mask-like semblance of depression. Frequency of spontaneous blinking diminishes, producing a *serpentine stare*.

**Tremor**
Tremor is the presenting symptom in 70% of patients. It typically starts in the fingers or hand (3–6 Hz) and is unilateral initially, spreading later to the leg on the same side and, after some years, to the opposite side. The tremor is present at rest, and reduces or stops completely when the hand is in motion. It is often described as *pill-rolling* because the patient appears to be rolling something between thumb and forefinger. As with most tremors, it is made worse by emotion or stress.

**Rigidity**
This is a sign rather than a symptom. Stiffness on passive limb movement is described as ‘lead pipe’, as it is present throughout the range of movement and, unlike spasticity, is not dependent on speed of movement. When stiffness occurs with tremor (not always visible), a ratchet-like jerkiness is felt, described as ‘cogwheel’ rigidity.

**Postural and gait changes**
A stooped posture is characteristic. Gait gradually becomes shuffling with small stride length, slow turns, freezing and reduced arm swing. Postural stability eventually deteriorates, leading to falls, but this is a late-stage feature that should arouse suspicion of an alternative diagnosis if present during the first 5 years.

Speech and swallowing
Speech becomes quiet, indistinct and flat. Drooling may be an embarrassing problem and swallowing difficulty is a late feature that may eventually lead to aspiration pneumonia as a terminal event.

Cognitive and psychiatric changes
Cognitive impairment is now recognized to be common in late-stage PD (80%) and may develop into dementia. Visual hallucinations on treatment, and psychosis are not uncommon, and may herald evolving cognitive decline. Cholinesterase inhibitors (see p. 879) may be helpful.

Depression is common, probably due to involvement of serotonergic and adrenergic systems, and is a cause of reduced quality of life in PD. Anxiety is also co-morbid with PD.

The clinical evolution of PD
Most patients respond well to treatment and there is generally a period of several years in which symptoms are well controlled with relatively little disability. Response to dopaminergic drugs is never lost but treatment-related fluctuations may develop (see below), which can be limiting, especially for patients with early age at onset. Eventually, usually by the mid-seventies, late-stage, treatment-unresponsive features, such as cognitive impairment, swallowing difficulty, loss of postural stability and falls, start to emerge.

The rate of progression is very variable, with a benign form running over several decades. Usually, the course is over 10–20 years, death resulting from bronchopneumonia and immobility.

Diagnosis
There is no laboratory test; diagnosis is made by recognizing physical signs and distinguishing idiopathic PD from other Parkinsonian syndromes. Patients with suspected PD should be referred to a specialist without initiation of treatment.

MRI is normal and not necessary in typical cases. Dopamine transporter (DAT) imaging using SPECT or PET makes use of a radio-labelled ligand binding to dopaminergic terminals to assess the extent of nigrostriatal cell loss. It may occasionally be needed to distinguish PD from other causes of tremor or from drug-induced parkinsonism, but it cannot discriminate between PD and other akinetic-rigid syndromes.

Management
Education about the condition is necessary and physical activity is beneficial and should be encouraged. Dopamine replacement with levodopa or a dopamine agonist improves motor symptoms and is the basis of pharmacological therapy. Treatment of non-motor symptoms, such as depression, constipation, pain and sleep disorders, is also necessary and significantly improves quality of life.

Dopamine replacement may not always be needed in early-stage PD and is only started when symptoms begin to cause disability. The mechanism of action of drugs in PD is shown in Figure 21.45.

**Figure 21.45** Drugs in Parkinson's disease. Levodopa crosses the blood–brain barrier, enters the nigrostriatal neurone and is converted to dopamine. (a) Carbidopa and benserazide reduce peripheral conversion of levodopa to dopamine, thus reducing the side-effects of circulating dopamine. (b) Dietary amino acids from high-protein meals can inhibit active transport across the blood–brain barrier by competing with levodopa. (c) Levodopa is converted (aromatic amino acid decarboxylase, AAAD) to dopamine. (d) Amantadine enhances dopamine release. (e) Dopamine agonists react with dopamine receptors. (f) Monoamine oxidase (MAO)-B inhibitors block dopamine breakdown. (g) Catechol-O-methyl transferase (COMT) inhibitors prolong dopamine activity by blocking breakdown.

**Levodopa**

Levodopa remains the most effective form of treatment and all patients with PD will eventually need it. It is combined with a dopa decarboxylase inhibitor – benserazide (co-beneldopa) or carbidopa (co-careldopa) – to reduce the peripheral adverse effects (e.g. nausea and hypotension); 50 mg of levodopa (e.g. co-careldopa 62.5 mg) three times daily, increasing after 1 week to 100 mg three times daily, is a typical starting dose. The response is often dramatic.

**Dopamine agonists**

Dopamine agonists (DAs) may be used in combination with levodopa or as initial monotherapy in younger patients (below age 65–70) with mild to moderate impairment. Although less efficacious in symptom control than levodopa and generally less well tolerated, DAs are
associated with fewer motor complications over a 5-year period. Non-ergot DAs (pramipexole and ropinirole or rotigotine via transdermal patch) are used in preference to ergot-derived drugs, which may be associated with fibrotic reactions, including cardiac valvular fibrosis. Domperidone is used as an antiemetic when initiating DA therapy (other antiemetics should not be used, as they may worsen symptoms by blocking central dopamine receptors).

Other drugs used in PD

- **Selegiline** 5–10 mg once daily (a monoamine oxidase (MAO)-B inhibitor) reduces catabolism of dopamine in brain. It has a mild symptomatic effect. **Rasagiline** is another MAO-B inhibitor.
- **Amantadine** has a modest anti-parkinsonian effect but is used mainly to improve dyskinesias in advanced disease.
- **Antimuscarinics** (e.g. orphenadrine, procyclidine, trihexyphenidyl) may help tremor but are rarely used in PD except in younger patients. They have a high propensity to cause confusion and cognitive impairment in older patients.
- **Apomorphine** is a potent, short-acting DA administered subcutaneously by an autoinjector pen as intermittent ‘rescue’ injection for off periods or by continuous infusion pump. It is used in advanced PD.

Long-term response to treatment

As the disease progresses, medical therapy for PD becomes more difficult as higher doses of dopamine replacement therapy are required and response becomes more unpredictable with the development of motor fluctuations and dyskinesias; response to dopaminergic drugs is never lost, however.

Approximately 10% of patients per year develop motor complications in the form of ‘wearing off’ (the duration of effect of individual doses of levodopa becomes progressively shorter), dyskinesias (involuntary choreiform movements) and, eventually, ‘on/off’ phenomena (sudden, unpredictable transitions from mobile to immobile). Eventually, patients may alternate between the ‘on’ state with dopamine-induced dyskinesias and periods of complete immobility (‘off’).

Management of the motor complications of treatment represents one of the greatest challenges in the management of PD. Strategies include:

- dose fractionation of levodopa – increasing dose frequency
- addition of the catechol-O-methyl transferase (COMT) inhibitor **entacapone** (200 mg with each levodopa dose) to prolong duration of action; this is also available as a combined preparation with levodopa and carbidopa
- slow-release levodopa – mostly used for overnight symptoms, as absorption is erratic and difficult to predict, so limiting effectiveness in control of daytime symptoms
- avoidance of protein-rich meals (which impair levodopa absorption) and taking doses at least
40 minutes prior to meals
• apomorphine continuous subcutaneous infusion (see above)
• deep brain stimulation and levodopa intestinal gel (see below).

Deep brain stimulation
Stereotactic insertion of electrodes into the brain has proved to be a major therapeutic advance in selected patients (usually under age 70) with disabling dyskinesias and motor fluctuations not adequately controlled with medical therapy. Targets include:
• the subthalamic nucleus – response similar to levodopa with reduction in dyskinesia
• the globus pallidus – improves dyskinesia but levodopa is still required for motor symptoms
• the thalamus – for tremor only.

Dopaminergic drugs can be reduced (but not withdrawn) after deep brain stimulation (DBS). Approximately 10% of patients will be candidates at some point, usually patients with younger onset, as they have a higher rate of motor complications such as dyskinesia. There is a trend towards earlier use of DBS before motor complications become severe.

Levodopa intestinal gel infusion
Continuous infusion of this gel into the small intestine via a jejunostomy using a patient-operated pump is effective for selected patients with severe motor complications. At present, it is used only where apomorphine and DBS are contraindicated, partly because of high costs.

Tissue transplantation
Transplantation of embryonic mesencephalic dopaminergic cells directly into the putamen has produced mixed results but is potentially promising; research is ongoing to refine the technique. Stem cells and gene therapy approaches are in development.

Physiotherapy, occupational therapy and physical aids
Physiotherapy, occupational therapy and speech therapy all have a role to play in managing PD and reducing disability, speech and swallowing problems, and falls. Walking aids are often a hindrance early on, but later a frame or a tripod may help. A variety of external cueing techniques may help with freezing.

Other akinetic–rigid syndromes

Drug-induced parkinsonism
Dopamine-blocking or depleting drugs, particularly neuroleptics (with the exception of clozapine), induce parkinsonism or worsen symptoms in affected patients, and may precipitate symptoms in elderly patients in the pre-symptomatic phase. Antimuscarinic drugs reduce these symptoms, although tardive dyskinesia may be made worse.
Atypical parkinsonism

A number of neurodegenerative disorders affect the basal ganglia, causing prominent parkinsonism as part of the clinical picture; they may be mistaken for idiopathic PD in the early stages. These include:

- **Progressive supranuclear palsy** (Steele–Richardson–Olszewski syndrome). This causes parkinsonism, postural instability with early falls, vertical supranuclear gaze palsy, pseudobulbar palsy and dementia. Tau deposition is seen pathologically in the substantia nigra, subthalamic nucleus and midbrain.

- **Multiple system atrophy** (**MSA**). Autonomic and cerebellar symptoms occur in addition to parkinsonism. Either parkinsonism or cerebellar symptoms predominate. Pathologically, α-synuclein-positive glial cytoplasmic inclusions are found in the basal ganglion, cerebellum and motor cortex. Patients do not respond to levodopa therapy. Management is symptomatic and they have a poorer prognosis than patients with Parkinson's disease.

- **Corticobasal degeneration**. Alien limb phenomena, myoclonus and dementia occur.

  These disorders are relentlessly progressive; although they sometimes respond to levodopa, they usually cause death within a decade. ‘Red flag’ symptoms suggesting one of these disorders include:

  - symmetrical presentation and absence of tremor
  - levodopa unresponsiveness (or poor response)
  - early falls (within first year)
  - additional neurological features.

Wilson's disease

This rare and treatable disorder of copper metabolism is inherited as an autosomal recessive trait. Copper deposition occurs in the basal ganglia, cornea and liver (see p. 479), where it can cause cirrhosis. All young patients (below age 50) with any hyperkinetic movement disorder or with liver cirrhosis should be screened for Wilson's disease (serum copper and caeruloplasmin should be checked). Intellectual impairment develops. Neurological damage is reversible with early treatment. Diagnosis and treatment with the chelating agent penicillamine are discussed on page 479.

Hyperkinetic movement disorders

There are five hyperkinetic movement disorders, which can sometimes be difficult to separate from one another and may occur in combination.

- **tremor** – rhythmic sinusoidal oscillation of a body part
- **chorea** – excessive, irregular movements flitting from one body part to another (‘dance-like’
• **myoclonus** – brief, electric shock-like jerks
• **tics** – stereotyped movements or vocalizations (may be temporarily suppressed)
• **dystonia** – sustained muscle spasms causing twisting movements and abnormal postures.

---

### Essential tremor

This common condition, often inherited as an autosomal dominant trait, causes a bilateral, fast, low-amplitude tremor, mainly in the upper limbs. The head and voice are occasionally involved. Tremor is postural, such as when holding a glass or cutlery. Essential tremor occurs at any age but usually starts in early life. Tremor is slowly progressive but rarely produces severe disability. There may be a cerebellar-type action tremor component. Anxiety exacerbates the tremor.

Treatment is often unnecessary or unsatisfactory. Many patients are reassured to find they do not have PD, with which essential tremor is often confused. Small amounts of alcohol, beta-blockers (propranolol), primidone or gabapentin may help. Sympathomimetics (e.g. salbutamol) make all tremors worse. Stereotactic thalamotomy and thalamic DBS are used in severe cases.

---

### Chorea

There are a wide variety of possible causes of chorea. These include:

- systemic disease – thyrotoxicosis, SLE, antiphospholipid syndrome, polycythemia vera
- genetic disorders – Huntington's disease and genetic phenocopies, neuroacanthocytosis, benign hereditary chorea
- structural and vascular disorders affecting the basal ganglia
- drugs (e.g. levodopa and the oral contraceptive pill)
- post-infectious (Sydenham's chorea) – following months after streptococcal infection or as part of acute rheumatic fever
- pregnancy.

Treatment is of the underlying cause but dopamine-blocking drugs, such as phenothiazines (e.g. sulpiride) and dopamine-depleting drugs (tetrabenazine), reduce chorea (as the prototypical excessive movement condition the treatment is the opposite of PD).

---

### Huntington's disease

Huntington's disease is a cause of chorea, usually presenting in middle life, initially with subtle ‘fidgetiness’ followed by development of progressive psychiatric and cognitive symptoms.

Prevalence worldwide is about 5/100,000. HD is due to a CAG trinucleotide repeat expansion, which forms the basis of the diagnostic test (see p. 115). This results in translation of an expanded polyglutamine repeat sequence in huntingtin, the protein gene product, the
function of which is unclear. The expansion is thought to be a toxic ‘gain-of-function’ mutation. Most adult-onset patients have 36–55 repeats and there is an inverse relationship between repeat length and age at onset, with juvenile-onset patients having over 60 repeats. Expansion of the unstable CAG repeat during meiosis, particularly spermatogenesis, is the molecular basis for the phenomenon of anticipation (a tendency for successive generations to have earlier onset and more severe disease), particularly when inherited from the father.

HD is inherited in an autosomal dominant manner with complete penetrance (all gene carriers will develop the disease eventually). Previous family history is often not known. There is no disease-modifying treatment at present, although chorea can improve with treatment, such as risperidone or sulpiride, but progressive neurodegeneration leads to dementia and ultimately death after 10–20 years. Patients with small or intermediate-range expansions may present in old age with isolated chorea.

Absence of treatment results in a low take-up rate for pre-symptomatic testing in at-risk individuals. Test centres have protocols for counselling families and addressing ethical issues.

**Hemiballismus**

Hemiballismus (see Fig. 21.11) describes violent swinging movements of one side, usually caused by infarction or haemorrhage in the contralateral subthalamic nucleus.

Acute chorea–hemiballismus also occurs after diabetic hyperosmolar hyperglycaemia, with signal change seen in the basal ganglia on CT or MRI; it is thought to be due to osmotic shifts causing myelinolysis.

**Myoclonus**

Cortical myoclonus is usually distal (hands and fingers especially) and stimulus-sensitive (spontaneous but also triggered by touch or loud noises). It is caused by a wide variety of pathologies affecting the cerebral cortex; spinal and brainstem myoclonus are caused by localized lesions affecting these structures.

**Primary myoclonus**

*Physiological myoclonus*. Nocturnal myoclonus consisting of sudden jerks (often with a feeling of falling) on dropping off to sleep or waking; it is common and not pathological. The startle response is also a form of brainstem myoclonus.

*Myoclonic dystonia (DYT11)*. Myoclonic ‘lightning jerks’, often with dystonia, are inherited as a rare autosomal dominant disorder due to mutations in the ε-sarcoglycan gene. The condition is thought to be allelic with benign essential myoclonus (caused by disruption of the same gene).

**Myoclonus in epilepsy**

Myoclonic jerks occurs in several forms of epilepsy (see p. 847). An antiepileptic drug, such
as valproate, may be helpful.

Progressive myoclonic epilepsy–ataxia syndromes
These rare conditions include genetic and metabolic disorders in which myoclonus accompanies progressive epilepsy, cognitive decline and/or ataxia. Lafora body disease, neuronal ceroid lipofuscinosi and Unverricht–Lundborg disease are examples.

Secondary myoclonus
Myoclonus may be seen in a wide variety of metabolic disorders, including hepatic and renal failure (asterixis), as part of several dementias and neurodegenerative disorders (e.g. Alzheimer's disease) and encephalitis.

Post-anoxic myoclonus sometimes follows severe cerebral anoxia.

Tics
Tics are common (15% lifetime prevalence), brief, stereotyped movements usually affecting the face or neck but which may involve any body part; they include vocal tics. Unlike other movement disorders, they may be transiently suppressed, leading to a build-up of anxiety and overflow after release.

Simple transient tics (e.g. blinking, sniffing or facial grimacing) are common in childhood but may persist. Adult-onset tics are rare and usually have a secondary cause. The borderland between normal and pathological is vague.

Tourette syndrome
The most common cause of tics, characterized by multiple motor tics and at least one vocal tic, starts in childhood and persists longer than a year. Boys are affected more often than girls in a 3:1 ratio. Behavioural problems, including attention deficit hyperactivity disorder (ADHD) and obsessive–compulsive disorder (OCD), are common and may sometimes be the major cause of disability. There is sometimes explosive barking and grunting of obscenities (coprolalia) and gestures (copropraxia) or echolalia (copying what other people say). Many affected individuals never come to medical attention. The cause is not known but it may be a complex problem with histaminergic neurotransmission.

Dystonias
Dystonia (Box 21.50) is most usefully classified by aetiology into:

• primary dystonias – where dystonia is the only, or main, clinical manifestation (usually genetic)
• secondary dystonia – due to brain injury, cerebral palsy or drugs, for example
• heredo-degenerative dystonia – part of a wider neurodegenerative disorder
• **paroxysmal dystonias** – rare, mostly genetic, attacks of sudden involuntary movements with elements of dystonia and chorea.

# Box 21.50

**A classification of dystonias**

- Generalized dystonia
- Primary torsion dystonia (PTD)
- Dopamine-responsive dystonia (DRD)
- Drug-induced dystonia (e.g. metoclopramide)
- Symptomatic dystonia (e.g. after encephalitis lethargica or in Wilson's disease)
- Paroxysmal dystonia (very rare, familial, with marked fluctuation)
- Focal dystonia
- Spasmodic torticollis
- Writer's cramp
- Oromandibular dystonia
- Blepharospasm
- Hemiplegic dystonia, e.g. following stroke
- Multiple sclerosis – rare

**Primary dystonias**

**Young onset.** Mutations in the *DYT1* gene locus, seen particularly in the Ashkenazi Jewish population, cause limb-onset dystonia (usually foot), before the age of 28. Most patients have a three base-pair GAG deletion in the torsinA endoplasmic reticulum ATPase protein encoded by the *DYT1* gene. Penetrance is low (autosomal dominant) and phenotype very variable, but the disorder often spreads over years to become generalized dystonia, and can result in severe disability. Cognitive function remains normal. The condition is rare and the definitive form of treatment for severe cases is DBS (electrodes inserted into the globus pallidus).

**Adult onset.** This is much the most common type of primary dystonia. Onset is usually around 55 and dystonia is usually focal (restricted to one body part), particularly affecting the head and neck, unlike *DYT1* dystonia. Various patterns are recognized.

**Torticollis**

Dystonic spasms gradually develop in neck muscles, causing the head to turn (torticollis) or to be drawn backwards (retrocollis). There may also be a jerky head tremor. A gentle touch with a fingertip at a specific site may relieve the spasm temporarily (sensory trick or ‘geste’).

**Writer's cramp and task-specific dystonias**
There is a specific inability to perform a previously highly developed, repetitive, skilled movement, such as writing. The movement provokes dystonic posturing. Other functions of the hand remain normal. Overuse may lead to task-specific dystonias in certain occupations, such as musicians, typists and even golfers.

**Blepharospasm and oromandibular dystonia**

These consist of spasms of forced blinking or involuntary movement of the mouth and tongue (e.g. lip-smacking and protrusion of the tongue and jaw). Speech may be affected.

**Dopa-responsive dystonia**

In this rare disorder, dystonia is completely abolished by small doses of levodopa. Typically, dystonic walking begins in childhood and may resemble a spastic paraparesis or even present as cerebral palsy. Dominantly inherited mutations in the GTP cyclohydrolase gene on chromosome 14q21.3 (necessary for synthesis of a co-factor – tetrahydrobiopterin – needed for dopamine synthesis) lead to brain dopamine deficiency. Patients with dystonic gaits are sometimes given test doses of levodopa.

**Neuroleptics and movement disorders**

Neuroleptics (antipsychotic drugs used to treat schizophrenia) and related drugs used as antiemetics (e.g. metoclopramide) can cause a variety of movement disorders:

- **Akathisia.** This is a restless, repetitive and irresistible need to move.

- **Parkinsonism.** This is due to D\(_1\) and D\(_2\) dopamine receptor blockade (see above).

- **Acute dystonic reactions.** Spasmodic torticollis, trismus and oculogyric crises (episodes of sustained upward gaze) develop, dramatically and unpredictably, after single doses.

- **Tardive dyskinesia.** These mouthing and lip-smacking grimaces occur after several years of neuroleptic use. They often become temporarily worse when the drug is stopped or the dose reduced. Even if treatment ceases, resolution seldom follows. Atypical neuroleptics are less prone to cause this complication.

**Management**

Targeted injection of botulinum toxin into affected muscles is now the principal form of treatment for all focal dystonias. Antimuscarinics (e.g. trihexyphenidyl) are sometimes helpful.

**Further reading**

Neuroinflammatory Disorders

Multiple sclerosis is by far the most common neuroinflammatory disorder in Western populations. Other CNS inflammatory conditions include post-infectious disorders such as acute disseminated encephalomyelitis (ADEM) and transverse myelitis, distinct autoimmune disorders such as neuromyelitis optica (NMO), and multisystem inflammatory disorders such as sarcoidosis and Behçet's disease.

Multiple sclerosis

Multiple sclerosis (MS) is a chronic autoimmune, T-cell-mediated, inflammatory disorder of the CNS. Multiple plaques of demyelination are found throughout the brain and spinal cord, occurring sporadically over years (dissemination in space and time is crucial for diagnosis).

MS is a major cause of disability in young adults but several disease-modifying therapies are now available.

Epidemiology

Prevalence. MS is a common neurological disorder with over 2 500 000 cases worldwide. In the UK, the prevalence is 1.2/1000. Approximately 80 000 people in the UK have MS.

Gender. Women outnumber men by 2 : 1. There is evidence that this ratio is widening, with an increasing proportion of women being affected.

Age. Presentation is typically between 20 and 40 years of age. Presentation after age 60 is rare, although diagnosis may sometimes be much delayed, occurring years after the initial symptoms.

Prevalence varies widely in different geographical regions and ethnic groups. This probably reflects both genetic (see below) and environmental influences in pathogenesis. MS is much more common in white populations and with increasing distance from the equator. Even within the UK, there is a north–south divide, prevalence being higher in Scotland than southern England. Migration studies show that children moving from a low-risk to a high-risk area (e.g. the UK) develop a higher risk of MS, similar to the population of the country to which they migrate, indicating that environmental factors are a factor in pathogenesis.

Other autoimmune disorders occur with increased frequency in patients with MS and their relatives, indicating a genetic predisposition to autoimmunity.

Aetiology and pathogenesis

MS is a T-cell-mediated autoimmune disease that causes an inflammatory process mainly
within the white matter of the brain and spinal cord. The aetiology of MS is complex and not yet fully understood.

**Genetic susceptibility**

Multiple genes interact to confer an increased risk of MS, giving a complex polygenic inheritance pattern. Genetic differences between different populations probably account for part of the observed variation in MS incidence around the world.

Family studies show that there is a much-increased risk of MS in first-degree relatives of affected patients (approximately 5% lifetime risk of developing MS). Twin studies confirm a major genetic component to susceptibility, with 30% of monozygotic twins being concordant for MS versus 5% of dizygotic twins.

**Genes.** Variations in some 60 different genes have been identified as conferring an increased risk of MS; 80% of these are genes relating to immune system function and regulation, including HLA and major histocompatibility complex (MHC) polymorphisms. HLA-associated genes include haplotypes HLA-DRB1*1501, DQA1*102 and DQB1*0602. HLA-DR15 appears to be associated with an earlier disease onset.

**Environmental factors**

Migration studies (see above) and twin studies indicate that environmental factors play a role in the development of MS but these factors are still largely unknown. Viral infections can precipitate MS relapses, and exposure to infectious agents at critical times in development may trigger MS in genetically susceptible individuals. There is evidence that exposure to Epstein–Barr virus (EBV) may be linked to MS; EBV seropositivity is higher in patients with MS than in the general population. Human herpesvirus 6 (HHV-6) has also been implicated. Exposure to infectious agents in childhood may reduce the risk of developing MS and other autoimmune disorders (the ‘hygiene hypothesis’). There is also some evidence that low levels of vitamin D and lack of sunlight exposure may be a risk factor for MS.

**Pathology**

Plaques of demyelination, 2–10 mm in size, are the cardinal features ([Fig. 21.46](#)). Plaques occur anywhere in CNS white matter but have a predilection for distinct CNS sites: optic nerves, the periventricular region, the corpus callosum, the brainstem and its cerebellar connections, and the cervical cord (corticospinal tracts and posterior columns). MRI studies show that most inflammatory plaques are asymptomatic. Recent advances in pathology and MRI techniques show that the grey matter of the cortex and the sub-pial meninges is also affected from an early stage in MS. Peripheral myelinated nerves are not directly affected in MS.
Acute relapses are caused by focal inflammation causing myelin damage and conduction block. Recovery follows as inflammation subsides and remyelination occurs. When damage is severe, secondary permanent axonal destruction occurs. Progressive axonal damage is the pathological basis of the progressive disability seen in progressive forms of MS. The extent of grey matter damage correlates with the severity of disability and cognitive involvement. The exact relationship between the inflammatory lesions seen in early relapsing–remitting forms of MS and the progressive axonal loss of chronic forms of MS is disputed.

Clinical features

No single group of signs or symptoms is diagnostic. A wide variety of possible symptoms may occur, depending on the anatomical site of the lesions; MS has been described as the modern ‘great imitator’. The clinical time course of attacks and tempo of evolution of symptoms are as helpful as the symptoms themselves in making the diagnosis of MS.

Types of MS

There are four main clinical patterns (Fig. 21.47):

- **Relapsing–remitting MS (RRMS)** (85–90%). This is the most common pattern of MS. Symptoms occur in attacks (relapses) with a characteristic time course: onset over days and typically recovery, either partial or complete, over weeks. On average, patients have one relapse per year but occasionally many years may separate relapses (benign MS – 10% of patients). Patients may accumulate disability over time if they do not recover fully after relapses.

- **Secondary progressive MS**. This late stage of MS consists of gradually worsening disability progressing slowly over years. Some 75% of patients with relapsing–remitting MS will eventually evolve into a secondary progressive phase by 35 years after onset. Relapses may sometimes occur in this progressive phase (relapsing–progressive MS).

- **Primary progressive MS (PPMS)** (10–15%). This pattern is characterized by gradually
worsening disability without relapses or remissions. It typically presents later and is associated with fewer inflammatory changes on MRI.

**Relapsing–progressive MS** (<5%). This is the least common form of MS. It is similar to PPMS but with occasional supra-added relapses on a background of progressive disability from the outset.

![Clinical patterns of multiple sclerosis.](image)

**Clinical presentations**
Three characteristic common presentations of MS are optic neuropathy (neuritis), brainstem demyelination and spinal cord lesions.

**Optic neuritis**
See page 803.

**Brainstem demyelination**
A relapse affecting the brainstem causes combinations of diplopia, vertigo, facial numbness/weakness, dysarthria or dysphagia. Pyramidal signs in the limbs occur when the corticospinal tracts are involved. A typical picture is sudden diplopia, and vertigo with nystagmus, but without tinnitus or deafness. Bilateral internuclear ophthalmoplegia (see p. 805) is pathognomonic of MS.

**Spinal cord lesions**
Paraparesis developing over days or weeks (see Box 21.60) is a typical result of a plaque in the cervical or thoracic cord, causing difficulty in walking and limb numbness with tingling, often asymmetric. Lhermitte's sign may be present (see p. 817). Sometimes the arms are also involved in high cervical cord lesions. A tight band sensation around the abdomen or chest is
common with thoracic cord lesions.

**Common symptoms in MS**

Disability and neurological impairments accumulate gradually over the years. Several symptoms are common and many can be improved with symptomatic treatments.

• Visual changes (see p. 803).

• Sensory symptoms – often unusual, e.g. a sensation of water trickling down the skin. Sensory symptoms are the presenting feature in 40% of patients. Reduced vibration sensation and proprioception in the feet are among the most common abnormalities on examination, but examination may be normal despite significant sensory symptoms.

• Clumsy/useless hand or limb – due to loss of proprioception (often a dorsal column spinal plaque).

• Unsteadiness or ataxia.

• Urinary symptoms – bladder hyper-reflexia causing urinary urgency and frequency. Treatment is with antimuscarinics or intravesical botulinum toxin injections.

• Pain – neuropathic pain is common.

• Fatigue – a common and often debilitating symptom, which can occur in patients with otherwise mild disease. This sometimes responds to amantadine or a fatigue management programme.

• Spasticity – may require baclofen or other muscle relaxants. Occasionally, botulinum toxin injections are used for focal spasticity.

• Depression.

• Sexual dysfunction.

• Temperature sensitivity – temporary worsening of pre-existing symptoms with increases in body temperature, e.g. after exercise or a hot bath, is known as Uhthoff’s phenomenon.

**Unusual presentations**

Epilepsy and trigeminal neuralgia (see p. 845) occur more commonly in MS patients than in the general population. Tonic spasms (frequent brief spasms of one limb) are rare but pathognomonic of MS.

**Late-stage MS**

Late MS causes severe disability with spastic tetraparesis, ataxia, optic atrophy, nystagmus, brainstem signs (e.g. bilateral internuclear ophthalmoplegia), pseudobulbar palsy and urinary incontinence. Cognitive impairment, often with frontal lobe features, may occur in late-stage disease. In a proportion of patients, disability eventually becomes severe, with median time to requiring walking aids of 15 years and time to wheelchair use 25 years from onset.
Diagnosis

Few other neurological diseases have a similar relapsing and remitting course. The diagnosis of MS requires two or more attacks affecting different parts of the CNS: that is, dissemination in time and space, and exclusion of other possible causes. History and support from investigations, particularly MRI, make the diagnosis. The McDonald criteria formalize the diagnostic features but are designed mainly for research purposes and rarely used in clinical practice.

When taking a history at the time of initial presentation, it is essential to ask about previous episodes of neurological symptoms, often years previously, that may represent episodes of unrecognized demyelination: for example, a severe episode of vertigo lasting weeks or loss of vision in one eye that gradually recovered.

Investigations

The purpose of investigations is to provide supportive evidence of dissemination in time and space (i.e. to show scattered demyelinating lesions that evolve over time), to exclude other diseases and to provide evidence of immunological disturbance.

- MRI of brain and cord is the definitive investigation, as it demonstrates areas of demyelination with high sensitivity. Multiple scattered plaques are usually seen (Fig. 21.48A), demonstrating dissemination in space. Typical lesions are oval in shape, up to 2 cm in diameter, and often orientated perpendicular to the lateral ventricles. Occasionally, large ‘tumefactive’ (swelling) lesions are seen (Fig. 21.48B). Acute lesions show gadolinium enhancement for 6–8 weeks. Although a sensitive technique to demonstrate plaques (normal MRI in MS is possible but distinctly rare), it is limited by lower specificity. Over the age of 50, small ischaemic lesions may be difficult to distinguish from demyelination, and in younger patients other neuroinflammatory disorders such as sarcoidosis, Behçet syndrome and vasculitis may produce similar imaging appearances. The presence of spinal cord lesions is quite specific for inflammatory disorders such as MS rather than ischaemic lesions, so cord imaging is often useful where there is diagnostic difficulty.
Multiple sclerosis.

A. T2-weighted magnetic resonance image. Brain plaques are shown (arrowed). Typical lesions are oval in shape, up to 2 cm in diameter, and often orientated perpendicular to the lateral ventricles. B. Tumefactive multiple sclerosis lesion.

• Plaques are rarely visible on CT.
• CSF examination is often unnecessary with suggestive MRI imaging and a compatible clinical picture. CSF analysis shows oligoclonal IgG bands in over 90% of cases but these are not specific for MS. The CSF cell count may be raised (5–60 mononuclear cells/mm$^3$).
• Evoked responses, e.g., visual evoked responses in optic nerve lesions, may demonstrate clinically silent lesions. However, since the advent of MRI, they are less used in diagnosis.
• Blood tests are used to exclude other inflammatory disorders such as sarcoidosis or SLE, or other causes of paraparesis, e.g., adrenoleucodystrophy, HIV, human T-cell lymphotropic virus 1 (HTLV-1) and vitamin B$_{12}$ deficiency.

The clinically isolated syndrome (CIS)

In patients presenting with a first ever episode of neurological symptoms suggestive of neuroinflammation, termed a ‘clinically isolated syndrome’ (CIS), a diagnosis of MS cannot be made by definition. In up to 70% of such patients, MRI shows multiple clinically silent lesions. An abnormal brain MRI at presentation, with multiple inflammatory-type lesions, confers an 85% chance of developing MS over subsequent years (50% if presenting with optic neuritis). Patients need to be made aware of this possibility.

A second clinical event indicative of a new lesion in a different anatomical location allows the diagnosis of MS to be confirmed. Alternatively, a repeat MRI brain scan at least 1 month later showing either a new lesion or a gadolinium-enhancing lesion is sufficient to demonstrate dissemination in time and space and confirm the diagnosis, even in the absence of new symptoms.

Management

There is no cure for MS but, in recent years, several immunomodulatory treatments have been introduced that have dramatically altered the ability to modify the course of the inflammatory
relapsing–remitting phase of MS. It is hoped that these will translate into reduced long-term disability but this has yet to be proven.

**General measures**

Education, provision of appropriate written materials and support from a multidisciplinary team, including an MS nurse specialist, are essentials. Treatments are available for various symptoms, e.g. pain, spasticity and urinary features (*Box 21.51*). Physiotherapy and occupational therapy are helpful where there is persisting impairment between relapses. Infections should be treated early, as they may precipitate relapses or lead to worsening of existing symptoms. Immunizations are safe (but not live vaccines if on disease-modifying drugs).

---

**Box 21.51**

**Symptomatic treatments in multiple sclerosis**

**Urinary symptoms**

- Antimuscarinics, e.g. oxybutynin, tolterodine, solifenacin, trospium
- Desmopressin spray ± antimuscarinic
- Intermittent self-catheterization (ISC)
- Botulinum toxin type A intravesical injections (usually also require ISC)
- Bladder training exercises
- Indwelling catheter

**Spasticity**

- Self-management, including stretching, physiotherapy, splinting
- Skeletal muscle relaxants: baclofen, tizanidine, clonazepam
- Gabapentin
- Botulinum toxin type A (electromyelography-guided injections) for focal spasticity
- Cannabis: oromucosal spray
- Intrathecal baclofen pump
- Intrathecal phenol – destructive procedure in advanced disease with paraplegia

**Pain**

- As for treatment of neuropathic pain (see pp. 819–820)
- Trigeminal neuralgia – carbamazepine, lamotrigine
- Lhermitte’s – carbamazepine

**Depression**
• Cognitive behavioural therapy
• Antidepressants (see p. 901)

**Impaired mobility**
• Physiotherapy ± walking aids
• Treat spasticity
• Fampridine – selected patients

**Erectile dysfunction**
• Sildenafil, tadalafil or vardenafil

**Tremor**
• Beta-adrenoceptor-blocking drugs
• Botulinum toxin type A injections (head or arms)
• Deep brain stimulation for severe Holmes tremor

**Fatigue**
• Fatigue management programme, treat depression
• Amantadine (often ineffective)

**Acute relapses**
Short courses of steroids, such as i.v. methylprednisolone 1 g/day for 3 days or high-dose oral steroids, are used for severe relapses. They speed recovery but do not influence long-term outcome.

**Disease-modifying drugs**
Immunomodulatory disease-modifying drugs (DMDs; *Box 21.52*), such as β-interferon (both IFN-β1b and 1a, and pegylated β1a) and glatiramer acetate, reduce relapse rate by one-third and serious relapses by up to half in RRMS. They also significantly reduce development of new MRI lesions and may reduce accumulation of disability over the short term. They are self-administered by subcutaneous or intramuscular injection and are generally well tolerated, apart from influenza-like side-effects and injection site irritation. From a health economics point of view, cost is an issue, as these drugs are very expensive. IFN-β and glatiramer acetate are considered first-line DMDs. *Current recommendations* in the UK are that DMDs are offered to ambulant patients with RRMS where there have been two or more significant relapses over a 2-year period or after one major disabling relapse. When used after CIS, the conversion rate to definite MS is reduced from 50% to 30% over 3 years, but in the UK treatment with DMDs after CIS is rarely recommended. DMDs are not effective in primary progressive or secondary progressive MS.

ITP, immune thrombocytopenic purpura; MCA, monoclonal antibody; PML, progressive multifocal leucoencephalopathy.

### Oral DMDs

Three oral agents, **fingolimod, teriflunomide** and **dimethyl fumarate**, have been licensed for treatment of RRMS. They all reduce relapse rate significantly and, in the case of fingolimod and dimethyl fumarate, are superior to interferons. In general, they seem well tolerated but have more serious adverse events than interferons. Their exact place in MS treatment is not yet established (cost is an issue); in some countries, they are used as first-line DMDs but in the UK are likely to be used where first-line drugs are not tolerated or not sufficiently effective.

### Treatment of aggressive RRMS

Immunomodulatory drugs and biological agents (monoclonal antibodies), such as **natalizumab** and **alemtuzumab**, have shown high efficacy in preventing relapses and may reduce
accumulation of disability significantly (Box 21.52). They have the potential to cause serious adverse effects and are generally used only in very aggressive disease or where relapses are not reduced by β-IFN or glatiramer acetate.

Other drugs and symptomatic therapies

- **Vitamin D.** There is some evidence that vitamin D supplementation may be beneficial in MS but this is still controversial. Some specialists advocate treatment with up to 2000 IU daily.
- **Fampridine** (4-aminopyridine, an oral potassium-channel blocker). This has been shown to improve walking significantly in selected patients with significant MS-related disability.
- **Other symptomatic treatments.** Symptomatic treatments are available for most complications of MS and significantly improve quality of life (Box 21.51). Urinary urgency and frequency, pain, spasticity and depression are all common and treatable.

### Prognosis

The clinical course of MS is unpredictable; a high MR lesion load at initial presentation, high relapse rate, male gender and late presentation are poor prognostic features but not invariably so. There is wide variation in severity. Many patients continue to live independent, productive lives; a minority become severely disabled. Life expectancy is reduced by 7 years on average.

### Transverse myelitis

Transverse myelitis is an acute inflammatory disorder affecting the spinal cord with cord swelling and loss of function. Typically, one or two spinal segments are affected with part or all of the cord area at that level involved (transverse indicates involvement of the whole cross-section of the cord at the affected level). Clinically, a myelopathy evolves over days, and recovery (often partial) follows over weeks or months. MRI is sensitive and shows cord swelling and oedema with gadolinium enhancement at the affected level(s). Usually, images are also taken of the brain to look for evidence of demyelination. CSF may be inflammatory with an excess of lymphocytes. Causes include:

- **Para-infectious autoimmune inflammatory response.** This is the most common cause and may follow viral infection or immunization, for example.
- **Systemic inflammatory disorders**, e.g. SLE, Sjögren's, sarcoidosis.
- **Infection.** This may be caused by viruses – e.g. herpesviruses, such as varicella zoster or EBV, HIV, HTLV-1 and 2 (tropical spastic paraparesis); mycobacteria, e.g. tuberculosis; bacteria – e.g. syphilis and Lyme disease; or flatworms – e.g. schistosomiasis.
- **Multiple sclerosis.** Transverse myelitis may occur as part of a relapse or be a presenting feature of MS. If the brain MRI is normal, the risk of later development of MS is around 20%; in those that do develop MS with a normal brain MRI, prognosis is better than average.
- **Neuromyelitis optica** – see below.
Treatment is usually with high-dose steroids or other immunosuppression, or antimicrobial therapy in the case of specific infections.

**Neuromyelitis optica**

This is a distinct inflammatory relapsing demyelinating disorder, previously thought to be a variant of MS. It is characterized by longitudinally extensive transverse myelitis (>3 segments) and bilateral or recurrent optic neuritis. Limited forms occur, such as recurrent myelitis only. Serum antibodies to aquaporin-4 water channels on astrocytes are diagnostic. It is rarer than MS but there is a higher incidence in Asians and Afro-Caribbeans.

Treatment with steroids and immunosuppressive drugs is essential from the time of diagnosis, as the relapse rate is high and relapses are much more disabling than in MS. A similar syndrome that follows a monophasic course occurs with myelin oligodendrocyte (MOG) antibodies.

**Acute disseminated encephalomyelitis**

Acute disseminated encephalomyelitis (ADEM) is usually post-infectious, following infections such as measles, mycoplasma, mumps and rubella, and occasionally following 1–2 weeks after immunization. There is a monophasic illness with multifocal brain, brainstem and often spinal cord inflammatory lesions in white matter, with demyelination. ADEM is caused by an immune-mediated host response to infection and occurs principally in children and young adults. Mild cases recover completely. Survivors often have permanent brain damage. Treatment is supportive, with steroids and anticonvulsants.

**Other neuroinflammatory conditions**

**Neurosarcoidosis**

Neurosarcoid with or without systemic sarcoid causes chronic meningoencephalitis, cord lesions, cranial nerve palsies – particularly bilateral VIIth nerve lesions, polyneuropathy and myopathy (see pp. 1118–1120). Diagnosis can be difficult if disease is confined to the CNS.

**Behçet's disease**

Behçet's principal features (see p. 702) are recurrent oral and/or genital ulceration, inflammatory ocular disease (uveitis; see pp. 1332–1333) and neurological syndromes. Brainstem and cord lesions, aseptic meningitis, encephalitis and cerebral venous thrombosis occur. There is a predilection for ethnic groups along the ancient ‘Silk Road’ – Turkey, the Middle East and Asia. Behçet's is associated with the HLA-B51 allele.

Nervous System Infection

Meningitis

Meningitis usually implies serious infection of the meninges (Box 21.53). Bacterial meningitis is fatal unless treated. Microorganisms reach the meninges either by direct extension from the ears, nasopharynx, cranial injury or congenital meningeal defect, or by bloodstream spread. Immunocompromised patients are at risk of infection with unusual organisms. Non-infective causes of meningeal inflammation include malignant meningitis, intrathecal drugs and blood following subarachnoid haemorrhage.

Box 21.53

Infecitive causes of meningitis in the UK

Bacteria

• *Neisseria meningitidis*
• *Streptococcus pneumoniae*\(^a\)
• *Staphylococcus aureus*
• *Streptococcus* group B
• *Listeria monocytogenes*
• Gram-negative bacilli, e.g. *Escherichia coli*
• *Mycobacterium tuberculosis*
• *Treponema pallidum*

Viruses

• Enteroviruses:
  – ECHO
  – Coxsackie
• (Poliomyelitis – mainly eradicated worldwide)
• Mumps
• Herpes simplex
• HIV
• Epstein–Barr

**Fungi**

• Cryptococcus neoformans
• Candida albicans
• Coccidioides immitis, Histoplasma capsulatum, Blastomyces dermatitidis (USA)

---

*These organisms account for 70% of acute bacterial meningitis outside the neonatal period. A wide variety of infective agents are responsible for the remaining 30% of cases. Haemophilus influenzae b (Hib) has been eliminated as a cause in many countries by immunization. Malaria often presents with cerebral symptoms and a fever.*

---

**Pathology**

In acute bacterial meningitis, the pia-arachnoid is congested with polymorphs. A layer of pus forms. This may organize to form adhesions, causing cranial nerve palsies and hydrocephalus.

In chronic infection (e.g. tuberculosis), the brain is covered in a viscous grey–green exudate with numerous meningeal tubercles. Adhesions are invariable. Cerebral oedema occurs in any bacterial meningitis.

In viral meningitis there is a predominantly lymphocytic inflammatory CSF reaction without pus formation, polymorphs or adhesions; there is little or no cerebral oedema unless encephalitis develops.

---

**Clinical features**

**The meningitic syndrome**

This is a simple triad: headache, neck stiffness and fever. Photophobia and vomiting are often present. In acute bacterial infection, there is usually intense malaise, fever, rigors, severe headache, photophobia and vomiting, developing within hours or minutes. The patient is irritable and often prefers to lie still. Neck stiffness and a positive Kernig's sign usually appear within hours.

In less severe cases (e.g. many viral meningitides), there are less prominent meningitic signs. However, bacterial infection may also be indolent, with a deceptively mild onset.

In uncomplicated meningitis, consciousness remains intact, although anyone with a high fever may be delirious. Progressive drowsiness, lateralizing signs and cranial nerve lesions indicate complications such as venous sinus thrombosis (see p. 848), severe cerebral oedema
or hydrocephalus, or an alternative diagnosis such as cerebral abscess (see p. 867) or encephalitis (see pp. 865–866).

Specific varieties of meningitis
Clinical clues point to the diagnosis (Box 21.54). If there is access to the subarachnoid space via skull fracture (recent or old) or occult spina bifida, bacterial meningitis can be recurrent, and the infecting organism is usually pneumococcus.

Acute bacterial meningitis
Onset is typically sudden, with rigors and high fever. Meningococcal septicaemia is associated with a petechial rash, sometimes sparse (Box 21.55 and Fig. 21.49). The meningitis may be part of a generalized meningococcal septicaemia with septic shock and peripheral vascular infarcts (see pp. 281–282). Acute septicaemic shock may develop in any bacterial meningitis.

Meningococcal meningitis and meningococcaemia: emergency treatment
Suspicion of meningococcal infection is a medical emergency requiring treatment immediately.

Clinical features
• Petechial or non-specific blotchy, red rash
• Fever, headache, neck stiffness.

All these features may not be present – and meningococcal infection may sometimes begin
Immediate treatment for suspected meningococcal meningitis at first contact before investigation

- Third-generation cephalosporin, e.g. cefotaxime, as empirical therapy (increasing rates of penicillin resistance)
- Switch to benzylpenicillin if sensitivity confirmed
- Dexamethasone 0.6 mg/kg i.v. with or before first dose of antibiotic

In meningitis, minutes count – delay is unacceptable.

On arrival in hospital

- Blood tests, including blood cultures, immediately
- Monitoring for septic shock.

For further management and prophylaxis, see text.

Viral meningitis

This is almost always a benign, self-limiting condition lasting 4–10 days. Headache may follow for some months. There are no serious sequelae, unless an encephalitis is present (see pp. 865–866).

Chronic meningitis (see below)
For further discussion on chronic meningitis, see below.

### Differential diagnosis

It may be difficult to distinguish between the sudden headache of subarachnoid haemorrhage, migraine and acute meningitis. Meningitis should be considered seriously in anyone with headache and fever, and in any sudden headache. Neck stiffness should be looked for; it may not be obvious.

**Chronic meningitis** sometimes resembles an intracranial mass lesion, with headache, epilepsy and focal signs. Cerebral malaria can mimic bacterial meningitis.

### Management

Recognition and immediate treatment of acute bacterial meningitis (*Box 21.55*) are vital. Minutes save lives. Bacterial meningitis has a high mortality and morbidity. Even with optimal care, mortality is around 15%. The following applies to adult patients; management is similar in children.

When meningococcal meningitis is diagnosed clinically by the petechial rash, immediate intravenous antibiotics should be given and blood cultures taken; lumbar puncture is unnecessary. In other causes of meningitis, an LP is performed if there is no clinical suspicion of a mass lesion (see p. 823). If the latter is suspected, an immediate CT scan must be performed because coning of the cerebellar tonsils may follow LP, but normal brain imaging does not exclude raised intracranial pressure and clinical features of raised pressure contraindicate LP. Typical CSF changes are shown in *Box 21.56*. CSF pressure is characteristically elevated.

Adjunctive immediate high-dose *steroid* (dexamethasone 0.6 mg/kg i.v. for 4 days), given with or before the first dose of antibiotics, has been shown to reduce neurological complications in bacterial meningitis (e.g. deafness), and some studies also show reduced mortality in Western populations.

Blood should be taken for cultures, glucose and routine tests. Chest and skull films should be obtained if appropriate.

CSF stains demonstrate organisms (e.g. Gram-positive intracellular diplococci – pneumococcus; Gram-negative cocci – *meningococcus*). Ziehl–Neelsen stain demonstrates acid-fast bacilli (tuberculosis), though TB organisms are rarely numerous. Indian ink stains fungi.

Meticulous attention should focus on microbiological studies in suspected CNS infection with close liaison between clinician and microbiologist. Specific techniques, such as polymerase chain reaction for *meningococci* and viruses, or CSF bacterial antigen testing, are invaluable. Syphilis serology should always be carried out.

Local infection (e.g. paranasal sinus) should be treated surgically if necessary. Repair of a depressed skull fracture or meningeal tear may be required.

**Prophylaxis**

Meningococcal infection should be notified to the public health authorities, and advice sought about immunization and prophylaxis of contacts. Chemoprophylaxis with rifampicin or ciprofloxacin should be offered to all close contacts. MenC vaccine is given in the UK and MenB, a meningococcal B vaccine, is now available for population immunization of infants and for use in outbreaks. A combined A and C meningococcal vaccine is sometimes used prior
to travel from the UK to endemic regions, such as Africa or Asia, and there is a quadrivalent ACWY vaccine for specific events, such as the Hajj and Umrah in Mecca.

Pneumococcal conjugated vaccine is now given to infants in many countries and pneumococcal polysaccharide vaccine is offered to older adults and those with, for example, immunodeficiency or splenectomy. Pneumococcal immunization has reduced the incidence of pneumococcal meningitis.

*Hib (Haemophilus influenzae)* vaccine is given routinely in childhood in the UK and many other countries, virtually eliminating a common cause of fatal meningitis.

### Chronic meningitis

**Tuberculous meningitis** (TBM) and *cryptococcal meningitis* typically commence with vague headache, lassitude, anorexia and vomiting. Acute meningitis can occur but is unusual. Meningitic signs often take some weeks to develop. Drowsiness, focal signs (e.g. diplopia, papilloedema, hemiparesis) and seizures are common. Syphilis, sarcoidosis and Behçet's also cause chronic meningitis. In some cases of chronic meningitis, an organism is never identified.

### Investigation and management of tuberculous meningitis

TBM is a common and serious disease worldwide. Brain imaging, usually with MRI, may show meningeal enhancement, hydrocephalus and tuberculomas (see pp. 870–871 and 867), although it may remain normal (see Box 21.56 for CSF changes). In many cases, the sparse tuberculous organisms cannot be seen on staining and PCR testing should be performed, although results may be negative. Repeated CSF examination is often necessary and it will be some weeks before cultures are confirmatory. Treatment with antituberculosis drugs (see p. 1111) – rifampicin, isoniazid and pyrazinamide – must commence on a presumptive basis and continue for at least 9 months. Ethambutol should be avoided because of its eye complications. Adjuvant corticosteroids, such as prednisolone 60 mg for 3 weeks, are now recommended (often tapered off). Relapses and complications (e.g. seizures, hydrocephalus) are common in TBM. The mortality remains over 60%, even with early treatment.

### Malignant meningitis

Malignant cells can cause a subacute or chronic, non-infective, meningitic process. A meningitic syndrome, cranial nerve lesions, paraparesis and root lesions are seen, often in confusing and fluctuating patterns. CSF cytology may demonstrate malignant cells but yield is low so multiple LPs may be required to confirm the diagnosis. Treatment with intrathecal cytotoxic agents is sometimes helpful.

### Cells in a sterile CSF (pleocytosis)

A raised CSF cell count is present without an evident infecting organism. CSF pleocytosis, i.e.
a mixture of lymphocytes and polymorphs, is the usual situation (Box 21.58).

### Box 21.58

**Causes of sterile CSF pleocytosis**

- Partially treated bacterial meningitis
- Viral meningitis
- Tuberculous or fungal meningitis
- Intracranial abscess
- Neoplastic meningitis
- Parameningeal foci, e.g. paranasal sinus
- Syphilis
- Cerebral venous thrombosis
- Cerebral malaria
- Cerebral infarction
- Following subarachnoid haemorrhage
- Encephalitis, including HIV
- Rarities, e.g. cerebral malaria, sarcoidosis, Behçet syndrome, Lyme disease, endocarditis, cerebral vasculitis

### Encephalitis

Encephalitis means acute inflammation of brain parenchyma, usually viral. In viral encephalitis, fever (90%) and meningism are usual; in contrast to meningitis, however, the clinical picture is dominated by brain parenchyma inflammation. Personality and behavioural change is a common early manifestation, which progresses to a reduced level of consciousness and even coma. Seizures (focal and generalized) are very common and focal neurological deficits, such as speech disturbance, often occur (especially in herpes simplex encephalitis).

### Viral encephalitis

(See p. 260.) The viruses isolated from adult UK cases are usually herpes simplex (HSV), varicella zoster (VZV) and other herpes group viruses, HHV-6, 7, enteroviruses and adenovirus. HSV encephalitis typically affects the temporal lobes initially, and is often asymmetric. Frequently, the virus is never identified. Outside the UK, in endemic regions, different pathogens cause encephalitis, including flaviviruses (Japanese encephalitis, West Nile virus, tick-borne encephalitis) and rabies.

Local epidemics can occur. For example, in New York in the 1990s, West Nile virus caused
an epidemic and Venezuelan equine virus was isolated from encephalitis cases in South America.

### Investigations

- MRI shows areas of inflammation and swelling, generally in the temporal lobes in HSV encephalitis. Raised intracranial pressure and midline shift may occur, leading to coning.
- EEG shows periodic sharp and slow-wave complexes.
- CSF shows an elevated lymphocyte count (95%).
- Viral detection by CSF PCR is highly sensitive for several viruses, such as HSV and VZV. However, a false-negative result may occur within the first 48 hours of symptom onset. Serology (blood and CSF) is also helpful.
- Brain biopsy is rarely required since the advent of MRI and PCR.

### Management

Suspected HSV and VZV encephalitis is treated immediately with intravenous aciclovir (10 mg/kg 3 times a day for 14–21 days), even before investigation results are available. Early treatment significantly reduces both mortality and long-term neurological damage in survivors. Seizures are treated with anticonvulsants. Occasionally, decompressive craniectomy is required to prevent coning but coma confers a poor prognosis.

Long-term complications are common and include memory impairment, personality change and epilepsy.

### Autoimmune encephalitis

This group of disorders are increasingly being recognized. Autoantibodies directed against neuronal epitopes cause a subacute encephalitic illness: limbic encephalitis or panencephalitis. Limbic encephalitis presents over weeks or months with memory impairment, confusion, psychiatric disturbance, and seizures – usually temporal lobe seizures, reflecting involvement of the hippocampus and mesial temporal lobes.

**Paraneoplastic limbic encephalitis (PLE).** PLE is seen particularly with small-cell lung cancer and testicular tumours, and is associated with a variety of antibodies, including anti-Hu and anti-Ma2. Antibodies can be detected in 60% of cases. MRI usually shows a hippocampal high signal. PLE precedes the diagnosis of cancer in most cases and should prompt investigation to identify the tumour.

**Voltage-gated potassium channel (VGKC) limbic encephalitis.** VGKC antibodies (which can be tested for) produce a variety of disorders, including limbic encephalitis with characteristic faciobrachial dystonic seizures, in combination with confusion, agitation and hyponatraemia. This usually occurs in patients over 50 years of age but is rarely associated with cancer (thymoma). Treatment is with high-dose steroids. Neuromyotonia and peripheral
nerve hyperexcitability syndromes may also be seen with antibodies to VGKC.

Anti-NMDA receptor antibody encephalitis. This presents as limbic encephalitis followed by coma and often status epilepticus. Orofacial dyskinesias are characteristic. Patients are usually younger and most have teratomas, such as ovarian.

Patients may respond to immunotherapy: intravenous immunoglobulin or plasma exchange initially, followed by steroids, rituximab or cyclophosphamide. PLE responds less well to treatment.

HIV and neurology

HIV-infected individuals frequently present with or develop neurological conditions. The human immunodeficiency virus itself is directly neuroinvasive and neurovirulent. Immunosuppression leads to indolent, atypical clinical patterns (see p. 337). HIV patients also have a high incidence of stroke. The pattern of disease is changing with anti-retroviral (ART) therapy.

CNS and peripheral nerve disease in HIV

HIV seroconversion can cause meningitis, encephalitis, Guillain–Barré syndrome and Bell’s palsy (the most common cause of Bell’s palsy in South Africa).

Chronic meningitis occurs with fungi (e.g. Cryptococcus neoformans or Aspergillus), tuberculosis, Listeria, coliforms or other organisms. Raised CSF pressure is common in cryptococcal meningitis.

AIDS–dementia complex (ADC). A progressive, HIV-related dementia, sometimes with cerebellar signs, is still seen where ART is unavailable.

Encephalitis and brain abscess. Toxoplasma, cytomegalovirus, herpes simplex and other organisms cause severe encephalitis. Multiple brain abscesses develop in HIV infection, usually due to toxoplasmosis.

CNS lymphoma. This is typically fatal (see p. 625).

Progressive multi-focal leucoencephalopathy (PML) is due to JC virus and occurs with very low CD4 counts (see p. 263).

Spinal vacuolar myelopathy. This occurs in advanced disease.

Peripheral nerve disease. HIV-related peripheral neuropathy is common (70%) and can be difficult to distinguish from the effects of ART, which is also toxic to peripheral nerves.

Other infections and post-infectious inflammatory conditions

Many other infections involve the CNS and are discussed in Chapter 11: for example, rabies, tetanus, botulism, Lyme disease and leprosy.
**Herpes zoster (shingles)**

This is caused by reactivation of varicella zoster virus (VZV), usually within dorsal root ganglia. Primary infection with VZV causes chickenpox, following which the virus remains latent in sensory ganglia. Development of shingles may indicate a decline in cell-mediated immunity, such as that due to age or malignancy.

**Clinical patterns and complications**

*Dermatomal shingles*. See pages 249–250 and 1344.

*Postherpetic neuralgia*. This is defined as pain lasting for more than 4 months after developing shingles; it occurs in 10% of patients (often elderly). Burning, intractable pain responds poorly to analgesics. Response to treatment is unsatisfactory but there is a trend towards gradual recovery over 2 years. Amitriptyline or gabapenten is commonly used and topical lidocaine patches may help.

*Cranial nerve involvement*. Only cranial nerves with sensory fibres are affected, particularly the trigeminal and facial nerves. Ophthalmic herpes is due to involvement of V1. This can lead to corneal scarring and secondary panophthalmitis. Involvement of the geniculate ganglion of the facial nerve is also called Ramsay Hunt syndrome (see p. 808).

*Myelitis*. This may occur in the context of shingles, when the inflammatory process spreads from the dorsal root ganglion to the adjacent spinal cord.

*Immunization*. Older adults (p. 250) can be vaccinated against herpes zoster (even those who have had shingles previously), as it boosts immunity against VZV and reduces the incidence of shingles by about 50%.

**Neurosyphilis**

Many neurological symptoms occur, sometimes mixed (see also syphilis; pp. 328–330).

*Asymptomatic neurosyphilis*

This means positive CSF serology without signs.

*Meningovascular syphilis*

This causes:

- subacute meningitis with cranial nerve palsies and papilloedema
- a gumma – a chronic expanding intracranial mass
- paraparesis – a spinal meningoovasculitis.

*Tabes dorsalis*

Demyelination in dorsal roots causes a complex deafferentation syndrome. The elements of tabes are:
• lightning pains
• ataxia, stamping gait, reflex/sensory loss, wasting
• neuropathic (Charcot) joints
• Argyll Robertson pupils (see p. 805)
• ptosis and optic atrophy.

**General paralysis of the insane**

The grandiose title describes dementia and weakness. The dementia of general paralysis of the insane (GPI) is typically similar to that of Alzheimer's (see pp. 876–878). Progressive cognitive decline, seizures, brisk reflexes, extensor plantar reflexes and tremor develop. Death follows within 3 years. Argyll Robertson pupils are a usual finding. GPI and tabes are rarities in the UK.

**Other forms of neurosyphilis**

In *congenital* neurosyphilis (acquired *in utero*), features of combined tabes and GPI develop in childhood: taboparesis.

*Secondary* syphilis can be symptomless or may cause a self-limiting subacute meningitis.

**Management**

Benzylpenicillin 1 g daily i.m. for 10 days in primary infection eliminates any risk of neurosyphilis. Allergic (Jarisch–Herxheimer) reactions can occur; steroid cover is usually given with penicillin (see pp. 329–330). Established neurological disease is arrested but not reversed by penicillin.

**Neurocysticercosis**

The pork tapeworm, *Taenia solium*, is endemic in Latin America, Africa, India and much of South-east Asia (see p. 315). Epilepsy is the most common clinical manifestation of neurocysticercosis and one of the most common causes of epilepsy in endemic countries. Most infected people remain asymptomatic.

Brain CT and MRI show ring-enhancing lesions with surrounding oedema when the cyst dies, and later calcification. Multiple cysts are often seen in both brain and skeletal muscle. Serological tests indicate infection but not activity. Biopsy of a lesion is rarely necessary. Management is primarily the control of seizures, and the anthelmintic agent, albendazole, is often given too (usually with steroid cover).

**Subacute sclerosing panencephalitis**

Persistence of measles antigen in the CNS is associated with this rare late sequel of measles. Progressive mental deterioration, fits, myoclonus and pyramidal signs develop, typically in a
child. Diagnosis is made by high measles antibody titre in blood and CSF. Measles immunization protects against subacute sclerosing panencephalitis (SSPE), which has now been almost eliminated in the UK.

**Progressive rubella encephalitis**
Some 10 years after primary rubella infection, this causes progressive cognitive impairment, fits, optic atrophy, cerebellar and pyramidal signs. Antibody to rubella viral antigen is produced locally within the CNS. It is even rarer than SSPE.

**Mollaret's meningitis**
Recurrent, self-limiting episodes of aseptic meningitis (i.e. no bacterial cause is found) occur over many years. Herpes simplex has been shown to be the cause in most cases.

**Whipple's disease**
CNS Whipple's disease, due to *Tropheryma whipplei* infection, is characterized by neurological symptoms, e.g. myoclonus, dementia and supranuclear ophthalmoplegia (see p. 400). Diagnosis of CNS involvement is made by CSF PCR (only 50% sensitivity) or brain biopsy.

**Brain and spinal abscesses**

**Brain abscess**
Focal bacterial infection behaves as any expanding mass. The typical bacteria found are *Streptococcus anginosus* and *Bacteroides* species (paranasal sinuses and teeth), and staphylococci (penetrating trauma). Mixed infections are common. Multiple abscesses develop, particularly in HIV infection. Fungi also cause brain abscesses. A parameningeal infective focus (e.g. ear, nose, paranasal sinus, skull fracture) or a distant source of infection (e.g. lung, heart, abdomen) may be present. Frequently, no underlying cause is found. An abscess is more than 10 times rarer than a brain tumour in the UK.

**Clinical features and management**
Headache, focal signs (e.g. hemiparesis, aphasia, hemianopia), epilepsy and raised intracranial pressure develop. Fever, leucocytosis and raised ESR are usual, although not invariable.

Urgent imaging is essential. MRI shows a ring-enhancing mass, usually with considerable surrounding oedema (*Fig. 21.50*). The search for a focus of infection should include a detailed examination of the skull, ears, paranasal sinuses and teeth, and distant sites such as heart and
abdomen. LP is dangerous and should not be performed. Neurosurgical aspiration with stereotactic guidance allows the infective organism to be identified. Treatment is with high-dose antibiotics and, sometimes, surgical resection/decompression. Despite treatment, mortality remains high at approximately 25%. Epilepsy is common in survivors.

**Brain tuberculoma**

Tuberculosis causes chronic caseating intracranial granulomatous masses: tuberculomas. These are the most common intracranial masses in countries where tuberculosis is common, such as India. Brain tuberculomas either present as mass lesions *de novo* or develop during tuberculous meningitis; they are also found as symptomless intracranial calcification on imaging. Spinal cord tuberculomas also occur. Treatment is described on pages 1110–1113.

**Subdural empyema and intracranial epidural abscess**

*Intracranial subdural empyema* is a collection of subdural pus, usually secondary to local skull or middle ear infection. Features are similar to those of a cerebral abscess. Imaging is diagnostic.

In *intracranial epidural abscess*, a layer of pus, 1–3 mm thick, tracks along the epidural space, causing sequential cranial nerve palsies. There is usually local infection: in the middle ear, for example. MRI shows the collection; CT is typically normal. Drainage is required, as are antibiotics.
Spinal epidural abscess

*Staphylococcus aureus* is the usual organism, reaching the spine via the bloodstream: for example, from a boil. Fever and back pain are followed by paraparesis and/or root lesions. Emergency imaging and antibiotics are essential and surgical decompression is often necessary.

http://www.meningitisnow.org/ Formed in 2013 by merger of Meningitis UK and the Meningitis Trust.

**Brain Tumours**

*Primary intracranial tumours* account for some 10% of neoplasms. The most common tumours are outlined in Box 21.59. *Cerebral metastases* are the most common intracranial tumours (*Fig. 21.51*). Symptomless meningiomas (benign) are found quite commonly on imaging or at autopsy.

</table>
These malignant tumours of neuroepithelial origin are usually seen within the hemispheres, but occasionally in the cerebellum, brainstem or cord (Fig. 21.52). Their cause is unknown. Gliomas are occasionally associated with neurofibromatosis. They tend to spread by direct extension, virtually never metastasizing outside the CNS.

- **Astrocytomas** are gliomas that arise from astrocytes. They are classified histologically into grades I–IV. Grade I astrocytomas grow slowly over many years, while grade IV tumours (glioblastoma multiforme) cause death within several months. Cystic astrocytomas of childhood are relatively benign and usually cerebellar.

- **Oligodendrogliomas** arise from oligodendrocytes. They grow slowly, usually over several decades. Calcification is common.
Meningiomas

These benign tumours (Fig. 21.53) arise from the arachnoid and may grow to a large size, usually over years. Those close to the skull erode bone or cause local hyperostosis. They often occur along the intracranial venous sinuses, which they may invade. They are unusual below the tentorium. Common sites are the parasagittal region, sphenoidal ridge, subfrontal region, pituitary fossa and skull base.
**Neurofibromas (schwannomas)**

These solid benign tumours arise from Schwann cells and occur principally in the cerebellopontine angle, where they arise from the VIIIth nerve sheath (acoustic neuroma; see p. 807). They may be bilateral in neurofibromatosis type 2 (see p. 881).

**Other neoplasms**

Other less common neoplasms include cerebellar haemangioblastomas, ependymomas of the IVth ventricle, colloid cysts of the IIIrd ventricle, pinealomas, chordomas of the skull base, glomus tumours of the jugular bulb, medulloblastomas (a cerebellar childhood tumour), craniopharyngiomas (see p. 1187) and primary CNS lymphomas (p. 625). For pituitary tumours, see pages 1185–1188.

**Clinical features**

Mass lesions within the brain produce symptoms and signs by three mechanisms:
• direct effect – brain is infiltrated and local function impaired
• secondary effects of raised intracranial pressure and shift of intracranial contents (e.g. papilloedema, vomiting, headache)
• provocation of generalized and/or partial seizures.

Although neoplasms, either secondary or primary, are the most common mass lesions in the UK, cerebral abscess, tuberculoma, neurocysticercosis, and subdural and intracranial haematomas can also produce features that are clinically similar.

Direct effects of mass lesions
The hallmark of a direct effect of a mass is local progressive deterioration of function. Tumours can occur anywhere within the brain. Three examples are given:

• **A left frontal meningioma** caused a frontal lobe syndrome over several years with vague disturbance of personality, apathy and impaired intellect. Expressive aphasia developed, followed by progressive right hemiparesis as the corticospinal pathways became involved. As the mass enlarged further, pressure headaches and papilloedema occurred.

• **A right parietal lobe glioma** caused a left homonymous field defect (optic radiation). Cortical sensory loss in the left limbs and left hemiparesis followed over 3 months. Partial seizures (episodes of tingling of the left limbs) developed.

• **A left VIIIth nerve sheath neurofibroma (acoustic neuroma, schwannoma)** in the cerebellopontine angle caused, over 3 years, progressive deafness (VIII), left facial numbness (V) and weakness (VII), followed by cerebellar ataxia on the same side.

  With a hemisphere tumour, epilepsy and the direct effects commonly draw attention to the problem. The rate of progression varies greatly, from a few days or weeks in a highly malignant glioma, to several years with a slowly enlarging mass such as a meningioma. Cerebral oedema surrounds mass lesions; its effect is difficult to distinguish from that of the tumour itself.

Raised intracranial pressure
Raised intracranial pressure causing headache, vomiting and papilloedema is a relatively unusual presentation of a mass lesion in the brain. These symptoms often imply hydrocephalus: obstruction to CSF pathways. Typically, this is produced early by posterior fossa masses that obstruct the aqueduct and IVth ventricle, but only later by lesions above the tentorium. Shift of the intracranial contents produces features that coexist with the direct effects of any expanding mass:
• **Distortion of the upper brainstem** as midline structures are displaced either caudally or laterally by a hemisphere mass (see *Fig. 21.52*). This causes impairment of consciousness, progressing to coning and death as the medulla and cerebellar tonsils are forced into the foramen magnum.

• **False localizing signs**, termed false only because they do not point directly to the site of the mass.

  Three examples of false localizing signs are:

• **A VIth nerve lesion**, first on the side of a mass and later bilaterally as the VIth nerve is compressed or stretched during its long intracranial course.

• **A IIIrd nerve lesion** developing as the temporal lobe uncus herniates caudally, compressing the IIIrd nerve against the petroclinoid ligament. The first sign is ipsilateral pupil dilatation as parasympathetic fibres are compressed.

• **Hemiparesis** on the same side as a hemisphere tumour – that is, the side that might not be expected – from compression of the contralateral cerebral peduncle on the edge of the tentorium.

**Seizures**

Seizures are a common presenting feature of malignant brain tumours. Partial seizures, simple or complex, that may evolve into generalized tonic–clonic seizures, are characteristic of many hemisphere masses, whether malignant or benign. The pattern of partial seizure is that of localizing value (see p. 847).

**Investigations**

**Imaging**

Both CT and MRI are useful in detecting brain tumours; MRI is superior for posterior fossa lesions. Benign and malignant tumours, brain abscess, tuberculosis, neurocysticercosis and infarction have characteristic, but not entirely reliable, appearances, and refined imaging techniques and biopsy are often necessary. MR angiography is used occasionally to define blood supply and MR spectroscopy to identify patterns typical of certain gliomas. PET is sometimes helpful to locate an occult primary tumour with brain metastases.

**Routine tests**

Since metastases are more common than primary tumours, routine tests, such as chest X-ray, should be performed.

**Lumbar puncture**

This is contraindicated when there is any possibility of a mass lesion, as withdrawing CSF may provoke immediate coning. CSF examination is rarely helpful and has been superseded by
Imaging.

**Biopsy and tumour removal**

Stereotactic biopsy via a skull burr-hole is carried out to ascertain the histology of most suspected malignancies. With a benign tumour, such as a symptomatic, accessible meningioma, craniotomy and removal are usual.

**Management**

Cerebral oedema surrounding a tumour responds rapidly to steroids: intravenous or oral dexamethasone. Epilepsy is treated with anticonvulsants.

While complete surgical removal of a tumour is an objective, it is often not possible; nor is surgery always necessary. Follow-up with serial imaging is sometimes preferable in low-grade gliomas. At exploration, some benign tumours can be entirely removed (e.g. acoustic neuromas, some parasagittal meningiomas). With a malignant tumour, it is not possible to remove an infiltrating mass entirely. Biopsy and debulking are performed.

Within the posterior fossa, tumour removal is often necessary because of raised pressure and danger of coning. Overall mortality for posterior fossa exploration remains around 10%.

For gliomas and metastases, radiotherapy is usually given and improves survival, if only slightly. Solitary metastases can often be excised successfully. Chemotherapy has little real value in the majority of primary or secondary brain tumours. Vincristine, procarbazine and temozolomide (an oral alkylating agent) can be used. Bevacizumab has been shown to have some benefit, although no effect on overall survival. Most malignant gliomas have a poor prognosis despite advances in imaging, surgery, chemotherapy and radiotherapy: survival for grade IV gliomas at 2 years is less than 50%. Surgical debulking and radiotherapy improve survival by 4–5 months.

**Stereotactic radiotherapy (gamma knife)**

Only available in selected centres, a collimated radiotherapy beam can deliver high doses of radiation to small targets up to 3 cm in diameter with precision. It may be used to target small metastases, and inaccessible skull-base tumours such as meningiomas or schwannomas. It may also be used to treat intracerebral AVMs.

**Further reading**

**Hydrocephalus**

Hydrocephalus is an excessive accumulation of CSF within the head, caused by a disturbance of formation, flow or absorption. High pressure and ventricular dilatation result (*Fig. 21.54*).
Infantile hydrocephalus

Head enlargement in infancy occurs in 1 in 2000 live births. There are several causes:

- **Arnold–Chiari malformations.** The cerebellar tonsils descend into the cervical canal (Fig. 21.55). Associated spina bifida is common. Syringomyelia may develop (see p. 874).

- **Stenosis of the aqueduct of Sylvius.** Aqueduct stenosis is either congenital (genetic), or acquired following neonatal meningitis/haemorrhage.

- **Dandy–Walker syndrome.** There is cerebellar hypoplasia and obstruction to IVth ventricle outflow foramina.

Hydrocephalus in adults

Hydrocephalus is sometimes an unsuspected finding on imaging. Stable childhood
hydrocephalus can become apparent in adult life (‘arrested hydrocephalus’) but can suddenly decompensate. Combinations of headache, cognitive impairment, features of raised intracranial pressure, and ataxia develop, depending on how high the CSF pressure rises and how rapid the onset is. Elderly patients with more compliant brains may present with gradual-onset gait apraxia and subtle cognitive slowing.

Hydrocephalus may be caused by:

- **posterior fossa and brainstem tumours** obstructing the aqueduct or IVth ventricular outflow
- **subarachnoid haemorrhage**, head injury or meningitis (particularly tuberculous), causing obstruction of CSF flow and reabsorption
- **a IIIrd ventricle colloid cyst** causing intermittent hydrocephalus – recurrent prostrating headaches with episodes of lower limb weakness
- **choroid plexus papilloma** (rare) secreting CSF.

Frequently, the underlying cause of hydrocephalus remains obscure.

## Management

Ventriculoperitoneal shunting is necessary when progressive hydrocephalus causes symptoms. Removal of tumours is carried out when appropriate. Endoscopic IIIrd ventriculostomy may be performed.

## Normal-pressure hydrocephalus

This describes a syndrome of enlarged lateral ventricles in elderly patients with the clinical triad of:

- a gait disorder – gait apraxia
- dementia
- urinary incontinence.

The term is a misnomer, as it is a low-grade hydrocephalus with intermittently raised ICP. Ventriculoperitoneal shunting may be required. A trial of prolonged drainage of lumbar CSF over several days predicts response to shunt insertion.

## Traumatic Brain Injury

In most Western countries, head injury accounts for about 250 hospital admissions per 100 000 population annually. Traumatic brain injury (TBI) describes injuries with potentially permanent consequences. For each 100 000 people, 10 die annually following TBI; 10–15 are transferred to a neurosurgical unit, the majority of these requiring rehabilitation for a prolonged period of 1–9 months. The prevalence of survivors with a major persisting handicap is around 100/100 000. Road traffic accidents and excessive alcohol use are the principal aetiological factors in this major cause of morbidity and mortality, in many countries.
Skull fractures

Linear skull fracture of the vault or base is one indication of the severity of a blow, but in itself is not necessarily associated with any brain injury. Healing of linear fractures takes place spontaneously. Depressed skull fracture is followed by a high incidence of post-traumatic epilepsy. Surgical elevation and debridement are usually necessary.

Principal local complications of skull fracture are:

- *meningeal artery rupture* causing extradural haematoma (see p. 841)
- *dural vein tears* causing subdural haematoma (see p. 841)
- *CSF rhinorrhea/otorrhoea* and consequent meningitis.

Mechanisms of brain damage

Older classifications attempted to separate concussion, transient coma for hours followed by apparent complete clinical recovery, from brain contusion – that is, bruising – with prolonged coma, focal signs and lasting damage. Pathological support for this division is poor. Mechanisms of TBI are complex and interrelated:

- diffuse axonal injury – shearing and rotational stresses on decelerating brain, sometimes at the site opposite impact (the *contre-coup* effect)
- neuronal and axonal damage from direct trauma
- brain oedema and raised intracranial pressure
- brain hypoxia
- brain ischaemia.

Clinical course

In a mild TBI, a patient is stunned or dazed for a few seconds or minutes. Following this, the patient remains alert without post-traumatic amnesia. Headache can follow; complete recovery is usual. In more serious injuries, duration of unconsciousness, and particularly of post-traumatic amnesia (PTA), helps grade severity. PTA lasting more than 24 hours defines severe TBI. The Glasgow Coma Scale (GCS; see p. 825) is used to record the degree of coma; this has prognostic value. A GCS below 5/15 at 24 hours implies a serious injury; 50% of such patients die or remain in a vegetative or minimal conscious state (see p. 829). However, prolonged coma of up to some weeks is occasionally followed by good recovery.

Recovery after severe TBI takes many weeks or months. During the first few weeks, patients are often intermittently restless or lethargic, and have focal deficits such as hemiparesis or aphasia. Gradually, they become more aware, though they may remain in PTA, being unable to lay down any continuous memory despite being awake. This amnesia may last some weeks or more, and may not be obvious clinically. PTA is one predictor of outcome. PTA of over a week implies that persistent organic cognitive deficit is almost inevitable, although return to unsupported paid work may be possible.
Late sequelae

Sequelae of TBI are major causes of morbidity and can have serious social and medicolegal consequences. They include:

- **Incomplete recovery**, e.g. cognitive impairment, hemiparesis.
- **Post-traumatic epilepsy** (see p. 848).
- **The post-traumatic (post-concussional) syndrome**. This describes the vague complaints of headache, dizziness and malaise that follow even minor head injuries. Litigation is frequently an issue. Depression is prominent. Symptoms may be prolonged.
- **Benign paroxysmal positional vertigo** (see pp. 1316–1317).
- **Chronic subdural haematoma** (see p. 841).
- **Hydrocephalus** (see pp. 870–871).
- **Chronic traumatic encephalopathy**. This follows repeated and often minor injuries. It is known as the ‘**punch-drunk syndrome**’ and consists of cognitive impairment and extrapyramidal and pyramidal signs, seen typically in professional boxers.

Management

Immediate management

Attention to the airway is vital. If there is coma, depressed fracture or suspicion of intracranial haematoma, CT imaging and discussion with a neurosurgical unit are essential. Indications for CT vary from imaging all minor head injuries in some US centres to more stringent criteria elsewhere.

In many severe TBI cases, assisted ventilation will be needed. Intracranial pressure monitoring is valuable. Hypothermia lowers intracranial pressure when used early after a TBI; an effect on outcome has been seen only in specialized neurotrauma centres. Care of the unconscious patient is described on pages 826–829. Prophylactic antiepileptic drugs have been shown to be of no value in prevention of late post-traumatic epilepsy. Trials using progesterone have shown no benefit.

Rehabilitation

TBI cases require skilled, prolonged and energetic support. Survivors with severe physical and cognitive deficits require rehabilitation in specialized units. Rehabilitation includes care from a multidisciplinary team with physiotherapeutical, psychological and practical skills. Many survivors are left with cognitive problems (amnesia, neglect, disordered attention and motivation) and behavioural/emotional problems (temper dyscontrol, depression and grief reactions). Long-term support for both patients and families is necessary.

Further reading

Spinal Cord Disease

The cord extends from C1, the junction with the medulla, to the lower vertebral body of L1, where it becomes the conus medullaris. Blood supply is from the anterior spinal artery and a plexus on the posterior cord. This network is supplied by the vertebral arteries and by several branches from lumbar and intercostal vessels, including the artery of Adamkiewicz.

Spinal cord compression

The principal features of chronic and subacute cord compression are spastic paraparesis or tetraparesis, radicular pain at the level of compression, and sensory loss below the compression (Box 21.60).

Box 21.60

Causes of spinal cord compression

- Spinal cord tumours
- Extramedullary, e.g. meningioma or neurofibroma
- Intramedullary, e.g. ependymoma or glioma
- Vertebral body destruction by bone metastases, e.g. prostate primary
- Disc and vertebral lesions:
  - Chronic degenerative and acute central disc prolapse
  - Trauma
- Inflammatory:
  - Epidural abscess
  - Tuberculosis
  - Granulomatous
- Epidural haemorrhage/haematoma

For example, in compression at T4 (see Fig. 21.16), a band of pain radiates around the thorax, characteristically worse on coughing or straining. Spastic paraparesis develops over months, days or hours, depending on underlying pathology. Numbness commencing in the feet rises to the level of compression. This is called the sensory level and is usually 2–3 dermatome levels below the level of anatomical compression. Retention of urine and constipation develop.

Aetiology
**Disc and vertebral lesions.** Central cervical disc and thoracic disc protrusion causes cord compression (see p. 887). Chronic compression due to cervical spondylotic myelopathy is frequently seen in clinical practice and is the most common cause of a spastic paraparesis in an elderly person.

**Trauma.** Stabilize the neck and back, and move patient with extreme caution in trauma. Any trauma to the back is potentially serious and the patient should be immobilized until the extent of the injury can be determined.

**Spinal cord tumours.** Extramedullary tumours, such as meningiomas and neurofibromas, cause cord compression ([Fig. 21.56](#) and **Box 21.61**) gradually over weeks to months, often with root pain and a sensory level (see p. 817). Vertebral body destruction by bony metastases, such as in prostate or breast cancer, is a common cause of spinal cord compression.

![Thoracic meningioma (arrowed) compressing the spinal cord: T2-weighted MRI.](#)

**Box 21.61**

**Principal spinal cord neoplasms**

**Extradural**

- Metastases:
  - Bronchus
  - Breast
  - Prostate
  - Lymphoma
  - Thyroid
  - Melanoma

**Extramedullary**

- Meningioma
- Neurofibroma
- Ependymoma

**Intramedullary**
• Glioma
• Ependymoma
• Haemangioblastoma
• Lipoma
• Arteriovenous malformation
• Teratoma

Intramedullary tumours (e.g. ependymomas) are less common and typically progress slowly, sometimes over many years. Sensory disturbances similar to syringomyelia may develop (see p. 874).

**Tuberculosis.** Spinal tuberculosis is the most common cause of cord compression in countries where the disease is common. There is destruction of vertebral bodies and disc spaces, with local spread of infection. Cord compression and paraparesis follow, culminating in paralysis: Pott's paraplegia.

**Spinal epidural abscess.** This is described on page 867.

**Epidural haemorrhage and haematoma.** These are rare sequelae of anticoagulant therapy, bleeding disorders or trauma, and can follow LP when clotting is abnormal. A rapidly progressive cord or cauda equina lesion develops.

### Management

Acute spinal cord compression is a medical emergency. Early diagnosis and treatment is vital. MRI is the imaging technique of choice.

Routine tests (e.g. chest X-ray) may indicate a primary neoplasm or infection. Surgical exploration is frequently necessary; if decompression is not performed promptly, irreversible cord damage ensues. Results are excellent if benign tumours and haematomas are removed early. Radiotherapy is used to treat cord malignancies, or compression due to inoperable malignant vertebral body disease causing cord compression.

### Other spinal cord disorders

**Inflammatory cord lesions (transverse myelitis)**

See page 862.

**Anterior spinal artery occlusion**

There is acute paraplegia and loss of spinothalamic (pain and temperature) sensation, with infarction of the anterior two-thirds of the spinal cord. This may result from aortic atherosclerosis, dissection, trauma or cross-clamping in surgery. Vasculitis, emboli,
haematological disorders causing thrombosis and severe hypotension are other causes. Occlusion of the artery of Adamkiewicz, which supplies the thoracic anterior spinal artery, causes watershed infarction of the cord, typically at the T8 level where perfusion is relatively poor.

### Arteriovenous malformations of the cord

Although rare, spinal arteriovenous malformations (AVMs) may be difficult to diagnose but are potentially curable. The two main types seen are dural arteriovenous fistulas (acquired) and true intramedullary AVMs (probably congenital but gradually enlarging). Dural arteriovenous fistulas occur mainly in middle-aged men due to formation of a direct connection between an artery and vein in a dural nerve root sleeve. This causes arterialization of veins with venous hypertension, and thus oedema and congestion of the spinal cord at and below the affected level. Presentation is with a gradually progressive myelopathy over months or a few years, often with thoracic back pain. MRI usually shows cord swelling (Fig. 21.57) and may show the enlarged arterialized veins over the surface of the cord. Spinal angiography demonstrates the fistula and allows endovascular ablation with glue, often with complete resolution of symptoms if permanent neuronal damage has not already occurred.

![Figure 21.57: Dural arteriovenous fistulas.](image)

### Genetic disorders – hereditary spastic paraparesis (HSP)

Several genetic disorders may present with a gradually evolving upper motor neurone syndrome resembling a myelopathy. Typically, spasticity and stiffness dominate the clinical picture rather than weakness, especially in hereditary spastic paraparesis (HSP). Muscle relaxants, such as baclofen, improve gait. There are 28 known genes associated with HSP, some causing ‘pure’ spasticity and others with associated neurological features, such as thinning of the corpus callosum.

Other genetic disorders such as adrenoleucodystrophy may cause a slowly progressive
spastic paraparesis (including in manifesting female carriers), as can the spinocerebellar ataxias (see p. 881) or presenilin-1 mutations (see p. 877).

### Vitamin B\(_{12}\) deficiency

Subacute combined degeneration of the cord resulting from vitamin B\(_{12}\) deficiency (see p. 886) is the most common example of metabolic disease causing spinal cord damage. Abuse of nitrous oxide may precipitate functional B\(_{12}\) deficiency with normal serum B\(_{12}\) levels.

### Other causes of a spastic paraparesis

Motor neurone disease may present initially with a spastic paraparesis before lower motor neurone features develop (see pp. 879–880). Paraneoplastic disorders, radiotherapy, copper deficiency, liver failure and rare toxins (e.g. lathyrisim) may cause spinal cord damage. Not all causes of paraparesis relate to spinal cord patholgy; beware a parasagittal cerebral menigioma presenting with a paraparesis due to bilateral compression of the leg area of the motor cortex.

### Care of the patient with paraplegia

Where patients are left with a severe paraplegia, there are several issues in long-term care, and specialist nursing is vital.

**Bladder management.** The bladder does not empty and urinary retention results. Patients self-catheterize or develop reflex bladder emptying, helped by abdominal pressure. Early treatment of urine infections is essential. Chronic kidney disease is a common cause of death.

**Bowel function.** Constipation and impaction must be avoided. Following acute paraplegia, manual evacuation is necessary; reflex emptying develops later.

**Skin care.** Risks of pressure ulcers and their sequelae are serious. Meticulous attention must be paid to cleanliness and regular turning. The sacrum, iliac crests, greater trochanters, heels and malleoli should be inspected frequently (see p. 1376). Pressure-relieving mattresses are useful initially until patients can turn themselves. If pressure ulcers develop, plastic surgical repair may be required. Pressure palsies, such as those of ulnar nerves, can occur.

**Lower limbs.** Passive physiotherapy helps to prevent contractures. Severe spasticity, with flexor or extensor spasms, may be helped by muscle relaxants such as baclofen or by botulinum toxin injections.

**Rehabilitation.** Many patients with traumatic paraplegia or tetraplegia return to self-sufficiency (especially if the level is at C7 or below). A specialist spinal rehabilitation unit is necessary. Lightweight, specially adapted wheelchairs provide independence. Tendon transfer operations may allow functional grip if hands are weak. Autonomic dysreflexia may be a problem. Patients with paraplegia have substantial practical, psychological and sexual needs.
Syringomyelia and syringobulbia

A syrinx is a fluid-filled cavity within the spinal cord. Syringobulbia means a cavity in the brainstem. Syringomyelia is frequently associated with the Arnold–Chiari malformation (see p. 870). The abnormality at the foramen magnum probably allows normal pulsatile CSF pressure waves to be transmitted to fragile tissues of the cervical cord and brainstem, causing secondary cavity formation. The syrinx is in continuity with the central canal of the cord. Syrinx formation may also follow spinal cord trauma and lead to secondary damage years later, and can also be caused by intrinsic cord tumours.

Pathophysiology

The expanding cavity in the cord gradually destroys spinothalamic neurones, anterior horn cells and lateral corticospinal tracts. In the medulla (syringobulbia), lower cranial nerve nuclei are affected.

Clinical features

Cases associated with the Arnold–Chiari malformation usually develop symptoms around the age of 20–30. Upper limb pain exacerbated by exertion or coughing is typical. Spinothalamic sensory loss – pain and temperature – leads to painless upper limb burns and trophic changes. Paraparesis develops. The following are typical signs of a substantial cervical syrinx (**Fig. 21.58**):

- **a ‘suspended’ area of dissociated sensory loss** – i.e. spinothalamic loss in the arms and hands without loss of light touch.
- **loss of upper limb reflexes**.
- **muscle wasting** in the hand and forearm.
- **spastic paraparesis** – initially mild.
- **brainstem signs** – as the syrinx extends into the brainstem (syringobulbia) there may be tongue atrophy and fasciculation, bulbar palsy, a Horner syndrome and impairment of facial sensation.
**Investigations and management**

MRI demonstrates the cavity and herniation of cerebellar tonsils. Syringomyelia is gradually progressive over several decades. Sudden deterioration sometimes follows minor trauma or occurs spontaneously. Surgical decompression of the foramen magnum often causes the syrinx to collapse.

**Further reading**

**Neurodegenerative Diseases**

Neurodegenerative disease is an umbrella term for disorders characterized by progressive neuronal cell loss with distinct patterns in different disorders. These disorders are increasing in an ageing population.

**Dementia**

Dementia is a clinical syndrome with multiple causes, defined by:

- an acquired loss of higher mental function, affecting two or more cognitive domains, including:
  - episodic memory (acquisition of new information) – usually (but not always) involved
  - language function
  - frontal executive function
– visuospatial function
– apraxia
• being of sufficient severity to cause significant social or occupational impairment
• being chronic and stable (which distinguishes it from delirium, which is acute and fluctuating).

Although dementia is usually progressive, it is not invariably so, and may even be reversible in some cases. Dementia robs patients of their independence, and is a serious burden on carers and a major socioeconomic challenge for society as a whole.

## Epidemiology

Dementia is common and becoming even more so as a result of an ageing population and better case ascertainment. Age is the main risk factor, followed by family history. Over the age of 65, there is a 6% prevalence; over the age of 85, the prevalence increases to 20%.

## Clinical assessment

There are two main considerations:
• Does the patient have dementia?
• Are the pattern of cognitive deficits, tempo of progression or associated features suggestive of a distinct cause? Cognitive problems need to be interpreted in the context of estimated premorbid abilities (e.g. based on educational attainments or occupation).

Taking a history from a spouse or relative is essential. Patients may tend to downplay or deny symptoms (anosognosia) or constantly look to the relative for answers (the ‘head-turning sign’). See Box 21.62 for the key elements in history-taking.

### Box 21.62

**Taking a dementia history**

- **Memory:**
  – Is (s)he repetitive, e.g. with questions?
  – Is there a temporal gradient of amnesia – preservation of more distant memories with amnesia for recent events?
  – Is there difficulty learning to use new devices, e.g. computer, mobile phone?
- **Functional ability:**
  – Has work performance or ability to cook and do domestic tasks declined?
  – Has responsibility for finances and administration shifted to the spouse?
  – Does (s)he get easily muddled?
- **Personality and frontal lobe function:**
– Has personality altered?
– More aggressive/apathetic/lacking initiative
– Disinhibition
– Change in food preference or religiosity

• Language:
  – Difficulty with word finding or remembering names

• Visuospatial ability:
  – Does (s)he get lost in familiar places?
  – Difficulty dressing, e.g. putting jacket on the wrong way round

• Psychiatric features:
  – Features of depression

• Tempo of progression

• Family history of dementia

• Alcohol and drug use

• Medication

• Any other neurological problems, e.g. parkinsonism, gait disorder, strokes

**Examination**

Conversation with the patient during history-taking may be as revealing as formal cognitive assessment but many patients hide deficits well behind an intact social façade.

**Bedside cognitive assessment**

The mini-mental state examination (MMSE; see pp. 893–897) is commonly used to assess cognitive function but has its limitations, such as relative insensitivity to milder cognitive impairment and to frontal lobe dysfunction, especially in those with premorbid abilities. The Addenbrooke's Cognitive Examination (ACE) is a tool developed to address the deficiencies of the MMSE but is short enough to use in clinical practice.

It is useful to ask patients to give an account of recent news events to assess episodic memory.

Individual cognitive domains can be tested separately in detail: for example, clock drawing for visuospatial (parietal lobe) function, naming and reading tasks for language function, verbal fluency, conceptual similarity to test abstract thinking, and stop–go tasks, which are components of the Frontal Assessment Battery (FAB).

Check for primitive reflexes (frontal release signs), such as grasp, palmo-mental and pout reflexes, and perseveration or utilization behaviour with frontal lobe involvement.

Test:

• limb praxis – copying hand gestures and miming tasks, e.g. ‘Show me how you brush your teeth’.

• oro-buccal praxis, e.g. ‘Show me how you would blow out a candle’.
Complete neurological examination to look for evidence of papilloedema, parkinsonism, myoclonus and gait disorders, for example, is also necessary, in addition to is general examination and assessment of mental state.

**Investigations**

Investigations *(Box 21.63)* are aimed at identifying treatable causes and helping support a clinical diagnosis of dementia type. For most patients, this should include the elements listed below.

<table>

</table>

AD, Alzheimer's disease; FTD, fronto-temporal dementia; HD, Huntington's disease.

**Blood tests.** These should include a full blood count and measurement of vitamin B$_{12}$, thyroid function, urea and electrolytes, liver function, glucose and ESR.

**Brain imaging.** CT is adequate to exclude structural lesions *(Fig. 21.59)*, such as tumours or hydrocephalus. The superior anatomical resolution of MRI helps identify patterns of regional brain atrophy and so distinguish between different types of degenerative dementia.
Mild cognitive impairment (MCI) is an intermediate state between normal cognition and
dementia. Often mild memory impairment, greater than expected for age but not sufficient to classify as dementia, is the only symptom (‘amnestic MCI’). MCI may be a pre-dementia state, with 10–15% of patients per year developing overt AD.

### Causes of dementia

There are many causes of dementia (Box 21.64), by far the most common being AD. Cause varies according to age (Fig. 21.60).

#### Box 21.64

**Causes of dementia**

**Degenerative**
- Alzheimer's disease
- Dementia with Lewy bodies
- Frontotemporal dementia
- Huntington's disease
- Parkinson's disease
- Prion diseases, e.g. Creutzfeldt–Jakob

**Vascular**
- Vascular dementia
- Cerebral vasculitis (rare)

**Metabolic**
- Uraemia
- Liver failure

**Toxic**
- Alcohol
- Solvent misuse
- Heavy metals

**Vitamin deficiency**
- $B_{12}$ and thiamine

**Traumatic**
- Severe or repeated brain injury

**Intracranial lesions**
• Subdural haematoma
• Tumours
• Hydrocephalus

**Infections**
• HIV
• Neurosyphilis
• Whipple's disease
• Tuberculosis

**Endocrine**
• Hypothyroidism
• Hypoparathyroidism

**Psychiatric**
• Depression causing ‘pseudo-dementia’
Alzheimer's disease

Although technically a definitive diagnosis can only be made by histopathology, in practice the clinical features are sufficiently characteristic that a diagnosis can usually be made with considerable accuracy in life, supported by diagnostic investigations. The key clinical features are:

- **Memory impairment.** Episodic (day-to-day) memory is affected. There is progressive loss of ability to learn, retain and process new information. There is a characteristic temporal gradient, with relative preservation of distant memory and amnesia for more recent events.
Patients often refer to this as ‘short-term memory loss’, which technically refers to loss of working memory: for example, digit span, which is preserved in AD.

• **Language.** This usually becomes impaired as the disease advances. Difficulty with word finding is characteristic.

• **Apraxia.** Ability to carry out skilled motor activities is impaired (see p. 798).

• **Agnosia.** There is a failure to recognize objects such as clothing, and places or people.

• **Frontal executive function.** Organizing, planning and sequencing are impaired.

• **Parietal presentation.** Presentation with visuospatial difficulties and difficulty with orientation in space and navigation may occur. Parietal lobe involvement is also seen as a later feature in more typical presentations.

• **Posterior cortical atrophy (PCA).** This is the least common presentation of AD with visual disorientation due to initial involvement of the occipital lobes and occipito-parietal regions. Patients have complex visual symptoms that may be difficult to describe; they often say that it is easier to see distant than close-up objects. Memory is initially well preserved.

• **Personality.** In contrast to other dementias such as frontotemporal dementia, basic personality and social behaviour remain intact until late AD.

• **Anosognosia.** Lack of insight by the patient into their difficulties is common; they may be reluctant to seek medical attention but be brought to clinic by a family member.

• **Tempo.** Onset is insidious and often not noticed by family members initially. Progression is gradual but inexorable over a decade or longer, with eventual severe deficits in multiple cognitive domains.

• **Late non-cognitive features.** Myoclonus may develop, sometimes followed by seizures (the cortex is the main site of pathology). Sleep–wake cycle reversal and incontinence may place a great strain on carers. Motor function is usually strikingly preserved so patients are capable of wandering and getting lost. Swallowing may become impaired, leading to aspiration pneumonia – often a terminal event.

**Investigations**

MRI typically shows characteristic atrophy of mesial temporal lobe structures, including hippocampi, progressing eventually to generalized cerebral atrophy. Imaging may be normal in the early stages and selective regional atrophy is seen in AD variants such as ‘posterior presentations’, such as posterior cortical atrophy (PCA) with occipital lobe atrophy. Characteristic MRI and psychometric testing abnormalities are sufficient to make a diagnosis if the clinical picture is suggestive (a progressive amnestic cognitive disorder in an older person). CSF tau and β-amyloid measurement is helpful in cases of diagnostic difficulty but not yet widely available (see above).

**Molecular pathology and aetiology**
Although the cause of AD is still not known, a great deal is now understood about the molecular pathology. The pathological hallmarks are:

- The deposition of β-amyloid (Aβ) in amyloid plaques in the cortex.
- Structural and conformational changes in tau protein, i.e. hyperphosphorylation and formation of paired helical filaments, which are the binding blocks of neurofibrillary tangles. These protein aggregates damage synapses and ultimately lead to neuronal death. Early pathological changes in the brain, including Aβ deposition, pre-date clinical symptoms and diagnosis by up to 25 years.

Amyloid may also be laid down in cerebral blood vessels, leading to amyloid angiopathy.

The amyloid precursor protein (APP) is processed by secretase enzymes to form pathogenic $\text{Aβ}_{1-42}$ monomers, which polymerize into amyloid plaques (Fig. 21.61).

A basal forebrain cholinergic deficit occurs and may explain the therapeutic response to cholinesterase inhibitor drugs.

**Genetics of AD**

A first-degree relative with AD confers a doubled lifetime risk of AD. There are rare autosomal dominant monogenic early-onset forms of familial AD with high penetrance, caused
by mutations in specific genes; taken together, these account for only 1% of cases of AD.

**Other genes.** The E4 allele of the apolipoprotein E gene confers an increased risk of AD (2–3 times lifetime risk), especially if two copies of the E4 allele are inherited (6–8 times risk). Several other candidate genes have been identified as risk factors for AD in large genome-wide association studies.

**Amyloid precursor protein (APP).** Point mutations in the APP gene can cause AD, and the presence of three copies of the APP gene on chromosome 21 in Down syndrome patients is responsible for the high incidence of AD in that condition.

**Presenilin (PS)-1 and 2.** Mutations in these genes affect the γ-secretase enzyme function ([Fig. 21.61](#)). PS1 mutations account for 50% of monogenic forms of AD. The PS1/2 and APP genes may be sequenced for mutations in selected early-onset cases with a family history.

### Environmental risk factors

Age is the main risk factor for AD, as incidence increases exponentially with age. Head trauma and vascular risk factors also increase AD risk. Epidemiological studies show that taking anti-inflammatory drugs over a long period may confer some protection.

### Dementia with Lewy bodies and Parkinson's disease dementia

Dementia with Lewy bodies (DLB) is characterized by the early feature of visual hallucinations, fluctuating cognition with variation in attention and alertness, sleep disorders (especially REM sleep behaviour disorder), dysautonomia and parkinsonism. The visual hallucinations often take the form of people or animals, or the sense of a presence (‘extracampine hallucinations’). Memory loss may be absent in the early stages. Delusions and transient loss of consciousness occur. Lewy bodies, inclusions containing aggregates of the protein α-synuclein first described in Parkinson's disease, are found in the cortex.

In DLB, the cognitive features dominate; parkinsonism may evolve later and is typically mild. In Parkinson's disease dementia (PDD), cognitive problems are a late feature, occurring at least 1 year after onset and usually after the age of 75. Both conditions may respond to cholinesterase inhibitors. Patients with DLB may be very sensitive to neuroleptic drugs with dramatic worsening.

### Vascular dementia

This common cause of dementia is due to different mechanisms, including multi-infarct dementia, cerebral small-vessel disease and post-stroke dementia. Most vascular dementias are of mixed cause. Vascular dementia is distinguished from AD by its clinical features and imaging. Dementia can be progressive and similar to AD. There is sometimes a history of TIAs or the dementia follows a succession of cerebrovascular events or has a stepwise course. Apraxic gait disorder, pyramidal signs and urinary incontinence are common additional features. Widespread small-vessel disease seen on MRI is the typical finding and may produce a variety of cognitive deficits, reflecting the site of ischaemic damage.
Frontotemporal dementia

Frontotemporal dementia (FTD) is the term used to describe a group of neurodegenerative disorders characterized by asymmetric frontal lobe and temporal lobe atrophy on MRI and at postmortem (also called Pick’s disease). Onset is usually below the age of 65 and there is often a family history. FTD is considerably less common than AD, prevalence being approximately 10 per 100,000 before the age of 65. There are three distinct presentations, depending on which anatomical region is affected first.

**Frontal presentation.** This *behavioural variant* is characterized by personality change, emotional blunting, apathy, disinhibition, carelessness and behavioural change with striking preservation of episodic memory.

**Temporal presentations.** *Primary progressive aphasia* is characterized by progressive impairment of language function. Involvement of the left temporal lobe produces ‘semantic dementia’, with fluent speech relatively lacking in meaningful content and progressive difficulty with comprehension of the meaning of words (e.g. a patient may respond to the MMSE question ‘What season is it?’ by asking ‘What is a season?’). The second temporal lobe presentation is *progressive non-fluent aphasia* due to peri-Sylvian atrophy, with loss of verbal fluency and increasingly telegraphic speech.

The frontal and temporal presentations eventually merge as cognitive decline becomes more widespread.

Pathology

About 25% of cases are familial, associated with mutations in the tau and progranulin genes or hexanucleotide repeat expansion in the C9ORF72 gene. The characteristic pathology consists of deposition of abnormally aggregated proteins: phosphorylated tau, transactive response DNA-binding protein 43 (TDP-43) or fused in sarcoma (FUS). 10% of patients have overlap syndromes with motor neurone disease or parkinsonian disorders such as progressive supranuclear palsy. There is no cure or specific treatment at present.

Prion diseases, including Creutzfeldt–Jakob disease

Prion diseases (see pp. 267–268) are transmissible neurodegenerative disorders with a long incubation period, caused by accumulation of misfolded native prion protein (PrP\(^c\)). Misfolding and conformational change in PrP\(^c\) is caused either by exposure to the abnormal misfolded isoform of the protein (PrP\(^sc\)) or by mutations in the PrP gene (PRNP), leading to toxic accumulation of PrP\(^sc\) as amyloid in beta-pleated sheets. Neuronal cell damage and ‘spongiform’ change in the brain result (see pp. 267–268), the clinical correlate being a rapidly progressive dementia in most cases.

Creutzfeldt–Jakob disease
Creutzfeldt–Jakob disease (CJD) is the most common prion disease in humans, the animal equivalents being bovine spongiform encephalopathy (BSE) in cattle and scrapie in sheep. CJD may be sporadic, iatrogenic or familial.

**Sporadic CJD** is the most common form, occurring over the age of 50, with an incidence of approximately 1 per million. It is thought to be due to spontaneous somatic mutations in the PRNP gene or stochastic conformational change in PrPc to PrPsc with a subsequent ‘domino effect’ inducing misfolding in other PrP molecules. A rapidly progressive dementia leads to death within 6 months of onset. Rapidly progressive cognitive decline should always lead to suspicion of CJD. The presence of myoclonus is also a clinical clue (present in 90%). New forms of monoclonal antibody treatment are being studied.

**Iatrogenic CJD** is transmitted from neurosurgical instruments (prions are resistant to sterilization), transplant material (e.g. corneal grafts) and cadaveric pituitary-derived growth hormone taken from patients with CJD or pre-symptomatic CJD. Iatrogenic CJD has a long incubation period of several years.

**Familial CJD** (rare) is associated with PRNP gene mutations. Other clinical phenotypes, such as familial fatal insomnia, also occur.

**Variant CJD**

Variant CJD (vCJD) was first seen in the UK in 1995. vCJD patients are younger than sporadic cases with a mean age of 29. Early symptoms are neuropsychiatric, followed by ataxia and dementia with myoclonus or chorea. The diagnosis can be confirmed by tonsillar biopsy but a sensitive blood test has been developed. vCJD has a longer course than sporadic CJD – up to several years. vCJD and BSE are caused by the same prion strain, giving rise to speculation that transmission from animal to human food chain took place: that is, infection from BSE-infected cattle to humans (see p. 267). Transmission via blood transfusion may also occur. Most patients with vCJD and sporadic CJD have a specific polymorphism at codon 129 of the PRNP gene that leads to susceptibility.

**Other dementias**

Other neurodegenerative disorders may include dementia as one of their clinical manifestations. For example, corticobasal degeneration (CBD), progressive supranuclear palsy (PSP) and dementia may be a feature of a number of genetic and metabolic disorders, such as Huntington's disease (see p. 856) and the leucodystrophies.

**Management of dementia**

It is rare for a reversible cause for dementia to be found, such as normal pressure hydrocephalus or frontal meningioma. Other disorders, such as limbic encephalitis or severe depression, may present as dementia mimics and every effort should be made to distinguish these treatable conditions from degenerative dementias.
Management is supportive, to preserve dignity and to provide care for as long as possible in the familiar home environment. The burden of illness frequently falls on relatives. Dementia clinical nurse specialists form a central part of the multidisciplinary team.

**General measures.** Some evidence suggests that participation in cognitively demanding activities in later life may protect against or delay the onset of dementia. High-dose B vitamins may possibly slow conversion from MCI to AD in patients with above-average levels of the amino acid homocysteine. There is some recent evidence supporting use of vitamin E to slow progression.

**Cognitive enhancing drugs.** These have a modest symptomatic benefit in AD, equivalent to an increase in 1–2 points on the MMSE. They are not disease-modifying, so do not slow or prevent progression. Whilst there has been some dispute about the place for these drugs, they contribute to patients being able to prolong independence and remain at home for longer than might otherwise be the case.

**Cholinesterase inhibitors** (donepezil, rivastigmine and galantamine) increase brain acetylcholine levels by inhibiting CNS acetylcholinesterase. Patients with AD have a central cholinergic deficit. There is usually a small but significant improvement in memory, cognition and function. Cholinesterase inhibitors are also effective in DLB and Parkinson's dementia but not in FTD or vascular dementia. Side-effects, particularly cholinergic gastrointestinal symptoms, may be a problem. An ECG should be performed to exclude cardiac conduction deficits before starting therapy.

**Memantine** is an NMDA receptor antagonist. It is used in moderate or severe AD or where cholinesterase inhibitors are not tolerated. There is some evidence that combination of memantine and cholinesterase inhibitors is better than either used alone. It is generally well tolerated.

**Psychiatric and behavioural problems.** Depression is common in dementia and may be difficult to distinguish from dementia symptoms, such as apathy and worsening cognitive function. A trial of an antidepressant is appropriate where depression is suspected. Distinguishing depressive pseudo-dementia from organic dementia can be difficult but is crucial. Behavioural disturbance (e.g. due to agitation or delusions) and hallucinations may occur in late-stage disease. Use of antipsychotic medications is associated with significantly increased stroke risk in patients with dementia and should be used only as a last resort.

**Drugs in development.** The greatest need is for disease-modifying therapies that halt or slow progression in early-stage disease before significant irreversible neuronal damage has accumulated. Potential treatments in development include anti-amyloid therapies, such as monoclonal antibodies directed against Aβ and inhibitors of secretase enzymes that process APP into Aβ fragments. Solanuzemab is a monoclonal antibody targeting Aβ that has shown efficacy in slowing progression in early-stage AD in phase III clinical trials.

**Financial and legal issues.** Patients may want to set up a Lasting Power of Attorney (if they retain mental capacity to do so in legal terms) to allow a spouse or relative to deal with their financial affairs on their behalf when they lose the capacity to do so. Patients and carers may be entitled to state financial benefits.
**Driving.** After a diagnosis of dementia, patients in the UK have a duty to inform the Driver and Vehicle Licensing Authority (DVLA), who may request a driving safety assessment.

**Further reading**

**Motor neurone disease**

Motor neurone disease (MND) is a devastating condition causing progressive weakness and eventually death, usually as a result of respiratory failure or aspiration. It is relatively uncommon, with an annual incidence of 2/100,000. Presentation is usually between the ages of 50 and 75. Below age 70, men are affected more often than women. Amyotrophic lateral sclerosis (ALS) is the term more commonly used for MND in some countries.

**Pathogenesis**

MND predominantly affects upper and lower motor neurones in the spinal cord, cranial nerve motor nuclei and cortex. However, other neuronal systems may also be affected; 5% of patients also develop FTD (see p. 878) and up to 40% have some measurable frontal lobe cognitive impairment. MND is usually sporadic and of unknown cause, with no established environmental risk factors. Ubiquinated cytoplasmic inclusions containing the RNA processing proteins TDP-43 and FUS are the pathological hallmarks found in axons, indicating that protein aggregation may be involved in pathogenesis, as with other neurodegenerative disorders. Oxidative neuronal damage and glutamate-mediated excitotoxicity have also been implicated in pathogenesis.

Between 5% and 10% of cases of MND are familial, and mutations in the free radical scavenging enzyme superoxide dismutase (SOD-1) and in a number of other genes, including TDP-43 and FUS, have been identified. A hexanucleotide GGGGCC repeat expansion in the C9ORF72 gene on chromosome 9 accounts for a significant proportion of familial cases of MND–FTD overlap.

**Clinical features**

Four main clinical patterns are seen. These different presentations usually merge as MND progresses. The sensory system is not involved and so sensory symptoms such as numbness, tingling and pain do not occur.

• **Amyotrophic lateral sclerosis (ALS).** This is the classic paraneoplastic presentation with
simultaneous involvement of upper and lower motor neurones, usually in one limb, spreading gradually to other limbs and trunk muscles. The typical picture is one of progressive focal muscle weakness and wasting (e.g. in one hand), with muscle fasciculations due to spontaneous firing of abnormally large motor units formed by surviving axons branching to innervate muscle fibres that have lost their nerve supply. Cramps are a common but non-specific symptom. Examination often reveals upper motor neurone signs, such as brisk reflexes (a brisk reflex in a wasted muscle is a classic sign), extensor plantar responses and spasticity. Sometimes, an asymmetric spastic paraparesis is the presenting feature, with lower motor neurone features developing months later. Relentless progression of signs and symptoms over months allows confirmation of a diagnosis that may initially be suspected.

• **Progressive muscular atrophy.** This is a pure lower motor neurone presentation with weakness, muscle wasting and fasciculations, usually starting in one limb and gradually spreading to involve other adjacent spinal segments.

• **Progressive bulbar and pseudobulbar palsy** (20%). The lower cranial nerve nuclei and their supranuclear connections are initially involved. Dysarthria, dysphagia, nasal regurgitation of fluids and choking are the presenting symptoms. A fasciculating tongue with slow, stiff tongue movements is the classic finding in a mixed bulbar palsy. Emotional incontinence with pathological laughter and crying may occur in pseudobulbar palsy.

• **Primary lateral sclerosis** (rare, 1–2%). This is the least common form of MND and is confined to upper motor neurones, causing a slowly progressive tetraparesis and pseudobulbar palsy.

### Diagnosis

Diagnosis is largely clinical. There are no diagnostic tests but investigations allow exclusion of other disorders and may confirm subclinical involvement of muscle groups, such as paraspinal muscles. Denervation of muscles due to degeneration of lower motor neurones is confirmed by EMG.

Cervical spondylosis causing radiculopathy with myelopathy (upper and lower motor neurone signs) can cause diagnostic difficulty. Motor neuropathies, such as multifocal motor neuropathy, can also appear like MND (see p. 884).

### Prognosis and management

Survival for more than 3 years is unusual, although there are rare MND cases who survive for a decade or longer.

No treatment has been shown to influence outcome substantially. Riluzole, a sodium-channel blocker that inhibits glutamate release, slows progression slightly, increasing life expectancy by 3–4 months on average. Non-invasive ventilatory support and feeding via a gastrostomy help prolong survival. Patients should be supported by a specialist multidisciplinary team with access to palliative care and a clinical nurse specialist.

Congenital Disorders

Cerebral palsy

Cerebral palsy (CP) is an umbrella term encompassing disparate disorders that are apparent at birth or in childhood and are characterized by non-progressive motor deficits. It is the most common form of physical disability in childhood and most affected children survive into adulthood. A variety of intrauterine and neonatal cerebral insults may cause CP, including prematurity and its complications, hypoxia, intrauterine infections and kernicterus. In many cases, no specific cause can be identified.

Clinical features

Failure to achieve normal milestones is usually the earliest feature. Specific motor syndromes become apparent later in childhood or, rarely, in adult life.

- **Spastic diplegia** – lower limb spasticity, with scissoring of gait.
- **Athetoid cerebral palsy** (see p. 856).
- **Infantile hemiparesis** – may be noted at birth or later. One hemisphere is hypotrophic and the contralateral, hemiparetic limbs small (hemiatrophy).
- **Ataxic and dystonic CP**.
- **Co-morbidity** – particularly epilepsy and learning difficulty, which are common and at least as disabling as the motor deficit.
Dysraphism

Failure of normal fusion of the fetal neural tube leads to a group of congenital anomalies. Folate deficiency during pregnancy is contributory and supplements should always be given (see p. 201). Antiepileptic drugs, such as valproate, are also implicated (see pp. 849–850). If there is access from the skin, such as from a sinus connecting to the subarachnoid space, bacterial meningitis may follow.

• **Meningoencephalocele** involves extrusion of brain and meninges through a midline skull defect; protrusion can be minor or massive.

• **Spina bifida** is failure of lumbosacral neural tube fusion. Several varieties occur.

• **Spina bifida occulta** is isolated failure of vertebral arch fusion (usually lumbar), often seen incidentally on X-rays (3% of the population). A dimple or a tuft of hair may overlie the anomaly; clinical abnormalities are unusual.

• **Meningomyelocele** may occur with spina bifida.

  Meningomyelocele consists of elements of spinal cord and lumbosacral roots within a meningeal sac. This herniates through a vertebral defect. In severe cases, both lower limbs and sphincters are paralysed. Meningocele is a meningeal defect alone. The defect should be closed in the first 24 hours after birth.

**Further reading**

**Neurogenetic Disorders**

Approximately 80% of the 20 000–30 000 human genes are expressed in the brain. It is therefore not surprising that of the 5000 or so Mendelian disorders of humans, a high proportion are neurological disorders. Several hundred neurological disease genes have been identified and molecular genetic testing is now part of the neurological diagnostic process. Many of these disorders are covered in largely individual disease sections of this chapter.

**Neurocutaneous syndromes**

*Neurofibromatosis type 1 (von Recklinghausen's disease)*

One of the most common neurogenetic disorders, neurofibromatosis type 1 (NF-1) has a prevalence of 1 in 3000. Inheritance is autosomal dominant but 50% of cases are due to new
mutations with no family history. The protein is called neurofibromin 1. NF-1 is characterized by multiple skin neurofibromas and pigmentation (café-au-lait patches – see p. 1367, axillary freckling and Lisch nodules of the iris). The neurofibromas arise from the neurilemmal sheath.

Skin neurofibromas present as soft subcutaneous, sometimes pedunculated, lumps (see p. 1367). They increase in number throughout life. Plexiform neurofibromas (Fig. 21.62) may develop on major nerves and proximal nerve roots, sometimes involving the spinal cord. Treatment is surgical removal if pressure symptoms develop. Associated features include learning difficulties, malignant transformation of neurofibromas, and bone abnormalities including scoliosis and fibrous dysplasia.

![Image of a foot with neurofibromas](image)

**FIGURE 21.62** Plexiform neurofibroma.

### Neurofibromatosis type 2

Neurofibromatosis type 2 (NF-2) is much less common than NF-1. It is also autosomal dominant; the gene product, merlin or schwannomin, is a cytoskeletal protein. Many neural tumours occur:

- acoustic neuromas (usually bilateral) in 90%
- meningiomas
- gliomas (including optic nerve glioma)
- cutaneous neurofibromas (30%).
Tuberous sclerosis (epiloia)

Features of this rare multisystem, autosomal dominant condition include adenoma sebaceum, renal tumours and glial overgrowth in the brain (cortical tubers and sub-ependymal nodules). Epilepsy (70%) and learning difficulties (50%) are common complications.

Von Hippel–Lindau disease

This rare condition is dominantly inherited. Cerebellar, spinal and retinal haemangioblastomas develop and can be surgically removed. Tumours – renal cell carcinoma and phaeochromocytomas – may also occur. Polycythaemia sometimes develops.

Spinocerebellar ataxias

A wide variety of genetic disorders cause cerebellar ataxia as the sole or predominant clinical feature. Many are due to trinucleotide repeat insertions (see p. 115).

Early-onset ataxia

Most early (<20 years of age) childhood-onset inherited ataxias are autosomal recessive. Friedreich's ataxia is by far the most common, caused by a GAA trinucleotide repeat expansion in the frataxin gene (involved in mitochondrial iron metabolism). Onset is in the early teens with progressive difficulty in walking due to cerebellar ataxia and sensory neuropathy. Associated features include scoliosis, cardiomyopathy, optic atrophy, areflexia and diabetes.

Ataxia telangiectasia and ataxia with vitamin E deficiency are other rarer forms of autosomal recessive inherited ataxia.

Late-onset ataxia

Adult-onset (>20 years of age) inherited ataxias are usually dominantly inherited and there are some 30 different genetic forms, many caused by CAG trinucleotide repeats. There are three main categories of autosomal dominant cerebellar ataxia (ADCA):

- **ADCA-1**: progressive ataxia with variable additional features, including peripheral neuropathy, pyramidal and extrapyramidal signs, and cognitive impairment. ADCA-1 is caused by mutations in loci SCA1–3.
- **ADCA-2**: progressive ataxia with macular dystrophy. ADCA-2 is rare and involves the SCA7 gene.
- **ADCA-3**: late adult-onset ‘pure’ ataxia. ADCA-3 is associated with the SCA6 gene in 50%. Non-genetic phenocopies must be excluded.
**Paraneoplastic Syndromes**

Neurological disease may accompany malignancy in the absence of metastases. These paraneoplastic syndromes are associated with anti-neuronal antibodies, believed to be involved in the generation of signs and symptoms. Numerous anti-neuronal antibodies have been described.

Clinical pictures include:

- sensorimotor neuropathy (see p. 884)
- Lambert–Eaton myasthenic–myopathic syndrome (LEMS; see p. 890) and myasthenia gravis with thymoma
- motor neurone disease variants (see pp. 879–880)
- spastic paraparesis (see p. 873)
- cerebellar syndrome (see p. 814)
- limbic encephalitis (see pp. 865–866)
- paraneoplastic stiff person syndrome (see p. 892).

The neurological syndrome usually precedes evidence of the neoplasm: often a small-cell bronchial carcinoma, or breast or ovarian cancer. Diagnosis is based on the clinical pattern and antibody profile. Neuroimaging is typically normal. Treatment is often unsatisfactory.

**Peripheral Nerve Disease**

**Mechanisms of damage to peripheral nerves**

Peripheral nerves consist of two principal cellular structures: the nerve nucleus with its axon, and the myelin sheath, which is produced by Schwann cells between each node of Ranvier (see Fig. 21.1). Blood supply is via vasa nervorum. Several mechanisms, some coexisting, cause nerve damage.

**Demyelination**

Schwann cell damage leads to myelin sheath disruption. This causes marked slowing of conduction, seen, for example, in Guillain–Barré syndrome and many genetic neuropathies.

**Axonal degeneration**

Axon damage causes the nerve fibre to die back from the periphery. Conduction velocity initially remains normal (compare demyelination) because axonal continuity is maintained in surviving fibres. Axonal degeneration typically occurs in toxic neuropathies. A wide range of toxic and metabolic disorders damage peripheral nerves, as their long axons (requiring cellular transport of proteins from cell body to nerve terminals) make them uniquely vulnerable. This explains the concept of length-dependent neuropathy with the longest, most vulnerable axons (to the toes) being affected first.
Compression
Focal demyelination at the point of compression causes disruption of conduction. This typically occurs in entrapment neuropathies, such as carpal tunnel syndrome.

Infarction
Microinfarction of vasa nervorum occurs in diabetes and arteritis, such as polyarteritis nodosa and eosinophilic granulomatosis with polyangiitis (see p. 1121). Wallerian degeneration occurs distal to the infarct.

Infiltration
Infiltration of peripheral nerves occurs by inflammatory cells in leprosy and granulomas, such as sarcoid, and by neoplastic cells.

Nerve regeneration
Regeneration occurs either by remyelination – Schwann cells produce new myelin sheaths around an axon – or by axonal growth down the nerve sheath with sprouting from the axonal stump. Axonal growth takes place at up to 1 mm/day.

Types of peripheral nerve disease
(See Fig. 21.63.)
- **Neuropathy** simply means a pathological process affecting a peripheral nerve or nerves.
- **Mononeuropathy** means a process affecting a single nerve.
- **Mononeuritis multiplex** means that several individual nerves are affected.
- **Polyneuropathy** describes diffuse, symmetrical disease, usually commencing peripherally. The course may be acute, chronic, static, progressive, relapsing or towards recovery. Polyneuropathies are motor, sensory, sensorimotor and autonomic. They are classified broadly into demyelinating and axonal types, depending on which principal pathological process predominates. It is often impossible to separate these clinically. Many systemic diseases cause neuropathies. Widespread loss of tendon reflexes is typical, with distal weakness and distal sensory loss.
- **Radiculopathy** means disease affecting nerve roots and **plexopathy**, the brachial or lumbosacral plexus.
Peripheral neuropathies. The type of neuropathy (axonal or demyelinating) can be assessed by electrical nerve studies (see pp. 822–823).

Diagnosis is made by clinical pattern, nerve conduction studies/EMG, nerve biopsy, usually sural or radial, and identification of systemic or genetic disease.

Mononeuropathies

Peripheral nerve compression and entrapment

Nerves are vulnerable to mechanical compression at a few key sites (Box 21.65), such as the common peroneal nerve at the head of the fibula, or the ulnar nerve at the elbow. Entrapment develops in relatively tight anatomical passages, such as the carpal tunnel. Focal demyelination predominates at the compression site, and some distal axonal degeneration occurs.

**Box 21.65**

Nerve compression and entrapment

</tr>
</tbody>
</table>

These neuropathies are recognized largely by their clinical features. Diagnosis is confirmed by nerve conduction studies.

The most common are mentioned here. All are seen more frequently in people with diabetes.

Carpal tunnel syndrome
This common mononeuropathy, median nerve entrapment at the wrist, is usually known as carpal tunnel syndrome (CTS; see p. 655). CTS is typically not associated with any underlying disease. It is, however, seen in:

- hypothyroidism
- pregnancy (third trimester)
- rheumatoid disease
- acromegaly
- amyloidosis, including in dialysis patients.

Symptoms, signs and management are discussed on page 655.

**Ulnar nerve compression**

The nerve is compressed in the cubital tunnel at the elbow. This follows prolonged or recurrent pressure and elbow fracture (‘tardy ulnar palsy’, as onset is very delayed).

There is clawing of the hand, wasting of interossei and hypothenar muscles, and weakness of interossei and medial two lumbricals with sensory loss in the little finger and splitting of the ring finger. Decompression and transposition of the nerve at the elbow is sometimes helpful but often disappointing.

The deep, solely motor branch of the ulnar nerve can be damaged in the palm by repeated trauma, such as from a crutch, screwdriver handle or cycle handlebars.

**Radial nerve compression**

The radial nerve is compressed acutely against the humerus: for example, when the arm is draped over a hard chair for several hours, known as Saturday night palsy. Wrist drop and weakness of brachioradialis and finger extension follow. Recovery is usual, though not invariable, within 1–3 months. Posterior interosseous nerve compression in the forearm also leads to wrist drop, without weakness of brachioradialis.

**Lateral cutaneous nerve of the thigh compression**

This is also known as meralgia paraesthetica and is described on page 659.

**Common peroneal nerve palsy**

The common peroneal nerve is compressed against the head of the fibula following prolonged squatting, yoga, pressure from a cast, prolonged bed rest or coma, or for no apparent reason. There is foot drop and weakness of ankle eversion. The ankle jerk (S1) is preserved. A patch of numbness develops on the anterolateral border of the dorsum of the foot and/or lateral calf. Confusion with an L5 motor radiculopathy may occur. Recovery is usual, though not invariable, within several months.

**Hereditary neuropathy with pressure palsies**

The genetic converse of Charcot–Marie–Tooth disease 1A (see p. 886), this dominantly
inherited disorder is due to deletion (as opposed to duplication) of the *PMP-22* gene. Patients are susceptible to pressure palsies after minor compression episodes; even the brachial plexus may be involved. There is also a mild background neuropathy that develops gradually. Genetic testing can be performed.

### Mononeuritis multiplex

This occurs in:

- diabetes mellitus
- leprosy
- vasculitis, including eosinophilic granulomatosis with polyangiitis
- amyloidosis
- malignancy
- neurofibromatosis
- HIV and hepatitis C infection
- multifocal motor neuropathy with conduction block.

Several nerves, such as the ulnar, median, radial and lateral popliteal, become affected sequentially or simultaneously. When multifocal neuropathy is symmetrical, there is difficulty distinguishing it from polyneuropathy.

### Polyneuropathies (peripheral neuropathy)

Many diseases cause polyneuropathy. The diagnosis should not stop with identification of the polyneuropathy, but should involve a full diagnostic work-up to identify the underlying cause (*Box 21.66*). However, despite thorough investigation, the aetiology remains unknown in 50% of cases.

#### Box 21.66

**Varieties of polyneuropathy**

- Guillain–Barré syndrome
- Chronic inflammatory demyelinating polyradiculoneuropathy
- Idiopathic sensorimotor neuropathy
- Metabolic, toxic and vitamin deficiency neuropathies (see *Box 21.68*)

**Clinical features.** Duration, distribution and pattern of the different types of polyneuropathy vary considerably.

**Neurophysiological features.** Nerve conduction studies allow separation into axonal and
Demyelinating forms.

*Diagnostic investigations* (in addition to neurophysiology). A stepped approach can be taken (*Box 21.67*).

### Box 21.67

**Investigations in peripheral neuropathy**

**Initial investigations**

- **Blood tests:**
  - Full blood count, erythrocyte sedimentation rate, vitamin $B_{12}$
  - Renal, liver, thyroid function
  - Glucose
  - Protein electrophoresis, immunoglobulins/immunofixation
  - Antinuclear antibody
- **Chest X-ray**
- **Urine:** Bence Jones proteins, casts

**Selected patients**

- **Nerve biopsy**
- **Blood tests:**
  - Anti-ganglioside antibodies
  - Anti-myelin-associated glycoprotein (anti-MAG) antibodies
  - HIV, Lyme disease, hepatitis C
  - Cryoglobulins, vasculitis screen
  - Anti-Ro and anti-La
  - Porphyrins
  - Genetic tests (e.g. Friedreich's ataxia)
  - Angiotensin-converting enzyme
  - Serum free light chains
  - Anti-neuronal antibodies
- **Search for malignancy**
- **CSF analysis** for protein
- **Labial salivary gland biopsy** for Sjögren's
- **Slit-skin smear** for leprosy
- **Nerve conduction studies:** to differentiate axonal from demyelinating forms

---

**Immune-mediated neuropathies**
Guillain–Barré syndrome (GBS)

Clinical features
Guillain–Barré syndrome (GBS) is also called acute inflammatory demyelinating polyradiculoneuropathy (AIDP). GBS is the most common acute polyneuropathy (3/100 000 per year); it is usually demyelinating or occasionally axonal, and has an immune-mediated, often post-infectious, basis. GBS is monophasic – it does not recur. The clinical spectrum of GBS extends to an acute motor axonal neuropathy (AMAN) and the Miller–Fisher syndrome – a rare proximal form causing ocular muscle palsies and ataxia.

Paralysis follows 1–3 weeks after an infection that is often trivial and seldom identified. Campylobacter jejuni and cytomegalovirus infections are well-recognized causes of severe GBS. Infecting organisms induce antibody responses against peripheral nerves. Molecular mimicry – that is, sharing of homologous epitopes between microorganism liposaccharides and nerve gangliosides (e.g. GM1) – is the possible mechanism.

The patient complains of weakness of the distal limb muscles and/or distal numbness. Low back pain is a frequent early feature. The weakness and sensory loss progress proximally, over several days to 6 weeks. Predominant proximal muscle involvement may occur and, rarely, pure sensory forms. Loss of tendon reflexes is almost invariable. In mild cases, there is mild disability before spontaneous recovery begins, but in some 20% respiratory and facial muscles become weak, sometimes progressing to complete paralysis. Autonomic features sometimes develop.

Diagnosis
This is established on clinical grounds and confirmed by nerve conduction studies; these show slowing of conduction in the common demyelinating form, prolonged distal motor latency and/or conduction block. CSF protein is often raised to 1–3 g/L; cell count and glucose level remain normal.

In the Miller–Fisher syndrome, antibodies against GQ1b (ganglioside) have a sensitivity of 90%.

The differential diagnosis includes other acute paralytic illnesses, such as botulism, cord compression, muscle disease and myasthenia.

Course and management
Paralysis may progress rapidly (hours/days) to require ventilatory support. It is essential for ventilation (vital capacity) to be monitored repeatedly to recognize emerging respiratory muscle weakness. Low-molecular-weight heparin (see p. 578) and compression stockings should be used to reduce the risk of venous thrombosis.

Immunoglobulin given intravenously within the first 2 weeks reduces duration and severity of paralysis. Patients should be screened for IgA deficiency before immunoglobulin is given, as severe allergic reactions due to IgG antibodies may occur when congenital IgA deficiency is present. Plasma exchange is an alternative. Prolonged ventilation may be necessary.
Improvement towards independent mobility is gradual over many months or even years but may be incomplete. Some 5–8% die and 30% are left disabled.

**Chronic inflammatory demyelinating polyradiculoneuropathy**

Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) develops over months, causing progressive or relapsing proximal and distal limb weakness with sensory loss. Variants, such as the sensory ataxic form and multifocal motor neuropathy, occur. In some cases, cranial nerves may be involved.

There is no single diagnostic test but CSF protein is raised and patchy demyelination is usually seen on nerve conduction studies. Some cases are associated with a serum paraprotein. Nerve biopsy is sometimes required. CIDP responds to long-term immunosuppression with steroids or to intravenous immunoglobulin in the acute stages.

**Multifocal motor neuropathy with conduction block**

A distal immune-mediated focal demyelinating motor neuropathy (often asymmetrical and predominantly in the hands) develops gradually over months with profuse fasciculation; hence there is confusion with motor neurone disease (see pp. 879–880). Conduction block and denervation are seen electrically. Antibodies to the ganglioside GM1 are found in over 50% of cases; this is non-specific, as antibodies are sometimes seen in other neuropathies, such as GBS.

Treatment is usually with regular intravenous immunoglobulin infusions that produce immediate improvement. Steroids may cause the condition to worsen and should be avoided.

**Paraproteinaemic neuropathies**

Up to 70% of patients with a serum paraprotein have a neuropathy and some 10% of patients with no other identifiable cause for their neuropathy have a paraprotein. Most are associated with monoclonal gammopathy of unknown signification (MGUS; see p. 628) but they are also seen in myeloma (see pp. 626–629). The antibody may be pathogenic for the neuropathy (e.g. anti-MAG) or coincidental in some cases.

**IgM paraproteins**: usually a demyelinating neuropathy. The paraproteins are often directed against myelin-associated glycoprotein (anti-MAG). The anti-MAG phenotype is a slowly progressive distal neuropathy with ataxia and prominent tremor.

**POEMS syndrome** (Polyneuropathy (demyelinating), Organomegaly (hepatomegaly 50%), Endocrinopathy (reduced testosterone usually), an M (para)protein band, and Skin changes): probably caused by vascular endothelial growth factor (VEGF) release from a plasmacytoma. Treatment is of the plasmacytoma/plasma cell dyscrasia.

**Chronic sensorimotor neuropathy: no cause found**

This situation is common. Progressive symmetrical numbness and tingling occur in hands and
feet, spreading proximally in a glove and stocking distribution. Distal weakness also ascends. Tendon reflexes are lost. Symptoms may progress, remain static or occasionally remit. Autonomic features are sometimes seen.

Nerve conduction studies usually show axonal degeneration. Nerve biopsy helps to classify some cases: for example, diagnosing CIDP or unsuspected vasculitis.

### Metabolic, toxic and vitamin deficiency neuropathies

Causes of the most common neuropathies are shown in **Box 21.68**.

### Box 21.68

**Metabolic, toxic and vitamin deficiency neuropathies**

**Metabolic**
- Diabetes mellitus
- Uraemia
- Hepatic disease
- Thyroid disease
- Porphyria
- Amyloid disease
- Malignancy
- Refsum's disease
- Critical illness

**Toxic**
- Drugs (see **Box 21.70**)
- Alcohol
- Industrial toxins, e.g. lead, organophosphates

**Vitamin deficiency**
- B₁ (thiamine)
- B₆ (pyridoxine)
- Nicotinic acid
- B₁₂

**Other**
- Hereditary sensorimotor neuropathies, e.g. Charcot–Marie–Tooth
- Other polyneuropathies:
Metabolic neuropathies

**Diabetes mellitus**
This is the most common cause of neuropathy in developed countries; 50% of patients with diabetes have neuropathy after 25 years. Good glycaemic control is protective against this microvascular complication of diabetes. Several varieties of neuropathy occur (see pp. 1270–1272):

- **distal symmetrical sensory neuropathy**: usually mild and asymptomatic; related to diabetes duration and glycaemic control
- **acute painful sensory neuropathy** (reversible with improved glycaemic control)
- **mononeuropathy and multiple mononeuropathy (mononeuritis multiplex)**:
  - cranial nerve lesions
  - individual mononeuropathies (e.g. carpal tunnel syndrome) or mononeuritis multiplex
- **diabetic amyotrophy**: a reversible vasculitic plexopathy or femoral neuropathy
- **autonomic neuropathy**.

**Uraemia**
Progressive sensorimotor neuropathy develops in chronic uraemia. Response to dialysis is variable; the neuropathy usually improves after transplantation.

**Thyroid disease**
A mild chronic sensorimotor neuropathy is sometimes seen in both hyperthyroidism and hypothyroidism. Myopathy also occurs in hyperthyroidism (see pp. 1205–1206).

**Porphyria**
In acute intermittent porphyria (see p. 1290), there are episodes of a severe, mainly proximal neuropathy in the limbs, sometimes with abdominal pain, confusion and coma. Alcohol, barbiturates and intercurrent infection can precipitate attacks.

**Amyloidosis**
Polyneuropathy or multifocal neuropathy develops (see pp. 1288–1289).

**Toxic neuropathies**
Alcohol
Polyneuropathy, mainly in the lower limbs, occurs with chronic alcohol use. It is a common cause of neuropathy. A myopathy may accompany it. For other neurological consequences of alcohol, see Box 21.69.

Box 21.69
Neurological effects of ethyl alcohol
• Acute intoxication:
  – Disturbance of balance, gait and speech
  – Coma
  – Head injury and sequelae
• Alcohol withdrawal:
  – Morning shakes
  – Tremor
  – Delirium tremens
• Thiamine deficiency:
  – Polyneuropathy
  – Wernicke–Korsakoff syndrome
• Epilepsy
• Acute intoxication
• Alcohol withdrawal
• Hypoglycaemia
• Cerebellar degeneration
• Cerebral infarction
• Cerebral atrophy, dementia
• Osmotic demyelination syndrome (ODS)
• Marchiafava–Bignami syndrome (corpus callosum degeneration, rare)

Drugs and industrial toxins
Many drugs (Box 21.70) and a wide variety of industrial toxins cause polyneuropathy. Toxins include:
• lead – motor neuropathy
• acrylamide (plastics industry), trichlorethylene, hexane, fat-soluble hydrocarbons, e.g. solvent abuse; see p. 923
• arsenic, thallium and heavy metals.
**Box 21.70**

**Vitamin deficiency neuropathies**

Vitamin deficiencies cause nervous system damage that is potentially reversible if treated early, and progressive if not. Deficiencies, often of multiple vitamins, develop in malnutrition.

**Thiamine (vitamin B<sub>1</sub>)**

Dietary deficiency causes *beriberi* (see p. 198). Its principal features are polyneuropathy and cardiac failure. Thiamine deficiency also leads to Wernicke's encephalopathy and Korsakoff psychosis. Alcohol is the most common cause in Western countries and, rarely, anorexia nervosa or vomiting of pregnancy.

**Wernicke–Korsakoff syndrome.** This thiamine-responsive encephalopathy is due to damage in the brainstem and its connections. It consists of:

- **eye signs** – nystagmus, bilateral lateral rectus palsies, conjugate gaze palsies
- **ataxia** – broad-based gait, cerebellar signs and vestibular paralysis
- **cognitive change** – acutely, stupor and coma; later, an amnestic syndrome with confabulation.

Wernicke–Korsakoff syndrome is under-diagnosed. Thiamine should be given parenterally if the diagnosis is a possibility. Untreated Wernicke–Korsakoff syndrome commonly leads to an irreversible amnestic state. Erythrocyte transketolase activity is reduced but the test is rarely available.
Pyridoxine (vitamin $B_6$)

Deficiency causes a mainly sensory neuropathy. In practical terms, this is seen as limb numbness developing during anti-tuberculosis therapy in slow isoniazid acetylators (see p. 1111). Prophylactic pyridoxine 10 mg daily is given with isoniazid.

Vitamin $B_{12}$ (cobalamin)

Deficiency causes damage to the spinal cord, peripheral nerves and brain.

**Subacute combined degeneration of the cord (SACD).** Combined cord and peripheral nerve damage is a sequel of addisonian pernicious anaemia and, rarely, other causes of vitamin $B_{12}$ deficiency (see p. 528). Initially, there is numbness and tingling of fingers and toes; distal sensory loss, particularly of the posterior column; absent ankle jerks; and, with cord involvement, exaggerated knee jerks and extensor plantars. Optic atrophy and retinal haemorrhage may occur. In later stages, sphincter disturbance, severe generalized weakness and dementia develop. Exceptionally, dementia develops in the early stages.

Activated vitamin $B_{12}$, methylmalonic acid and homocysteine levels should be checked. Macrocytosis with megaloblastic marrow is usual, though not invariable, in SACD. Parenteral $B_{12}$ reverses nerve damage but has little effect on the cord and brain. Copper deficiency is a very rare cause of a similar picture. Nitrous oxide abuse may cause functional $B_{12}$ deficiency.

Genetic neuropathies

Inherited neuropathy may occur as ‘pure’ neuropathy disorders (e.g. Charcot–Marie–Tooth disease) or as part of a neurological multisystem disorder (e.g. spinocerebellar ataxias; see p. 881).

Charcot–Marie–Tooth disease

Charcot–Marie–Tooth (CMT) disease is a complex group of heterogeneous hereditary motor and sensory neuropathies (HMSNs) with multiple causative genes. Distal limb wasting and weakness typically progress slowly over many years, mostly in the legs, with variable loss of sensation and reflexes. In advanced disease, severe foot drop results but patients usually remain ambulant. Mild cases have pes cavus and toe clawing that can pass unnoticed.

- **HSMN Ia (CMT 1A)** – the most common (70% of CMT; 1 : 2500 births) autosomal dominant demyelinating neuropathy, caused by duplication (or point mutation) of a 1.5 megabase portion p11.2 of chromosome 17 encompassing the peripheral myelin protein 22 gene ($PMP-22$, 17p11.2)

- **HSMN Ib (CMT 1B)** – the second most common autosomal dominant demyelinating neuropathy due to mutations in the myelin protein zero gene ($MPZ$) on chromosome 1 (1q22)

- **HSMN II (CMT 2)** – rare axonal polyneuropathies also caused by $MFN2$ or $KIFIB$ on chromosome 1p36 and other mutations; there is prominent sensory involvement with pain and paraesthesias.
• **distal spinal muscular atrophy** – a rare cause of the CMT phenotype

• **CMT with optic atrophy**, deafness, retinitis pigmentosa and spastic paraparesis

• **CMTX** – an X-linked dominant HSMN on chromosome Xq13.1; the gene product is a gap junction B1 protein (GJB1) or connexin 32 (see pp. 94–95).

### Hereditary motor and sensory neuropathy type III

HSMN III is a rare childhood demyelinating sensory neuropathy (Déjérine–Sottas disease) leading to severe incapacity during adolescence. Nerve roots become hypertrophied. CSF protein is greatly elevated to ≥10 g/L. Point mutations, either of *PMP-22* gene or of *P0*, can generate this phenotype.

#### Other polyneuropathies

### Neuropathy in cancer

Polyneuropathy is seen as a paraneoplastic syndrome (non-metastatic manifestation of malignancy). Polyneuropathy occurs in myeloma and other plasma cell dyscrasias via several mechanisms, including direct effects of paraproteins, amyloidosis and nerve infiltration, POEMS and effects of chemotherapy. Individual nerves may be infiltrated with malignant cells, such as lymphoma.

### Neuropathies in systemic diseases

Vasculitic neuropathy occurs in SLE (see pp. 692–695), polyarteritis nodosa (p. 701), granulomatosis with eosinophilia (p. 1121) and rheumatoid disease (p. 678). Both multifocal neuropathy and symmetrical sensorimotor polyneuropathy occur.

### Autonomic neuropathy

Autonomic neuropathy causes postural hypotension, urinary retention, erectile dysfunction, nocturnal diarrhoea, diminished sweating, impaired pupillary responses and cardiac arrhythmias. This can develop in diabetes and amyloidosis, and may complicate GBS and Parkinson's disease. Many varieties of neuropathy cause autonomic problems in a mild form. Occasionally, such as with amyloidosis, a severe autonomic neuropathy may occur.

### Neuromuscular weakness complicating critical illness

Some 50% of critically ill intensive care unit patients with multiple organ failure and/or sepsis develop an axonal polyneuropathy (see p. 1167). Typically, distal weakness and absent reflexes are seen during recovery from critical illness. Resolution is usual.

### Plexus and nerve root lesions

The common conditions that cause these are summarized in *Box 21.71*. 
Box 21.71

Common root and plexus problems

Nerve root

• Cervical and lumbar spondylosis
• Trauma
• Herpes zoster
• Tumours, e.g. neurofibroma, metastases
• Meningeal inflammation, e.g. syphilis, arachnoiditis

Plexus

• Trauma
• Malignant infiltration
• Neuralgic amyotrophy
• Thoracic outlet syndrome (cervical rib)

Cervical and lumbar degeneration

Spondylosis (Box 18.10) describes vertebral and ligamentous degenerative changes occurring during ageing or following trauma. Several factors produce neurological signs and symptoms:

• osteophytes – local overgrowth of bony spurs or bars
• thickening of spinal ligaments
• congenital narrowing of the spinal canal
• disc degeneration and protrusion (posterior and lateral protrusion: cord and root compression)
• vertebral collapse (osteoporosis, infection)
• rheumatoid synovitis (see p. 677)
• ischaemic changes within cord and nerve roots.

Narrowing of disc spaces, osteophytes, narrowing of exit foramina and narrowing of the spinal canal are also seen on X-rays and MRI in the symptomless population, commonly in the mid- and lower cervical and lower lumbar region, and so imaging must not be over-interpreted.

Lateral cervical disc protrusion

The patient complains of pain in the arm. A C7 protrusion is the most common problem (Fig. 21.64). There is root pain that radiates to the C7 myotome (triceps, deep to scapula and extensor aspect of forearm), with a sensory disturbance, tingling and numbness in the C7
In an established C7 root lesion there is:

- weakness/wasting – triceps, wrist and finger extensors
- loss of the triceps jerk (C7 reflex arc)
- C7 dermatome sensory loss.

Although the initial pain can be very severe, most cases recover with rest and analgesics. It is usual to immobilize the neck. Disc protrusion with root compression is seen on MRI. Root decompression is sometimes helpful.

**Lateral lumbar disc protrusion**

The L5 and S1 roots are commonly compressed by lateral prolapse of L4–L5 and L5–S1 discs; the root number below a disc interspace is compressed. There is low back pain and **sciatica**: pain radiating from the back to buttock and leg. Onset is typically acute. This can follow lifting, bending or minor injury. When pain follows such an event, it is tempting to ascribe the disc protrusion to it. However, commonly, lateral lumbar disc protrusion is apparently spontaneous; lifting or injury is usually only bringing forward an inevitable disc prolapse.

Straight-leg raising is limited. There is reflex loss, such as ankle jerk in an S1 root lesion, and weakness of plantar flexion (S1) or great toe extension (L5). Sensory loss is found in the affected dermatome.

Most sciatica resolves with initial rest and analgesia, followed by early mobilization. MRI is sometimes appropriate. Surgery is indicated when a substantial persistent symptomatic disc lesion is shown.

**Acute low back pain**
Acute low back pain is extremely common. Often, pain is of disc or facet joint origin. Significant nerve root compression is unusual. Maintenance of activity and a trial of gentle manipulation are recommended (see also p. 657).

**Cervical spondylotic myelopathy**

This is a relatively common disorder of older adults. Posterior disc protrusion (*Fig. 21.65*), common at C4–5, C5–6 and C6–7 levels, causes spinal cord compression. Congenital spinal canal narrowing, osteophytic bars, ligamentous thickening and ischaemia are contributory. Usually, there are no or few neck symptoms. The patient complains of slowly progressive difficulty walking as a spastic paraparesis develops. A reflex level in the upper limbs and evidence of cervical radiculopathy may coexist. MRI demonstrates the level and extent of cord compression and T2 signal change is usually evident in the cervical cord at the point of maximal compression. Neck manipulation should be avoided.

![C5/6 disc (arrowed) compressing the cord: T2-weighted MRI.](image)

Decompression by anterior cervical discectomy may be necessary when cord compression is severe or progressive. Complete recovery of the pyramidal signs may occur; progression is generally halted.
Central thoracic disc protrusion

Central protrusion of a thoracic disc is an unusual cause of paraparesis, as the thoracic spine is relatively non-mobile and disc degeneration and protrusion, other than that due to trauma, is rare.

The cauda equina syndrome

A central lumbosacral disc protrusion causes a cauda equina syndrome: that is, bilateral flaccid (compare spasticity in higher lesions) lower limb weakness, sacral numbness, retention of urine, erectile dysfunction and areflexia, usually with back pain. Multiple lumbosacral nerve roots are involved. Onset is either acute – an acute flaccid paraparesis – or chronic, sometimes with intermittent claudication. A central lumbosacral protrusion should be suspected if a patient with back pain develops retention of urine or sacral numbness. Urgent imaging and surgical decompression are indicated for this emergency. Neoplasms in the lumbosacral region can present with similar features.

Spinal stenosis

A narrow spinal canal is developmental and frequently symptomless, but a congenital narrowing of the cervical canal predisposes the cervical cord to damage from minor disc protrusion later.

In the lumbosacral region, further narrowing of the canal by disc protrusion causes root pain and/or buttock and lower limb claudication. As the patient walks, nerve roots become hyperaemic and swell, producing buttock and lower limb pain with numbness (claudication). Surgical decompression is required.

Neuralgic amyotrophy

Severe pain in the muscles around one shoulder is followed by wasting, usually of infraspinatus, supraspinatus, deltoïd and serratus anterior. A demyelinating brachial plexopathy develops over several days. The cause is unknown; an allergic or viral basis is postulated. Rarely, a similar condition develops in distal upper limb muscles or in a lower limb. Recovery of wasted muscles is usual, but not invariable, over several months.

Thoracic outlet syndrome

A fibrous band or cervical rib extending from the tip of the C7 transverse process towards the first rib compresses the lower brachial plexus roots, C8 and T1. There is forearm pain (ulnar border), T1 sensory loss and thenar muscle wasting, principally of abductor pollicis brevis. A Horner syndrome may develop. The rib or band can be excised. Frequency of this diagnosis varies widely; thoracic outlet problems are sometimes invoked to explain ill-defined arm symptoms, typically on poor evidence.

A rib or band can also produce subclavian artery or venous occlusion. Neurological and
vascular problems rarely occur together.

Malignant infiltration and radiation plexopathy

Metastatic disease of nerve roots or the brachial or lumbosacral plexus causes a painful radiculopathy and/or plexopathy. An example is apical bronchial carcinoma (Pancoast's tumour) causing a T1 and sympathetic outflow lesion: wasting of small hand muscles, pain and T1 sensory loss with an ipsilateral Horner syndrome. This also occurs in apical tuberculosis. In the upper limb, radiotherapy following breast cancer can produce a plexopathy.

Muscle Diseases

Definitions

- **Myopathy** means a disease of voluntary muscle.
- **Myositis** indicates inflammation.
- **Muscular dystrophies** are inherited disorders of muscle cells.
- **Myasthenia** means fatiguable (worse on exercise) weakness – seen in neuromuscular junction diseases.
- **Myotonia** is sustained contraction/slow relaxation.
- **Channelopathies** are ion channel disorders of muscle cells.

**Weakness** is the predominant feature of muscle disease. A selection of these conditions is given in **Box 21.72**.

<table>
<thead>
<tr>
<th>Box 21.72</th>

**Muscle disease: classification**

- Acquired
  - Inflammatory
  - Polymyositis
  - Dermatomyositis
  - Inclusion body myositis
  - Viral, bacterial and parasitic infection
  - Sarcoidosis
- Endocrine and toxic
  - Corticosteroids/Cushing's
  - Thyroid disease
  - Calcium disorders
  - Alcohol misuse
  - Drugs, e.g. statins
• Myasthenic
  – Myasthenia gravis
  – Lambert–Eaton myasthenic–myopathic syndrome (LEMS)
• Genetic dystrophies
  – Duchenne
  – Facioscapulohumeral
  – Limb girdle and others
• Myotonic
  – Myotonic dystrophy
  – Myotonia congenita
• Channelopathies
  – Hypokalaemic periodic paralysis
  – Hyperkalaemic periodic paralysis
• Metabolic
  – Myophosphorylase deficiency (McArdle syndrome)
  – Other defects of glycogen and fatty acid metabolism
• Mitochondrial disease

Pathophysiology
Muscle fibres are affected by:
• acute inflammation and fibre necrosis (e.g. polymyositis, infection)
• genetically determined metabolic failure (e.g. Duchenne muscular dystrophy)
• infiltration by inflammatory tissue (e.g. sarcoidosis)
• fibre hypertrophy and regeneration
• mitochondrial diseases
• immunological damage, e.g. myasthenia gravis and Lambert–Eaton myasthenic syndrome
• ion channel disorders, e.g. chloride channel mutations in hereditary myotonias.

Diagnosis
Clinical features, including the distribution of weakness, wasting or hypertrophy, and the tempo of progression and presence of family history contribute to a clinical diagnosis. Several investigations help make a definitive diagnosis.

Serum muscle enzymes
Serum creatine kinase (CK) is a marker of muscle fibre damage and is greatly elevated in many dystrophies, such as Duchenne, and in inflammatory muscle disorders, such as polymyositis.
Neurogenetic tests
These are essential in muscular dystrophies and mitochondrial disease.

Electromyography
Characteristic EMG patterns are as follows:

- **Myopathy.** Short-duration spiky polyphasic muscle action potentials are seen. Spontaneous fibrillation is occasionally recorded.
- **Myotonic discharges.** A characteristic high-frequency whine is heard.
- **Decrement and increment.** In myasthenia gravis, a characteristic decrement in evoked muscle action potential follows repetitive motor nerve stimulation. The reverse occurs, i.e. increment, following repetitive stimulation in LEMS (see p. 890).
- In **denervation**, profuse fibrillation potentials are seen.

Muscle biopsy
Unlike neural tissue skeletal muscle can be easily biopsied to provide a definitive diagnosis using powerful molecular immunohistochemical techniques. Histology and muscle histochemistry of fibre types demonstrate denervation, inflammation and dystrophic changes. Electron microscopy is often valuable. In dystrophies, immunohistochemistry in specialist laboratories allows identification of the abnormal muscle protein and a precise molecular diagnosis.

Imaging
MRI shows **signal changes** within muscles in some cases of myositis, and fatty replacement of muscle in chronically damaged muscles.

Inflammatory myopathies
Inflammatory myopathies, including polymyositis, dermatomyositis and inclusion body myositis, are described on pages 697 and 698. Granulomatous muscle infiltration and inflammation may occur in sarcoidosis and other disorders such as rheumatoid arthritis, causing a mild myopathy. Viral myositis may also occur and muscles may be involved in other infections such as neurocysticercosis (see pp. 866–867).

Metabolic and endocrine myopathies

Corticosteroids and Cushing syndrome
Proximal weakness occurs with prolonged high-dose steroid therapy and in Cushing syndrome (see pp. 1197–1199). Selective type-2 fibre atrophy is seen on biopsy.
Thyroid disease
Several myopathies occur (see also p. 1207). Thyrotoxicosis can be accompanied by severe proximal myopathy. There is also an association between thyrotoxicosis and myasthenia gravis, and between thyrotoxicosis and hypokalaemic periodic paralysis (see p. 891). Both associations are seen more frequently in South-east Asia. In ophthalmic Graves’ disease, there is swelling and lymphocytic infiltration of extraocular muscles (see p. 1208).

Hypothyroidism is sometimes associated with muscle pain and stiffness, resembling myotonia. A proximal myopathy also occurs.

Disorders of calcium and vitamin D metabolism
Proximal myopathy develops in hypocalcaemia, rickets and osteomalacia (see p. 717).

Hypokalaemia
Acute hypokalaemia (e.g. with diuretics) causes flaccid paralysis reversed by potassium, given slowly (see p. 167). Chronic hypokalaemia leads to mild, mainly proximal, weakness. (See also periodic paralysis; p. 891).

Alcohol and drugs
Severe myopathy with muscle pain, necrosis and myoglobinuria occurs in acute excess. A subacute proximal myopathy occurs with chronic alcohol use. A similar syndrome occurs in diamorphine and amfetamine addicts.

Drugs
Drug-induced muscle disorders include proximal myopathy (steroids), muscle weakness (lithium), painful muscles (fibrates), rhabdomyolysis (a fibrate combined with a statin, or interaction between statins and other drugs such as certain antibiotics) and malignant hyperpyrexia. Most respond to drug withdrawal.

Myophosphorylase deficiency (McArdle syndrome)
McArdle syndrome is a muscle only glycogenosis where there is a deficiency of muscle glycogen phosphorylase (PYGM). It presents with muscle cramps, fatigue, anaesthetic problems and myoglobinuria after exercise in adults. Diagnosis is made on a muscle biopsy with analysis of PYGM at 11q13. Patients have a normal life span. Sucrose should be given before exercise.

Malignant hyperpyrexia
Widespread skeletal muscle rigidity with hyperpyrexia as a sequel of general anaesthesia or neuroleptic drugs, such as haloperidol, is due to a genetic defect in the sarcoplasmic reticulum calcium-release channel of the muscle ryanodine receptor, RyR1. Death during or following anaesthesia can occur in this rarity, sometimes inherited as an autosomal dominant trait. Dantrolene is of some help for rigidity.

---

**Neuromuscular junction disorders**

### Myasthenia gravis

Myasthenia gravis (MG) is an autoimmune disorder of neuromuscular junction (NMJ) transmission, characterized by weakness and fatiguability of proximal limb, bulbar and ocular muscles, the latter sometimes in isolation. The prevalence is about 4 in 100 000. MG is twice as common in women as in men, with a peak age incidence around 30 and a second smaller peak in incidence in older men.

Antibodies to acetylcholine receptor protein (anti-AChR antibodies) are pathogenic. Immune complexes of anti-AChR IgG and complement are deposited at the postsynaptic membranes, causing destruction of AChRs. Antibodies against muscle-specific receptor tyrosine kinase (anti-MuSK antibodies) have been identified in anti-AChR antibody-negative cases.

Thymic hyperplasia is found in 70% of MG patients below the age of 40. In some 10%, a thymic tumour is found (paraneoplastic myasthenia), the incidence increasing with age; antibodies to striated muscle can be demonstrated in some of these patients.

There is an association between MG and other autoimmune disorders: thyroid disease, rheumatoid disease, pernicious anaemia and SLE. Transient MG is sometimes caused by D-penicillamine treatment.

### Clinical features

Weakness and fatiguability are typical. Limb muscles (proximal), extraocular muscles, speech, facial expression and mastication muscles are commonly affected. Symptoms are worse towards the end of the day. Fluctuating diplopia and ptosis (often asymmetric) are frequently early symptoms and symptoms may be confined to the eyes: ocular myasthenia. Respiratory difficulties can occur in generalized myasthenia. Early complaints of fatigue are frequently dismissed.

Complex extraocular palsies, ptosis and fatiguable proximal weakness are found on examination (prolonged upgaze should be checked and limb power tested after repetitive contractions). The reflexes are initially preserved but may be fatiguable: that is, they disappear following repetitive activity. Wasting is sometimes seen after many years.

### Investigations
• **Serum anti-AChR and anti-MuSK antibodies.** Anti-AChR antibodies are present in some 80–90% of cases of generalized MG. In pure ocular MG, anti-AChR antibodies are detectable in less than 30% of cases. These antibodies are highly specific for MG and confirm the diagnosis. Anti-MuSK antibodies define a subgroup of MG patients characterized by weakness predominantly in bulbar, facial and neck muscles.

• **Repetitive nerve stimulation and single-fibre EMG.** A characteristic decrement occurs in the evoked muscle action potential during repetitive stimulation. Single-fibre EMG of orbicularis oculi is more sensitive than repetitive stimulation and shows block and jitter.

• **Imaging and other tests.** Mediastinal MRI or CT is needed to look for thymoma in all cases. Antibodies to striated muscle suggest a thymoma.

• **Tensilon (edrophonium) test.** This is seldom required and the drug is not available worldwide. Edrophonium 10 mg is given intravenously following a 1–2 mg test dose from the 10 mg vial. When the test is positive, there is substantial improvement in weakness within seconds and this lasts for up to 5 minutes. A control test using saline is performed. The sensitivity of the test is 80% but there are false-negative and false-positive tests. Occasionally, edrophonium (an anticholinesterase) causes bronchospasm and syncope. Resuscitation facilities must be available.

### Course and management

MG fluctuates in severity; most cases have a protracted, life-long course. Respiratory impairment, nasal regurgitation and dysphagia occur; emergency ventilation may be required. Simple monitoring tests, such as the duration for which an arm can be held outstretched, and the vital capacity are useful.

Exacerbations are usually unpredictable and unprovoked but may be brought on by infections and by aminoglycosides and other drugs.

### Drug treatment

#### Oral anticholinesterases

Pyridostigmine (60 mg tablet) is widely used. The duration of action is 3–4 hours, the dose (usually 3–16 tablets daily) determined by response. Pyridostigmine prolongs acetylcholine action by inhibiting cholinesterase. Overdose of anticholinesterases causes severe weakness (cholinergic crisis). Muscarinic side-effects, such as colic and diarrhoea, are common; oral atropine (antimuscarinic) 0.5 mg helps to reduce this. Anticholinesterases help weakness but do not alter the natural history of myasthenia.

#### Immunosuppressant drugs

These drugs are used in patients who do not respond to pyridostigmine or who have severe weakness. Steroids are usually used. There is improvement in 70%, although this may be preceded by an initial relapse; steroid dose should be increased slowly. Azathioprine,
mycophenolate and other immunosuppressants are also used as steroid-sparing agents.

**Thymectomy**

Thymectomy improves myasthenia in patients with thymic hyperplasia and positive AChR antibodies (approximately one-third improve, one-third enter remission and one-third do not benefit). When a thymoma is present, the potential for malignancy makes surgery necessary but the myasthenia may not improve.

**Plasmapheresis and intravenous immunoglobulin**

These produce a rapid dramatic response and are used in exacerbations and severe myasthenic crisis.

*Other rare myasthenic syndromes* exist, such as congenital myasthenia.

**Lambert–Eaton myasthenic–myopathic syndrome**

Lambert–Eaton myasthenic–myopathic syndrome (LEMS) is a paraneoplastic manifestation of small-cell bronchial carcinoma due to defective acetylcholine release at the neuromuscular junction. A smaller proportion of cases are autoimmune without underlying malignancy. Proximal limb muscle weakness, sometimes with ocular/bulbar muscles, develops, with some absent tendon reflexes: a cardinal sign. Weakness tends to improve after a few minutes of muscular contraction, and absent reflexes return (compare myasthenia). Diagnosis is confirmed by repetitive nerve stimulation (increment; see above). Antibodies to voltage-gated calcium channels are found in most cases (90%). Treatment with 3,4-diaminopyridine (DAP) is reasonably safe and effective.

**Muscular dystrophies**

These progressive, genetically determined disorders of skeletal and sometimes cardiac muscle have a complex clinical and neurogenetic classification.

**Duchenne muscular dystrophy and Becker's muscular dystrophy**

These are inherited as X-linked recessive disorders, though one-third of cases are spontaneous mutations. Duchenne muscular dystrophy (DMD) occurs in 1 in 3000 male infants. There is absence of the gene product dystrophin, a rod-shaped cytoskeletal muscle protein in DMD. In Becker's dystrophy, dystrophin is present but levels are low. DMD is usually obvious by the fourth year, and often causes death by the age of 20.

Dystrophin is essential for cell membrane stability. Deficiency leads to reduction in three glycoproteins (α-, β- and γ-sarcoglycans) in the dystrophin-associated protein complex (DAP complex) that links dystrophin to laminin within cell membranes.

Becker's muscular dystrophy is less severe than Duchenne and weakness only becomes
apparent in young adults.

Clinical features
A boy with DMD is noticed to have difficulty running and rising to his feet; he uses his hands to climb up his legs (Gowers' sign). There is initially a proximal limb weakness with calf pseudohypertrophy. The myocardium is affected. Severe disability is typical by the age of 10.

Investigations
The diagnosis is often suspected clinically. CK is grossly elevated (100–200 times normal). Biopsy shows variation in muscle fibre size, necrosis, regeneration and replacement by fat, and on immunochemical staining, absence of dystrophin.

Management
There is no curative treatment but new gene-editing therapies are in development. Steroids may delay progression. Physiotherapy helps prevent contractures in the later stages. Non-invasive respiratory support and multidisciplinary care improve life expectancy.

Carrier detection. Females with an affected brother have a 50% chance of carrying the DMD gene. In carriers, 70% have a raised CK, and usually EMG abnormalities and/or changes on biopsy. Carrier and prenatal diagnosis is available with genetic counselling.

Limb-girdle and facioscapulohumeral dystrophy
These less severe but disabling dystrophies are summarized in Box 21.73. There are many other varieties of dystrophy; facioscapulohumeral dystrophy is one of the most common. Genes for numerous forms of limb-girdle muscular dystrophy have been identified. CK is usually moderately elevated.

**Myotonias**

Myotonias are characterized by continued, involuntary muscle contraction after cessation of voluntary effort: that is, failure of muscle relaxation. EMG is characteristic (see p. 823). The two most common myotonias are described below. Patients with myotonia tolerate general anaesthetics poorly.

**Myotonic dystrophy**

This autosomal dominant condition is a genetic disorder with two different triple repeat mutations: most commonly, an expanded CTG repeat in a protein-kinase (DMPK) gene (DM1). The less common variety (DM2) is caused by an expanded CCTG repeat in a zinc finger protein gene. There is a correlation between disease severity, age at onset and approximate size of triplet repeat mutations. There is progressive distal muscle weakness, with ptosis, weakness and thinning of the face and sternomastoids. Myotonia is typically present. Muscle disease is part of a syndrome comprising:

- cataracts
- frontal baldness
- cognitive impairment (mild)
- oesophageal dysfunction (and aspiration)
- cardiomyopathy and conduction defects (sudden death can occur in type 1)
- small pituitary fossa and hypogonadism
- glucose intolerance
- low serum IgG.

This gradually progressive condition usually becomes evident between 20 and 50 years. Phenytoin or procainamide helps.
**Myotonia congenita**

Autosomal dominant myotonia, usually mild, becomes evident in childhood. The gene, *CLC1*, codes for a muscle chloride channel. The myotonia, which persists, is accentuated by rest and by cold. Diffuse muscle hypertrophy occurs; the patient has bulky muscles.

**Channelopathies**

**Hypokalaemic periodic paralysis**

This disorder is characterized by generalized weakness, including that of bulbar muscles, which often starts after a heavy carbohydrate meal or following exertion. Attacks last for several hours. The disorder often first comes to light in the teenage years and tends to remit after the age of 35. Serum potassium is usually below 3.0 mmol/L in an attack. The weakness responds to (slow) intravenous potassium chloride. It is usually inherited as an autosomal dominant trait caused by mutation in a muscle voltage-gated calcium channel gene (*CACLN1A3*). Other mutations in the sodium channels (*SCNA4*) and potassium channels (*KCNE3*) also occur. Acetazolamide sometimes helps prevent attacks. Weakness can be caused by diuretics. A similar condition can also occur with thyrotoxicosis.

**Hyperkalaemic periodic paralysis**

This condition, also autosomal dominant, is characterized by attacks of weakness, sometimes with exercise. Attacks start in childhood and tend to remit after the age of 20; they last about 30–120 minutes. Myotonia may occur. Serum potassium is elevated. An attack can be terminated by intravenous calcium gluconate or chloride. There are point mutations in a muscle voltage-gated sodium channel gene (*SCN4A*). Acetazolamide or a thiazide diuretic can be helpful.

A very rare normokalaemic, sodium-responsive periodic paralysis also occurs.

**Stiff person syndrome**

Stiff person syndrome (SPS) is a rare autoimmune disease, more common in females, causing axial muscle stiffness with abnormal posture, spasms and falls. Attacks of stiffness are sometimes provoked by noise or emotion, but sometimes occur spontaneously. Between attacks, which last from hours to days or even weeks, the patient may appear normal.

Widespread muscle stiffness is typical during an attack; there are no other neurological signs. SPS has been mistaken for Parkinson's, dystonia and non-organic conditions. Anti-glutamic acid decarboxylase antibodies (anti-GAD) are found in very high titre in >50% of cases and are believed to be involved in the generation of muscle stiffness. Continuous motor activity in paraspinal muscles is seen on EMG.

Treatment with diazepam, other muscle relaxants and intravenous immunoglobulin can be
helpful during attacks.
A form of SPS is also seen occasionally as a paraneoplastic condition associated with antibodies to the synaptic protein amphiphysin (see Box 17.8).

**Mitochondrial diseases**

These comprise a complex group of rare disorders involving muscle, peripheral nerves and CNS, characterized by morphological and biochemical abnormalities in mitochondria. Mitochondrial DNA is inherited maternally (see p. 109). The spectrum is wide, ranging from optic atrophy (see Leber's; p. 112) to myopathies, neuropathies and encephalopathy.

• **MELAS** (mitochondrial encephalomyopathy, lactic acidosis, stroke-like episodes) is one well-recognized form.

• Chronic progressive ophalmoplegia (CPEO) is another.

• **MERRF** describes myoclonic epilepsy with abnormal muscle histology, the muscle appearance being described as ragged red fibres.

Introduction
Psychiatry is concerned with the study and management of disorders of mental function: primarily, thoughts, perceptions, emotions and purposeful behaviours. Psychological medicine, or liaison psychiatry, is concerned primarily with psychiatric disorders in patients who have physical complaints or conditions. This chapter will mainly address this branch of psychiatry.

The long-held belief that diseases are either physical or mental has been replaced by the accumulated evidence that the brain is functionally or anatomically abnormal in psychiatric disorders. Physical, psychological and social factors, and their interactions, must be looked into, in order to understand psychiatric conditions – replacing the mind/body biomedical model with an integrated biopsychosocial one.

Epidemiology
The point prevalence of psychiatric disorders in adults in the UK is about 20%, mostly composed of depressive and anxiety disorders and substance misuse (mainly alcohol) (Box 22.1). The prevalence is about twice as high in patients attending the general hospital, with the highest rates in the accident and emergency department and medical wards.

Box 22.1

\(^{a}\)Total in the community (general population) is 20% due to co-morbidity.

\(^{b}\)An under-estimate.

### Culture and ethnicity

These can alter either the presentation or the prevalence of psychiatric ill-health. Biological factors in mental illness are similar across cultural boundaries but may vary by ethnic groups, whereas psychological and social factors will vary across culture. For example, the prevalence and presentation of schizophrenia vary little between countries, suggesting that biological factors operate independently of cultural ones. In contrast, disorders in which social factors play a greater role vary between cultures, so that anorexia nervosa is found more often in Western-influenced cultures. Culture can also influence the presentation of illnesses, such that physical symptoms are more common presentations of depressive illness in Asia than in Europe. Similarly, culture will influence the healthcare that is both sought and provided for the same condition.

### Clinical Approach to the Patient with a Psychiatric Disorder

#### The psychiatric history

The history is essential in making a diagnosis. The method is similar to that used in all specialties, but tailored to help to make a psychiatric diagnosis, determine possible aetiology and estimate prognosis. The history may be taken from the patient, or a friend or relative (usually with the patient's permission), or from relevant healthcare professionals. The patient interview also enables a doctor to establish a therapeutic relationship with the patient. **Box 22.2** gives essential guidance on how to conduct such an interview safely, although it is rare for a patient to harm a healthcare professional. When interviewing a patient for the first time, follow the guidance outlined on page 10.
The essentials of a safe psychiatric interview

• **Beforehand:** Ask someone with experience who knows the patient whether it is safe to interview the patient alone.

• **Access to others:** If in doubt, interview in the view or hearing of others, or accompanied by another member of staff.

• **Setting:** If safe, conduct the interview in a quiet room alone for confidentiality, not by the bed.

• **Seating:** Place yourself between the door and the patient.

• **Alarm:** If one is available, find out where the alarm is and how to use it.

Components of the history are summarized in *Box 22.3*.

<table>
<thead>
<tr>
<th>Box 22.3</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Summary of the components of the psychiatric history</strong></td>

<tr>
<td>Present illness</td>
</tr>
<tr>
<td>Past psychiatric history</td>
</tr>
<tr>
<td>Past medical history</td>
</tr>
<tr>
<td>Family history</td>
</tr>
</tbody>
</table>
| Personal (biographical) history | *Childhood*: mother's pregnancy and patient's birth (complications, nature of delivery), early development and attainment of developmental milestones (e.g. learning to crawl, walk, talk). School history: age started and finished; truancy, bullying, reprimands; qualifications  
|                                | *Adulthood*: employment (age at first job, total number of jobs, reasons for leaving, problems at work), relationships (sexual orientation, age at first relationship, total number of relationships, reasons for ending them), children and dependants |
| Reproductive history            | Women: menstrual problems, pregnancies, terminations, miscarriages, contraception and menopause |
| Social history                  | Current employment, benefits, housing, current stressors                    |
| Personality                     | This may help to determine prognosis. How do they normally cope with stress? Do they trust others and make friends easily? Irritable? Moody? A loner? This list is not exhaustive |
| Drug history                    | Prescribed and over-the-counter medication, units and type of alcohol/week, tobacco, caffeine and illicit drugs |
| Forensic history                | Explain that you need to ask about this, since ill-health can sometimes lead to problems with the law. Note any violent or sexual offences. This is part of a risk assessment. Worst harm they have ever inflicted on someone else? Under what circumstances? Would they do the same again, were the situation to recur? |
| Systematic review               | Psychiatric illness is not exclusive of physical illness! The two may not only coexist but also have a common aetiology |

**The mental state examination**

The history will already have assessed several aspects of the mental state examination (MSE), but several of these will need to be expanded on and specific areas, such as cognition, tested. The MSE is typically followed by a physical examination, and concluded with an assessment of insight and risk, and a formulation that takes into account a differential diagnosis and aetiology. Each domain of the MSE is given below; abnormalities that might be detected and the disorders in which they are found are summarized in Box 22.4.

### Box 22.4

**Aspects of the MSE**

**Appearance and general behaviour**

The state and colour of the clothes, facial appearance, eye contact, posture and movement provide information about a patient's affect. Agitation and anxiety cause an easy startle response, sweating, tremor, restlessness, fidgeting and visual scanning (for danger).
Speech
The rate, rhythm, volume and content of the patient's speech should be examined for abnormalities. Note that speech is the only way that you can examine thoughts and, as such, disorders of thought form are typically observed in this section. Thought content (literally, the content of the patient's thoughts) is dealt with separately (see below). Abnormalities that may reflect neurological lesions, such as dysarthria and dysphasia, should also be assessed.

Mood and affect
The patient has an emotion or feeling, tells you about their mood, and what you observe is the patient's affect. Mood may be altered in three ways: persistent change in mood, fluctuation and incongruity.

Thoughts
Abnormalities of thought content and thought possession are recorded here. Delusions (see Box 22.4) can be further categorized as primary or secondary, depending on whether they arise de novo or secondary to other abnormalities of the mental state.

Abnormal perceptions
Assessing perceptions will involve you observing the patient as well as asking questions of them. For example, patients experiencing auditory hallucinations may appear startled by sounds or voices that you cannot hear, or may interact with them: for example, appearing to be engaged in conversation when nobody else is in the room. Hallucinations can affect any sensory modality and specific types of hallucination will be addressed later in the chapter along with the disorders in which they most commonly occur.

Cognitive state
Examination of the cognitive state is necessary to diagnose organic brain disorders, such as delirium and dementia. Poor concentration, confusion and memory problems are the most common subjective complaints. Clinical testing involves the screening of cognitive functions, which may suggest the need for more formal psychometry. Simple questioning will detect about 90% of people who have cognitive impairments, with about 10% false positives. Testing can be divided into tests of diffuse and focal brain functions, and the means of assessment are set out in Box 22.5.

Box 22.5
Cognitive examination

---
a
## Cognitive domain

### Assessment

<table>
<thead>
<tr>
<th>Cognitive domain</th>
<th>Diffuse functions</th>
</tr>
</thead>
<tbody>
<tr>
<td>Premorbid intelligence</td>
<td>An estimate is helpful in assessing changes in cognitive abilities: Ask the patient about the final year and level of their education, and the highest qualifications or skills they achieved.</td>
</tr>
<tr>
<td>Orientation</td>
<td>Assess orientation to time, place and person. Consciousness can be defined as the awareness of the self and the environment. Clouding of consciousness is more accurately a fluctuating level of awareness and is commonly seen in delirium.</td>
</tr>
<tr>
<td>Attention</td>
<td>Ask the patient to say the months of the year or days of the week backwards.</td>
</tr>
</tbody>
</table>
| Verbal memory | **Immediate recall or registration:** ask the patient to repeat a name and address with 10 or so items, noting how many times it takes to recall it with 100% accuracy (normal is 1 or 2).  
**Short-term memory:** ask the patient to try to remember the address and then ask it of them again after 5 min (0 or 1 error is normal). |
| Long-term memory | Ask the patient to recall the news from that morning or recently. If they are not interested in the news, find out their interests (football team, favourite soap opera) and ask relevant questions. *Amnesia* is literally an absence of memory; *dysmnesia* indicates a dysfunctioning memory. |

<table>
<thead>
<tr>
<th>Focal functions</th>
</tr>
</thead>
<tbody>
<tr>
<td>Frontal, temporal and parietal lobe function</td>
</tr>
<tr>
<td>Behaviour</td>
</tr>
</tbody>
</table>
| Sequential tasks | Ask the patient to alternate making a fist with one hand at the same time as a flat hand with the other.  
Ask the patient to tap a table once if you tap twice, and vice versa.  
Note any motor perseveration whereby the patient cannot change the movement once established.  
Observe for verbal perseveration, in which the patient repeats the same answer as given previously for a different question. |
| Abstract thinking | Ask the patient the meaning of common proverbs: a literal meaning may suggest frontal lobe dysfunction, assuming reasonable premorbid intelligence. |

*This correlates well with more time-consuming intelligence quotient (IQ) tests, but it will not pick up cognitive problems caused by focal brain lesions as easily.

---

**Insight and illness beliefs**

**Insight** is the degree to which a person recognizes that he or she is unwell, and is minimal in people with a psychosis. **Illness beliefs** are the patient’s own explanations of their ill-health, including diagnosis and causes. These beliefs should be elicited because they can help to determine prognosis and adherence to treatment.

**Defence mechanisms**

Although not strictly part of the mental state examination, it is useful to be able to identify psychological defences in ourselves and our patients. Defence mechanisms are unconscious mental processes. Some of the most commonly used defence mechanisms are described in **Box 22.6** and are useful in understanding many aspects of behaviour.

---

**Box 22.6**
## Common defence mechanisms

<table>
<thead>
<tr>
<th>Defence mechanism</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Repression</td>
<td>Exclusion from awareness of memories, emotions and/or impulses that would cause anxiety or distress if allowed to enter consciousness</td>
</tr>
<tr>
<td>Denial</td>
<td>Similar to repression and occurs when patients behave as though unaware of something that they might be expected to know, e.g. a patient who, despite being told that a close relative has died, continues to behave as though the relative were still alive</td>
</tr>
<tr>
<td>Displacement</td>
<td>Transferring of emotion from a situation or object with which it is properly associated to another that gives less distress</td>
</tr>
<tr>
<td>Identification</td>
<td>Unconscious process of taking on some of the characteristics or behaviours of another person, often to reduce the pain of separation or loss</td>
</tr>
<tr>
<td>Projection</td>
<td>Attribution to another person of thoughts or feelings that are in fact one's own</td>
</tr>
<tr>
<td>Regression</td>
<td>Adoption of primitive patterns of behaviour appropriate to an earlier stage of development. It can be seen in ill people who become child-like and highly dependent</td>
</tr>
<tr>
<td>Sublimation</td>
<td>Unconscious diversion of unacceptable behaviours into acceptable ones</td>
</tr>
</tbody>
</table>

## Risk assessment

The assessment of risk may sound daunting but it is common to all clinical practice: for instance, when determining whether a patient with chest pain should be reviewed in the resuscitation room of the emergency department rather than a normal cubicle. Risk must be assessed in people with a psychiatric diagnosis, although the nature of ‘risk’ is different.

Risk can be broken down into two parts: the risk that the patient poses to themselves and that which they pose to others (Box 22.7). An appraisal of risk will already have been made in the initial preparations for seeing a patient (see Box 22.2) and in checking ‘forensic history’ (see Box 22.3). Additional information from family, friends or professionals who know the patient may prove invaluable.

### Box 22.7

**The assessment of risk**

<table>
<thead>
<tr>
<th>Risk to self</th>
<th>Risk to others</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Active</strong></td>
<td>Acts of self-harm or suicide attempts</td>
</tr>
<tr>
<td></td>
<td>Look for prior history of self-harm and what may have precipitated or prevented it</td>
</tr>
<tr>
<td></td>
<td>Aggression towards others – this may be actual violence or threatening behaviour</td>
</tr>
<tr>
<td></td>
<td>A past history of aggression is a good predictor of its recurrence. Look at the severity and quality of, and remorse for, prior violent acts, as well as identifiable precipitants that might be avoided in the future (e.g. alcohol)</td>
</tr>
<tr>
<td><strong>Passive</strong></td>
<td>Self-neglect</td>
</tr>
<tr>
<td></td>
<td>Manipulation by others</td>
</tr>
<tr>
<td></td>
<td>Neglect of others – always find out whether there are children or other dependants at home</td>
</tr>
</tbody>
</table>
Severe behavioural disturbance

Patients who are aggressive or violent cause understandable apprehension in all staff, and are most commonly seen in the accident and emergency department. Information from anyone accompanying the patient, including police or carers, can help considerably. Box 22.8 lists the main causes of disturbed behaviour.

**Box 22.8**

The main causes of disturbed behaviour

- Drug intoxication (especially alcohol)
- Delirium (acute confusional state)
- Acute psychosis
- Personality disorder

**Management of the severely disturbed patient**

The primary aims of management are the control of dangerous behaviour and the establishment of a provisional diagnosis. Four specific strategies may be necessary when dealing with the violent patient:

- reassurance and explanation
- medication
- physical restraint
- monitoring.

These are explained in Box 22.9. Remember that the behaviour exhibited is normally a reflection of an underlying disorder and, as such, portrays suffering and often fear. The approach to the agitated or even the violent patient must therefore take this into account and the steps listed are used with the intention of alleviating this suffering whilst maintaining the safety of the individual, and of other patients and staff. Management begins at the point of an initial assessment that takes into account prior episodes of disturbed behaviour and its precipitants. Armed with this knowledge, it may be possible to prevent a recurrence.

**Box 22.9**

The management of the severely disturbed patient
The relevant physical examination

This should be guided by the history and mental state examination. Particular attention should be paid to the neurological and endocrinological examinations when organic brain syndromes and affective illnesses are suspected.

Summary or formulation

When the full history and mental state have been assessed, you should make a concise assessment or ‘formulation’ of the case. In addition to summarizing the essential features of the history and examination, the formulation includes a differential diagnosis, possible causal factors, and any further investigations or interviews that are needed. It concludes with a concise plan of treatment and a statement of the likely prognosis.

Further reading

Classification of Psychiatric Disorders

The classification of psychiatric disorders into categories is mainly based on symptoms and behaviours, since there are few diagnostic tests for psychiatric disorders. There currently exists an unhelpful dualistic division of psychiatric disorders from neurological diseases into separate chapters in the main classification system. Since the brain or nervous system is the organ affected in both groups of conditions, some have argued that neurological and psychiatric disorders should be classified in future in one chapter as disorders of the nervous system.

Psychiatric classifications have traditionally divided up disorders into neuroses and psychoses:

• **Neuroses** are illnesses in which symptoms vary only in severity from normal experiences, such as depressive illness.

• **Psychoses** are illnesses in which symptoms are qualitatively different from normal experience, with little insight into their nature, such as schizophrenia.

There are several problems with a neurotic–psychotic dichotomy. First, neuroses may be as severe in their effects as psychoses. Second, neuroses may cause symptoms that fulfil the definition of psychotic symptoms. For instance, someone with anorexia nervosa may be convinced that they are fat when they are thin, and this belief would meet all the criteria for a delusional belief, yet we would traditionally classify the illness as a neurosis.

The *ICD-10 Classification of Mental and Behavioural Disorders*, published by the World Health Organization, has largely abandoned the traditional division between neurosis and psychosis, although the terms are still used. The disorders are now arranged in groups according to major common themes (e.g. mood disorders and delusional disorders). A classification of psychiatric disorders derived from ICD-10 is shown in **Box 22.10**, and this is the classification mainly used in this chapter (ICD-11 will be available in 2017).

**Box 22.10**

**International Classification of Psychiatric Disorders (ICD-10)**

- Organic disorders
- Mental and behavioural disorders due to psychoactive substance use
- Schizophrenia and delusional disorders
- Mood (affective) disorders
- Neurotic, stress-related and somatoform disorders
- Behavioural syndromes
• Disorders of adult personality and behaviour
• Mental retardation

The Diagnostic and Statistical Manual of the American Psychiatric Association (DSM-5) is an alternative classification system.

White PD, Rickards H, Zeman AZJ. Time to end the distinction between mental and neurological illnesses. BMJ 2012; 344:e3454.

Aetiology of Psychiatric Disorders
A psychiatric disorder may result from several causes, which may interact. It can be helpful to divide causes into the three ‘Ps’, as having predisposing, precipitating and perpetuating factors:

• **Predisposing factors** often stem from early life and include genetic factors, pregnancy- and delivery-related factors, previous emotional traumas and personality factors.

• **Precipitating factors** are ‘triggers’ that may be physical, psychological or social. Whether or not they produce a disorder depends on their nature and severity, and the presence of predisposing factors.

• **Perpetuating factors** maintain the disorder once it has been triggered and may be physical, psychological or social. There may be more than one and these may interact.

Psychiatric Aspects of Physical Diseases
People with non-psychiatric, ‘physical’ diseases are more likely to suffer from psychiatric disorders than those who are well. The most common psychiatric disorders in such patients are mood and acute organic brain disorders (delirium). The relationship between mental and physical conditions may be understood in one of four ways:

• Psychological distress and disorders can precipitate physical diseases (e.g. the cardiac risk associated with depressive disorders, or hypokalaemia causing arrhythmias in anorexia nervosa).
• Physical diseases and their treatments can cause mental symptoms or ill-health (*Box 22.11*).

---

**Box 22.11**

**Psychiatric conditions sometimes caused by physical diseases**

**Depressive illness**
- Hypothyroidism
- Cushing syndrome
- Steroid treatment
- Brain tumour

**Anxiety disorder**
- Thyrotoxicosis
- Hypoglycaemia (transient)
- Phaeochromocytoma
- Complex partial seizures (transient)
- Alcohol withdrawal

**Irritability**
- Post-concussion syndrome
- Frontal lobe syndrome
- Hypoglycaemia (transient)

**Memory problem**
- Brain tumour
- Hypothyroidism

**Altered behaviour**
- Acute drug intoxication
- Post-ictal state
- Acute delirium
- Dementia
  - Brain tumour

• Both the mental and physical symptoms are caused by a common disease process (e.g. Huntington's chorea, Parkinson's disease).

• Physical and mental symptoms and disorders may be independently co-morbid, particularly in the elderly.
Factors that increase the risk of a psychiatric disorder in someone with a physical disease are shown in **Box 22.12**.

</tbody>
</table>

**Differences in management**

Although the basic principles are the same as in treating psychiatric illnesses in the physically healthy, there are some differences:
• **A physical disease or treatment** may be exacerbating the psychiatric condition and may be revealed in the history (see *Box 22.11*); this should then be addressed. For example, dopamine agonists may precipitate a psychosis.

• **Disorders affecting pharmacokinetics** entail a reduction in dosage when psychotropics are prescribed, e.g. fluoxetine in acute kidney injury or hepatic failure.

• **Drug interactions** should be of particular concern, e.g. lithium and non-steroidal anti-inflammatory drugs (NSAIDs).

• **Women who might become pregnant** need to avoid certain drugs, such as sodium valproate, which can cause fetal malformations.

• **A planned physical treatment** may sometimes exacerbate the psychiatric condition. An example would be high-dose steroids as part of chemotherapy in a patient with leukaemia and depressive illness.

• **The risk of suicide** should always be remembered in an inpatient with a mood disorder and steps should be taken to reduce that risk, e.g. by moving the patient to a room on the ground floor and/or having a registered mental health nurse attend the patient while at risk.

---

**Further reading**

---

**The Sick Role and Illness Behaviour**

The *sick role* describes the behaviour usually adopted by ill people. Such people are not expected to fulfil their normal social obligations. They are treated with sympathy by others and are only obliged to see their doctor and take medical advice or treatments.

**Illness behaviour** is the way in which given symptoms may be differentially perceived, evaluated and acted (or not acted) upon. We all have illness behaviour when we choose what to do about a symptom. Going to see a doctor is generally more likely with more severe, disabling and numerous symptoms. It is also more likely in introspective individuals who focus on their health.

**Abnormal illness behaviour** occurs when there is a discrepancy between the objective pathology present and the patient's response to it, in spite of adequate medical investigation and explanation.

**Functional Somatic Syndromes**

So-called *functional* (in contrast to ‘organic’) somatic syndromes are illnesses in which no obvious pathology is found and there is an assumed dysfunction of an organ or system. Examples are given in *Box 22.13*. The psychiatric classification of these disorders might be *somatoform disorders*, if there are clear psychological precipitating or perpetuating factors,
but they do not fit easily within either medical or psychiatric classification systems, since they occupy the borderland between them. This classification also implies a dualistic ‘mind or body’ dichotomy, which is not backed up by evidence. Since current classifications still support this outmoded understanding, this chapter will address these conditions in this way.

### Box 22.13

**‘Functional’ somatic syndromes**

- ‘Tension’ headaches
- Atypical facial pain
- Atypical chest pain
- Fibromyalgia (chronic widespread pain)
- Other chronic regional pain syndromes
- Chronic fatigue syndrome
- Multiple chemical sensitivity
- Premenstrual syndrome
- Irritable or functional bowel syndrome
- Irritable bladder

The word *psychosomatic* has had several colloquial meanings, including ‘all in the mind’ and imaginary, but the modern concept is that psychosomatic disorders are syndromes in which both physical and psychological factors are likely to be causative. So-called medically unexplained symptoms and syndromes are very common in both primary care and the general hospital (over half the outpatients in gastroenterology and neurology clinics have these syndromes). Because orthodox medicine has not been particularly effective in treating or understanding these disorders, many patients perceive their doctors as unsympathetic and seek out complementary or even alternative treatments of uncertain efficacy.

Because epidemiological studies suggest that having one of these syndromes significantly increases the risk of having another, some doctors believe that these conditions represent different manifestations of a single ‘functional syndrome’, indicating a global somatization process, particularly since they are also associated with depressive and anxiety disorders. Against this view is the evidence that the majority of primary care patients with one of these disorders do not have a mood or other functional disorder. It also seems that it requires a major stress or the development of a co-morbid psychiatric disorder in order for such sufferers to see their doctor, which might explain why doctors are overly impressed with the associations with both stress and psychiatric disorders. Doctors have historically tended to diagnose ‘stress’ or ‘psychosomatic disorders’ in people with symptoms that they cannot explain. History is full of such disorders being reclassified as research clarifies the pathology. An example is writer's cramp (see p. 857), which most neurologists agree is a dystonia rather
than a neurosis.

The likelihood is that these functional disorders will be reclassified as their causes and pathophysiology are revealed. Functional brain scans and peripheral sensory testing suggest that central nervous system sensitization is found in a number of these disorders, which might help to explain their clustering together.

# Chronic fatigue syndrome

There has probably been more controversy over the existence and causes of chronic fatigue syndrome (CFS) than any other functional somatic syndrome in recent decades. This is reflected in its uncertain classification as *neurasthenia* in the psychiatric classification and as *myalgic encephalomyelitis (ME)* under neurological diseases. There is good evidence for the independent existence of this syndrome, although the diagnosis is made clinically and by exclusion of other fatiguing disorders. Its prevalence is 0.5–2.5% worldwide, mainly depending on how it is defined. It occurs most commonly in women between the ages of 20 and 50 years.

## Clinical features

The cardinal symptom is chronic fatigue made worse by minimal exertion. The fatigue is usually both physical and mental, and is most commonly associated with:

- poor concentration
- impaired registration of memory
- alteration in sleep pattern (either insomnia or hypersomnia)
- muscular pain.

Mood disorders are present in a significant minority of patients, and can cause problems in diagnosis because of the overlap in symptoms. These mood disorders may be secondary, independent (co-morbid) or primary (with a misdiagnosis of CFS).

## Aetiology

Functional disorders often have some aetiological factors in common with each other (*Box 22.14*), as well as more specific aetiologies. For instance, CFS can be triggered by certain infections, such as infectious mononucleosis and viral hepatitis. About 12% of patients who have infectious mononucleosis have CFS 6 months after the onset of infection, yet there is no evidence of persistent infection in these patients. Those fatigue states that clearly do follow on from a viral infection can also be classified as *post-viral fatigue syndromes*.

---

*Box 22.14*
Aetiological factors commonly seen in ‘functional’ disorders

Predisposing

• Perfectionist and introspective personality traits
• Childhood traumas (physical and sexual abuse)
• Similar illnesses in first-degree relatives

Precipitating (triggering)

• Infections (CFS, irritable bowel syndrome)
• Traumatic events (especially accidents)
• Acute painful conditions (‘fibromyalgia’ and other chronic pain syndromes)
• Life events that precipitate changed behaviours (e.g. taking time off sick)
• Incidents where the patient believes others are responsible

Perpetuating (maintaining)

• Inactivity with consequent physiological adaptation (CFS, ‘fibromyalgia’)
• Avoidant behaviours (MCS, CFS)
• Maladaptive illness beliefs (that maintain maladaptive behaviours) (CFS, MCS)
• Excessive dietary restrictions (‘food allergies’)
• Stimulant drugs (e.g. caffeine)
• Sleep disturbance
• Mood disorders
• Somatization disorder
• Unresolved anger or guilt
• Disputed compensation claim

CFS, chronic fatigue syndrome; MCS, multiple chemical sensitivities.

Other aetiological factors are uncertain. Immune and endocrine abnormalities noted in CFS may be secondary to the inactivity or sleep disturbance commonly seen. The role of stress is uncertain, with some indication that the influence of stress is mediated through consequent psychiatric disorders exacerbating fatigue, rather than any direct effect.

Management

The general principles of the management of functional disorders are given in Box 22.15. Specific management of CFS should include a mutually agreed and supervised programme of gradually increasing activity. However, only about a quarter of patients recover after treatment. It is sometimes difficult to persuade a patient to accept what are inappropriately perceived as ‘psychological therapies’ for such a physically manifested condition. Antidepressants do not
work in the absence of a mood disorder or insomnia.

**Box 22.15**

**Management of functional somatic syndromes**

- The first principle is the identification and treatment of maintaining factors (e.g. dysfunctional beliefs and behaviours, mood and sleep disorders).

**Communication**

- Explanation of ill-health, including diagnosis and causes
- Education about management (including self-help leaflets)

**Stopping drugs**

- e.g. Caffeine causing insomnia, analgesics causing dependence

**Rehabilitative therapies**

- Cognitive behaviour therapy (to challenge unhelpful beliefs and change coping strategies)
- Supervised and graded exercise therapy for approximately 3 months (to reduce inactivity and improve fitness)

**Pharmacotherapies**

- Specific antidepressants for mood disorders, analgesia and sleep disturbance (e.g. 10–50 mg of amitriptyline at night for sleep and pain)
- Symptomatic medicines (e.g. appropriate analgesia, taken only when necessary)

**Prognosis**

Prognosis is poor without treatment, with less than 10% of hospital attenders recovered after 1 year. Outcomes are worse with greater severity, increasing age, co-morbid mood disorders, and the conviction that the illness is entirely physical. A large trial showed that about 60% improve with active rehabilitative treatments, such as graded exercise therapy and cognitive behaviour therapy, when added to specialist medical care.

**Fibromyalgia (chronic widespread pain)**

This controversial condition of unknown aetiology overlaps with chronic fatigue syndrome, both conditions causing fatigue and sleep disturbance. Diffuse muscle and joint pains are more constant and severe in chronic widespread pain (CWP); the ‘tender points’, previously thought to be pathognomonic (see pp. 664–665), are now known to be of no diagnostic importance, but this is disputed by some.

CWP occurs most commonly in women aged 40–65 years, and has a prevalence in the
community of 1–11%, varying by definition. There are associations with depressive and anxiety disorders, other functional disorders, physical deconditioning and a possibly characteristic sleep disturbance (see Box 22.14). Functional brain scans suggest that patients perceive greater pain, supporting the idea of abnormal sensory processing that may be related to abnormal regulation of central opioidergic mechanisms.

**Management**

Apart from the general principles set out in Box 22.15, management consists of:
- centrally acting analgesia
- reversal of the sleep disturbance
- a physically orientated rehabilitation programme.

A meta-analysis suggests that tricyclic antidepressants such as amitriptyline and dosulepin that inhibit reuptake of both serotonin (5-hydroxytryptamine, 5-HT) and noradrenaline (norepinephrine) have the greatest effect on sleep, fatigue and pain. The doses used are too low to exert an antidepressant effect and the drugs may work primarily through their hypnotic effects. Other centrally acting anti-nociceptive agents that are also antidepressants include duloxetine and milnacipran (not available in the UK), used at full doses, or anticonvulsants, such as pregabalin and gabapentin.

**Other chronic pain syndromes**

A chronic pain syndrome is a condition of chronic disabling pain for which no medical cause can be found. The psychiatric classification would be a persistent somatoform pain disorder; this is unsatisfactory since the criteria include the stipulation that emotional factors must be the main cause, and it is clinically difficult to be that certain.

The main sites affected in chronic pain syndromes are the head, face, neck, lower back, abdomen, genitalia or all over (fibromyalgia). ‘Functional’ low back pain is the most common ‘physical’ reason for being off sick long-term in the UK (see pp. 655–659). Quite often, a minor abnormality will be found on investigation (such as mild cervical spondylosis on the neck X-ray), but this will not be severe enough to explain the severity of the pain and resultant disability. These pains are often unremitting and respond poorly to analgesics. Sleep disturbance is almost universal and co-morbid psychiatric disorders are commonly found.

**Aetiology**

The perception of pain involves sensory (nociceptive), emotional and cognitive processing in the brain. Functional brain scans suggest that the brain responds abnormally to pain in these conditions, with increased activation in response to chronic pain. This could be related to conditioned physiological and behavioural responses to an initial acute pain. The brain may then adapt to the prolonged stimulus of the pain by changing its central processing.
striatum, thalamus and cingulate gyrus seem to be particularly affected, all of which are involved in the experience of pain in general. Thus, it is possible to start to understand how cognitions, emotions and behaviour might influence the perception of chronic pain (see Box 22.14).

Management

Management involves the same principles as are applied in other functional syndromes (Box 22.15). Since analgesics are rarely effective and can cause long-term harm, patients should be encouraged to reduce their use gradually. It is often helpful to involve the patient’s immediate family or partner, to ensure that the partner is also supported and not unconsciously discouraging progress.

Specific drug treatments are few:

- **Nerve blocks** are not usually effective.
- **Anticonvulsants** include gabapentin and pregabalin (see p. 820).
- **Antidepressants** may be dual-acting drugs (serotonin and noradrenaline reuptake inhibitors, SNRIs) that affect both serotonin and noradrenaline (norepinephrine) reuptake; these demonstrate the greatest efficacy (e.g. duloxetine). Low-dose tricyclic antidepressants that affect both of these neurotransmitters (e.g. amitriptyline, dosulepin) are also effective, although this may be primarily through an improvement in sleep. Serotonergic antidepressants (selective serotonin reuptake inhibitors, SSRIs) tend to be less effective, except in the presence of comorbid anxiety and depressive disorders.

Irritable bowel syndrome

This is one of the most common functional somatic syndromes, affecting some 10–30% of the population worldwide. The clinical features and management of the irritable bowel syndrome (IBS) and the related functional bowel disorders are described in more detail in on pages 430–431. Although the majority of people with IBS do not have a psychiatric disorder, depressive illness should be excluded in those with constipation and a poor appetite. Anxiety disorders should be excluded in individuals with nausea and diarrhoea. Persistent abdominal pain or a feeling of emptiness may occasionally be the presenting symptom of a severe depressive illness, particularly in the elderly, with a nihilistic delusion that the body is empty or dead inside (see pp. 906–913).

Management

This is dealt with in more detail in Box 22.15. Seeing a physician who provides specific education that addresses individual illness beliefs and concerns can provide lasting benefit.

Antidepressants are frequently indicated in moderate to severe cases and the choice of agent will depend on the presence of pain, sleep disturbance and psychiatric comorbidity, as well as
the effect of drug families on bowel transit times (e.g. this is reduced with SSRIs). Milder cases will often respond well to low doses of amitriptyline, although this may be poorly tolerated if constipation is predominant. Non-pharmacological treatments are also effective, and these include:

- cognitive behaviour therapy
- hypnotherapy
- brief interpersonal psychotherapy.

Multiple chemical sensitivity, *Candida* hypersensitivity and food allergies

Some complementary health practitioners, doctors and patients themselves make diagnoses of multiple chemical sensitivities (MCS) (e.g. to foods, smoking, perfumes, petrol), *Candida* hypersensitivity and allergies (to food, tap water and even electricity). Symptoms and syndromes attributed to these putative disorders are numerous and variable, and include all the functional disorders, *mood disorders* and *arthritis*. Scientific support for the existence of these disorders is weak, particularly when double-blind methodologies have been used.

*Type 1 hypersensitivities* to foods such as nuts certainly exist, although they are fortunately uncommon (approximately 3/1000) (see p. 142). Direct *specific food intolerances* also occur (e.g. chocolate with migraine, caffeine with IBS).

*Candidiasis* can occur in the gastrointestinal tract in immunocompromised individuals, such as those with the acquired immunodeficiency syndrome (AIDS). Vaginal candidiasis can follow antibiotic treatment in otherwise healthy women. A double-blind and controlled study of nystatin in women diagnosed as having candidiasis hypersensitivity syndrome showed that vaginitis was the only condition relieved more by nystatin than placebo. There is little evidence of *Candida* having a systemic role in other symptoms. In spite of this evidence, the patient is often convinced of the legitimacy and usefulness of these diagnoses and their treatments.

Aetiology

Surveys of patients diagnosed with MCS or food allergies have shown high rates of current and previous mood and anxiety disorders (see *Box 22.14*). Eating disorders (see pp. 927–928) should be excluded in people with food intolerances. Some patients taking very-low-carbohydrate diets as putative treatments may develop reactive hypoglycaemia after a high carbohydrate meal, which they then interpret as a food allergy.

Classical conditioning can produce intolerance to foods and smells in healthy people and this may be a causative mechanism in some individuals with intolerances. This supports the existence of these intolerance conditions, but suggests they may be conditioned responses with attendant physiological consequences. This might explain why double-blinding sometimes abolishes the reaction to the stimulus.
Management

The general principles in **Box 22.15** apply. If one assumes a phobic or conditioned response is responsible, graded exposure (systematic desensitization) to the conditioned stimulus may be worthwhile. Preliminary studies do suggest that this approach may successfully treat such intolerances, in the context of cognitive behaviour therapy.

Premenstrual syndrome

The premenstrual syndrome (PMS) consists of both physical and psychological symptoms that regularly occur during the premenstrual phase and substantially diminish or disappear soon after the period starts.

- **Physical symptoms** include headache, fatigue, breast tenderness, abdominal distension and fluid retention.
- **Psychological symptoms** can include irritability, emotional lability or low mood, and tension.

The **premenstrual (late luteal) dysphoric disorder (PMDD)** is a severe form of PMS with marked mood swings, irritability, depression and anxiety accompanying the physical symptoms. Women who generally suffer from mood disorders may be more prone to experience this. The prevalence of PMS does not vary between cultures and is reported by the majority (75%) of women at some time in their lives. Severely disabling PMS (PMDD) occurs in about 3–8% of women.

The cause of PMS remains unclear, although exacerbating factors include some of those outlined in **Box 22.14**. Abnormalities of reproductive hormone receptors may also play a role.

Management

The general principles in **Box 22.15** apply. Treatments with vitamin B₆ (see p. 200), diuretics, progesterone, oral contraceptives, oil of evening primrose, and oestrogen implants or patches (balanced by cyclical norethisterone) remain empirical. Psychotherapies aimed at enhancing the patient's coping skills can reduce disability. Two trials suggest that graded exercise therapy improves symptoms. Several studies have demonstrated that SSRIs (see p. 910) are effective treatments for PMDD.

The menopause

The clinical features and management of the menopause are described on pages 1296–1297. A prospective study has shown that there is no increased incidence of depressive disorders at this time. Such a significant bodily change, sometimes occurring at the same time as children leave home, is naturally accompanied by an emotional adjustment that does not normally amount to a pathological state.
Somatoform Disorders

As explained in the section on functional disorders (see pp. 899–902), the classification of somatoform disorders is unsatisfactory because of the uncertain nature and aetiology of these disorders. However, there are certain disorders, beyond those described in ‘functional somatic syndromes’, that present frequently and coherently enough to be usefully recognized.

Somatization disorder

One in 10 patients presenting with a functional disorder will fulfil the criteria of a chronic somatization disorder. The condition is composed of multiple, recurrent, medically unexplained physical symptoms, usually starting early in adult life. Symptoms may be referred to almost any part or bodily system. The patient has often had multiple medical opinions and repeated negative investigations. Medical reassurance that the symptoms do not have a demonstrable physical cause fails to reassure the patient, who will continue to ‘doctor-shop’. The patient is usually reluctant to accept that psychological and/or social factors may play a role. Abnormal illness behaviour is evident and patients can be attention-seeking and dependent on doctors.

The aetiology is unknown, but both mood and personality disorders are often also present. Somatization disorder is frequently associated with dependence upon or overuse of prescribed medication, usually sedatives and analgesics. There is often a history of significant childhood traumas, or chronic ill-health in the child or parent, which may play an aetiological role or help to explain difficult therapeutic relationships (see Box 22.14). The condition is probably the somatic presentation of psychological distress, although iatrogenic damage (from postoperative and drug-related problems) soon complicates the clinical picture. The course of the disorder is chronic and disabling, with longstanding family, marital and/or occupational problems.
Hypochondriasis

The conspicuous feature is a preoccupation with an assumed serious disease and its consequences. Patients commonly believe that they suffer from cancer, AIDS or some other serious condition. Characteristically, such patients repeatedly request investigations either to prove they are ill or to reassure themselves that they are well. Such reassurance rarely lasts long before another cycle of worry and requests begins. The symptom of hypochondriasis may be secondary to or associated with a variety of psychiatric disorders, particularly depressive and anxiety disorders. Occasionally, the hypochondriasis is delusional, secondary to schizophrenia or a depressive psychosis. Hypochondriasis may coexist with physical disease but the diagnostic point is that the patient’s concern is disproportionate and unjustified.

Management of somatoform disorders

The principles outlined in Box 22.15 apply to these disorders. Since they have a poor prognosis, the aim is to minimize disability. Furthermore, it is vital that all members of staff and close family members adopt the same approach to the patient’s problems. The patients often, consciously or unconsciously, split both medical staff and family members into ‘good’ and ‘bad’ (or caring and uncaring) people, as a way of projecting their distress.

Patients appreciate a discussion and explanation of their symptoms. You should sensitively explore possible psychological and social difficulties, if possible by asking about or demonstrating links between symptoms and stresses. Such discussion usually gives information that can be used to formulate an agreed plan of management. A contract of mutually agreed care, involving the appropriate professionals (general practitioner, and a choice of psychotherapist, health psychologist, complementary health professional, physician or psychiatrist), with agreed frequency of visits and a review date, can be helpful in managing the condition. Management also includes cessation of reassurance that no serious disease has been uncovered, since this simply reinforces dependence on the doctor. Repeated investigations should be discouraged. Cognitive behaviour therapy has been shown to provide effective rehabilitation in significant numbers of patients suffering from a somatoform disorder.

Dissociative/Conversion Disorders

A dissociative disorder is a condition in which there is a profound loss of awareness or cognitive ability without medical explanation. The term dissociative indicates the disintegration of different mental activities, and covers such phenomena as amnesia, fugues and pseudoseizures (non-epileptic attacks).

Conversion disorder occurs when an unresolved conflict is converted into, usually symbolic, physical symptoms as a defence against it. Such symptoms commonly include paralysis, abnormal movements, sensory loss, aphony, disorders of gait and pseudocyesis (false pregnancy). The lifetime prevalence has been estimated at 3–6 per 1000 in women, with a lower prevalence in men. Most cases begin before the age of 35 years. Conversion is unusual
in the elderly.

### Clinical features

The various symptoms are usually divided into dissociative and conversion categories (*Box 22.16*). Dissociative disorders have the following three characteristics that are necessary in order to make the diagnosis:

- They occur in the absence of physical pathology that would fully explain the symptoms.
- They are produced unconsciously.
- Symptoms are not caused by over-activity of the sympathetic nervous system.

#### Box 22.16

**Common dissociative/conversion symptoms**

**Dissociative (mental)**

- Amnesia
- Fugue
- Pseudodementia
- Dissociative identity disorder

**Conversion (physical)**

- Paralysis
- Disorders of gait
- Tremor
- Aphonia
- Mutism
- Sensory symptoms
- Globus
- Pseudoseizures
- Blindness

Other characteristics include:

- Symptoms and signs often reflect a patient's ideas about illness.
- There is usually abnormal illness behaviour, with exaggeration of disability.
- There may have been significant childhood traumas.
- **Primary gain** is the immediate relief from the emotional conflict.
• **Secondary gain** refers to the social advantage gained by the patient by being ill and disabled (sympathy of family and friends, time off work, disability pension).

• Physical disease is, not uncommonly, also present (e.g. pseudoseizures are more common in someone with epilepsy).

**Dissociative amnesia** commences suddenly. Patients are unable to recall long periods of their lives and may even deny any knowledge of their previous life or personal identity. In a **dissociative fugue**, patients not only lose their memory but also wander away from their usual surroundings; when found, they have no memory of their whereabouts during this wandering. The differential diagnosis of a fugue state includes post-epileptic automatism, depressive illness and alcohol misuse.

**Multiple personality disorder** is rare but dramatic, and may be triggered by suggestion on the part of a psychotherapist. There are rapid alterations between two or more ‘personalities’ in the same person, each of which is repressed and dissociated from the other ‘personalities’. A differential diagnosis is rapid-cycling manic depressive disorder which would explain sudden apparent changes in personality.

### Differential diagnosis

Dissociation is usually a stable and reliable diagnosis over time, although high rates of co-morbid mood and personality disorders are found in chronic sufferers. Particular care should be taken to make the diagnosis on positive grounds, and not simply on the basis of an absence of a medical diagnosis. Care should also be taken to exclude or treat co-morbid psychiatric disorders.

### Aetiology

Functional brain scans differ between healthy controls feigning a motor abnormality and people with a similar conversion motor symptom, which suggests that dissociation involves different areas of the brain from simulation (*Fig. 22.1*). Functional brain scanning of a patient with conversion paralysis has shown that recalling a past trauma not only activated the emotional areas, such as the amygdala, but also reduced motor cortex activity. This would suggest that conversion involves a disinhibition of voluntary will at an unconscious level, so that the patient can no longer *will* something to happen.
The psychoanalytical theory of dissociation is that it is the result of emotionally charged memories that are repressed into the unconscious at some point in the past. Symptoms are explained as the combined effects of repression and the symbolic conversion of this emotional energy into physical symptoms. This hypothesis is difficult to test, although there is some evidence that people with dissociative disorders are more likely to have suffered childhood abuse, particularly when the abuse was both sexual and physical, and started early in childhood. Caution should be taken with such a history obtained by therapies that ‘recover’ childhood memories that were previously completely unknown to the patient.

### Management

The treatment of dissociation is similar to the treatment of somatoform disorders in general, outlined above and in Box 22.15. The first task is to engage the patient and their family with an explanation of the illness that makes sense to them, is acceptable, and leads to the appropriate management. An invented example of a suitable explanation is given in Box 22.17. Such an explanation would be modified by mutual discussion until an agreed understanding was achieved, which would serve as a working model for the illness. Provision of a rehabilitation programme that addresses both the physical and the psychological needs and problems of the patient would then be planned.

- **A graded and mutually agreed plan for a return to normal function** can usually be led by the appropriate therapist (e.g. speech therapist for dysphonia, physiotherapist for paralysis).
- **A psychotherapeutic assessment** should be made at the same time, in order to determine the
appropriate form of psychotherapy. For instance, couple therapy will address a significant relationship difficulty; individual psychotherapy could ease an unresolved conflict from childhood (see management of post-traumatic stress disorder, p. 918).

<table>
<thead>
<tr>
<th>Box 22.17</th>

<tbody>
<tr>
<td><strong>An example of an explanation that might be given for a dissociative disorder</strong></td>
</tr>
</tbody>
</table>

‘You told me about the tremendous shock you felt when your mother suddenly died. This was particularly the case since you hadn’t spoken to her for so long beforehand, after that big disagreement with her over your wedding to John. You weren’t able to say good-bye before she died. Your brain was overloaded with grief, guilt and anger all at once. I wonder whether that is why you aren’t able to speak now. I wonder whether it’s difficult to think of anything to say that would make things right, particularly since you can’t speak with your mother now.’

**Abreaction** brought about by **hypnosis** or by intravenous injections of small amounts of midazolam may produce a dramatic, if sometimes short-lived, recovery. In the abreactive state, the patient is encouraged to relive the stressful events that provoked the disorder and to express the accompanying emotions: that is, to abreact. Such an approach has been useful in the treatment of acute dissociative states in wartime but appears to be of less value in civilian life. It should only be contemplated in the presence of an anaesthetist with suitable resuscitation equipment to hand.

**Hypnotherapy** is psychotherapy applied while the patient is in a hypnotic trance, the idea being that therapy is more easily possible because the patient is relaxed and not using repression. This may allow the therapist access to the previously unconscious emotional conflicts or memories. There are no published trials of this technique in dissociation, which Freud gave up as unsuccessful in order to found psychoanalysis, but some hypnotherapists claim good results. Care should be taken to avoid a catastrophic emotional reaction when the patient is suddenly faced with the previously repressed memories.

**Prognosis**

Most cases of recent onset recover quickly with treatment, which is why a positive diagnosis should be made early. Those cases that last longer than a year are likely to persist, with entrenched abnormal illness behaviour patterns. One study found that 83% were still unwell at 12 years' follow-up.

**Sleep Difficulties**

Sleep is divided into rapid eye movement (REM) and non-REM sleep:
As drowsiness begins, the alpha rhythm on an electroencephalogram (EEG) disappears and is replaced by deepening slow-wave activity (non-REM).

After 60–90 minutes, this slow-wave pattern is replaced by low-amplitude waves, on which are superimposed rapid eye movements lasting a few minutes.

This cycle is repeated during the duration of sleep, with the REM periods becoming longer and the slow-wave periods shorter and less deep (Fig. 22.2).

**REM sleep** is accompanied by dreaming and physiological arousal. **Slow-wave sleep** is associated with release of anabolic hormones and cytokines, with an increased cellular mitotic rate. It helps to maintain host defences, metabolism and repair of cells. For this reason, slow-wave sleep is increased in those conditions where growth or conservation is required (e.g. adolescence, pregnancy, thyrotoxicosis).

**Insomnia**

Insomnia is difficulty in sleeping; a third of adults complain of insomnia, and in a third of these it can be severe.

**Primary sleep disorders**

These include sleep apnoea (see pp. 1085–1086), narcolepsy (pp. 851–852), the restless legs syndrome (Ekbom syndrome; see p. 852) and the related periodic leg movement disorder, in which the legs (and sometimes the arms) jerk while asleep.

**Delayed sleep phase syndrome**

This occurs when the circadian pattern of sleep is delayed, so that the patient sleeps from the early hours until midday or later; it is most common in young people. Night terrors, sleep-
walking and sleep-talking are non-REM phenomena, called parasomnias; they are most commonly found in children, but can recur in adults when under stress or suffering from a mood disorder. Sleep disorders secondary to another medical diagnosis will not be discussed here.

**Psychophysiological insomnia**

This is commonly secondary to functional, mood and substance misuse disorders, and is frequently present in individuals under stress (Box 22.18). It can often be triggered by one of these factors, but then becomes a habit on its own, driven by anticipation of insomnia and daytime naps.

---

**Box 22.18**

**Common causes of insomnia**

**Primary sleep disorders**

- Periodic leg movements
- Restless legs syndrome

**Secondary sleep disorders**

- Psychiatric disorders:
  - Mood disorders (mania, depressive and anxiety disorders)
  - Delirium and dementia
- Drug use or misuse:
  - Addictive drug withdrawal (alcohol, benzodiazepines)
  - Stimulant drugs (caffeine, amphetamines)
  - Prescribed drugs (steroids, dopamine agonists)
- Physical conditions:
  - Pain (classically with carpal tunnel syndrome)
  - Nocturia (e.g. from prostatism)
  - Malnutrition

---

Insomnia causes daytime sleepiness and fatigue, with consequences such as road traffic accidents. Assessment should pay particular attention to mood, life difficulties and drug intake (especially alcohol, nicotine and caffeine), and the timing of the insomnia should be ascertained:

- **Initial insomnia** (trouble going off to sleep) is common in mania, anxiety, depressive disorders and substance misuse.
- **Middle insomnia** (waking up in the middle of the night) occurs with medical conditions such
as sleep apnoea and prostatism.

- **Late insomnia** (early morning waking) is caused by depressive illness and malnutrition (anorexia nervosa).

Habitual alcohol consumption should be carefully estimated, since even a small excess can be a potent cause of insomnia, as well as recent withdrawal. Caffeine is perhaps the most commonly taken drug in the UK, and its effects are easily under-estimated. Six cups of coffee a day are likely to cause insomnia in the average healthy adult. Caffeine is found not only in tea and coffee, but also in chocolate, cola drinks and some analgesics. Prescription drugs that can either disturb sleep or cause vivid dreams include most appetite suppressants, glucocorticoids, dopamine agonists, lipid-soluble beta-blockers (e.g. propranolol) and certain psychotropic drugs (especially when first prescribed, e.g. fluoxetine, reboxetine, risperidone).

### Hypersomnia

This is not uncommon in adolescents with depressive illness. It occurs in narcolepsy, and may temporarily follow infections such as infectious mononucleosis.

### Management of insomnia

This is determined by diagnosis. Where none is immediately apparent, it is worth educating the patient about sleep hygiene. In addition:

- **Simple measures**, such as decreasing alcohol intake, having supper earlier, exercising daily, having a hot bath prior to going to bed and establishing a routine of going to bed at the same time, should all be tried.

- **Relaxation techniques and cognitive behaviour therapy** have a role in those with intractable insomnia.

- **Short-half-life benzodiazepines** can be useful for acute insomnia, but should not be used for more than 2 weeks continuously to avoid dependence.

- **Non-benzodiazepine hypnotics** (zaleplon, zopiclone, zolpidem) act at γ-aminobutyric acid type A (GABA-A) receptors and occasional dependence has been reported.

- **Certain antihistamines** (e.g. diphenhydramine and promethazine) and **antidepressants** (e.g. amitriptyline, trimipramine, trazodone, mirtazapine) are not addictive and can be used as hypnotics in low dose, with the added advantage of improving slow-wave sleep. The most common adverse effects are morning sedation and weight gain.

### Further reading

Mood (Affective) Disorders

The central feature of these disorders is an abnormality of mood. Mood is best described in terms of a continuum ranging from severe depression at one extreme to severe mania at the other, with the normal, stable mood in the middle. Mood disorders are divided into unipolar and bipolar affective disorders.

Unipolar affective disorders

Patients suffer from depressive episodes alone, although they are commonly recurrent.

Bipolar affective disorder

Patients suffer bouts of both depression and mania. Although mania can rarely occur by itself without depressive mood swings (thus being ‘unipolar’), it is far more commonly found in association with depressive swings, even if sometimes it takes several years for the first depressive illness to appear.

- **Bipolar I** disorder is defined as one or more manic or mixed (signs of mania and depression) episodes.
- **Bipolar II** is defined as a depressive episode with at least one episode of hypomania (this is shorter-lived than mania and is not accompanied by psychotic symptoms). Hypomania is noticeably abnormal but does not result in functional impairment or hospitalization.
- **Bipolar III** disorder is less well established and describes depressive episodes, with hypomania occurring only when taking an antidepressant.

About 10% of patients who have depressive illness are eventually found to have a bipolar illness.

Depressive disorders

Depressive disorders or ‘episodes’ are classified by the ICD-10 as mild, moderate or severe, with or without somatic symptoms. Severe depressive episodes are divided according to the presence or absence of psychotic symptoms.

Clinical features of depressive disorder

Whereas everyone will, at some time or other, feel ‘fed up’ or ‘down in the dumps’, it is when such symptoms become qualitatively different and pervasive or interfere with normal functioning that a depressive illness has occurred. Depressive disorder, clinical or ‘major’ depression, is characterized by disturbances of mood, speech, energy and ideas (Box 22.19). Patients often describe their symptoms in physical terms. Marked fatigue and headache are the two most common physical symptoms in depressive illness and may be the first symptoms to appear. Patients describe the world as looking grey, and themselves as lacking a zest for living, and being devoid of pleasure and interest in life (anhedonia). Anxiety and panic attacks are
common; secondary obsessional and phobic symptoms may emerge. Symptoms should last for at least 2 weeks and cause significant incapacity (e.g. trouble working or relating to others) in order to be considered an illness.

</table>

In the more severe forms, diurnal variation in mood can occur, patients feeling worse in the morning, after waking in the early hours with apprehension. Suicidal ideas are more frequent, intrusive and prolonged. Delusions of guilt, persecution and bodily disease are not uncommon, along with second-person auditory hallucinations insulting the patient or suggesting suicide. In severe depressive illness, particularly in the elderly, concentration and memory can be so badly affected that the patient appears to have dementia (pseudodementia). Delusions of poverty and non-existence (nihilism) occur particularly in this age group. Suicide is a real risk; lifetime risk is approximately 6% in all patients, but higher in those with depressive illness severe enough to warrant admission to hospital, those with bipolar affective disorder and those with co-morbid substance misuse. Screening questions for depressive illness are shown in **Box 22.20**.

**Box 22.20**

**Screening questions for depressive illness**

- During the last month, have you often been bothered by feeling down, depressed or hopeless?
- During the last month, have you often been bothered by having little interest or pleasure in doing things?
If the answer to one or both of these questions is ‘yes’, assess further for depressive illness.

**Epidemiology**

About a third of the population will feel unhappy at any one time but this is not the same as depressive illness; the middle-aged feel least happy compared to the young and elderly. The point prevalence of depressive illness is 5% in the community, with a further 3% having dysthymia (see below). It is more common in women, but there is no increase with age, and no difference by ethnic group or socioeconomic class (apart from a clear association with unemployment). Married and never-married people have similar prevalence rates, with separated and divorced people having two to three times the prevalence. Depressive illnesses are becoming more common.

Depressive illnesses are more frequently found in the presence of:

- physical diseases, particularly if chronic, stigmatizing or painful
- excessive and chronic alcohol use
- social stresses, particularly loss events, such as separation, redundancy and bereavement
- interpersonal difficulties with those close to the patient, especially when socially humiliated
- lack of social support, with no confiding relationship.

Depressed people with another physical disorder view themselves as more sick and disabled, visit their doctors almost four times as often as the non-depressed physically ill, stay in hospital longer, adhere less to medical advice and medication, and undergo more medical and surgical procedures. Depressive illness may be associated with increased mortality (excluding suicide) in people with physical illness, such as myocardial infarct.

**Dysthymia**

Dysthymia is a mild or moderate depressive illness that lasts intermittently for 2 years or more and is characterized by tiredness and low mood, lack of pleasure, low self-esteem and feelings of discouragement. The mood relapses and remits, with several weeks of feeling well, soon followed by longer periods of being unwell. It can be punctuated by depressive episodes of greater severity, so-called ‘double depression’.

**Seasonal affective disorder**

Seasonal affective disorder is characterized by recurrent episodes of depressive illness occurring during the winter months in the northern hemisphere. Symptoms are similar to those found with atypical depressive illness, in that patients complain of hypersomnia, increased appetite (with carbohydrate craving) and weight gain, with profound fatigue. Such patients have a higher prevalence of bipolar affective disorder, and some doctors are uncertain whether
the condition is different from normal depressive illness, with the accentuation of mood that naturally occurs by season. However, there is evidence that seasonal depressive illness can be successfully treated with bright light therapy given in the early morning, which causes a phase advance in the circadian rhythm of melatonin. In contrast, the same treatment given in the early evening, with consequent phase delay of melatonin secretion, is less antidepressant. Selective serotonin reuptake inhibitors (SSRIs) are alternative treatments.

## Puerperal affective disorders

Affective illnesses and distress are common in women soon after they have given birth.

‘Maternity blues’ describe the brief episodes of emotional lability, irritability and tearfulness that occur in about 50% of women 2–3 days postpartum and resolve spontaneously in a few days.

Postpartum psychosis occurs once in every 500–1000 births. Over 80% of cases are ‘affective’ in type and the onset is usually within the first 2 weeks following delivery. In addition to the classical features of an affective psychosis, disorientation and confusion are often noted. Severely depressed patients may have delusional ideas that the child is deformed, evil or otherwise affected in some way, and such false ideas may lead to either attempts to kill the child or suicide. The response to speedy treatment is generally good. The recurrence rate for a psychosis in a subsequent puerperium is 20–30%.

Non-psychotic postnatal depressive disorders occur during the first postpartum year in 10% of mothers, especially in the first 3 months, with a higher prevalence in developing countries. Risk factors are first pregnancy, poor relationship with the partner, ambivalence about the pregnancy, and emotional personality traits. The Edinburgh Postnatal Depression Scale (EPDS) is a ten-item questionnaire that can be used as an effective screening tool. Depressive illness after childbirth is clinically similar to other depressive illnesses, but lack of emotional bonding with the baby is common.

## Differential diagnosis of depressive disorders

The differential diagnoses of depressive illness are shown in **Box 22.21**. Other psychiatric disorders are the most common misdiagnoses. Some 90% of patients presenting with a depressive illness while misusing alcohol will no longer be depressed 2 weeks after their last drink.

### Box 22.21

**Common differential diagnoses of depressive illness**

**Other psychiatric disorders**

- Alcohol misuse
• Amfetamine (and derivatives) misuse and withdrawal
• Borderline personality disorder
• Dementia
• Delirium
• Schizophrenia
• Normal and pathological grief

**Organic (secondary) affective illness**

*Physical causes that are both necessary and sufficient as a cause*
• Cushing syndrome
• Thyroid disease (although sometimes depression persists after treatment)
• Hyperparathyroidism
• Corticosteroid treatment
• Brain tumour (rarely without other neurological signs)

Pathological (abnormal) grief and normal grief are described on page 918. Pathological grief is closely associated with depressive illness.

**Investigation of depressive disorders**

A corroborative history can be valuable in helping to exclude differential diagnoses such as alcohol misuse, and in elucidating maintaining factors such as a poor relationship with a partner. Investigations should be guided by the history and examination but those commonly performed are:

• full blood count, urea and electrolytes, serum creatinine, estimated glomerular filtration rate (eGFR)
• liver biochemistry (including glutamyl transpeptidase)
• serum calcium
• erythrocyte sedimentation rate/C-reactive protein (ESR/CRP)
• thyroid function tests (free T₄, thyroid-stimulating hormone (TSH))

Other tests include:
• serum cortisol (morning and evening)
• antinuclear antibody
• chest X-ray
• EEG or brain scan, as indicated

**Aetiology of unipolar depressive disorders**
The aetiology of unipolar depressive disorders is multifactorial and is composed of a mixture of genetic and environmental factors.

Genetic factors
Unipolar depression is probably polygenic but no linkage has been firmly identified. The risk of unipolar depression in a first-degree relative of a patient is approximately three times that in the non-affected. The concordance of unipolar depression in monozygotic twins is between 30% and 60%, increasing with more recurrent illnesses. Polymorphisms that increase the risk of depression involve monoamines and their receptors, but studies are inconclusive. Recent research suggests a possible role for epigenetic changes. The issue is complicated by the genetic influence on sleep habits, emotional personality and even life events, which are all involved in the genesis of depressive illness.

Biochemical changes

Monoamines
The monoamine deficiency theory of depressive illness is supported by the efficacy of monoamine reuptake inhibitors and the depressive effect of dietary tryptophan depletion, but the timing of changes in neurotransmitter metabolism and clinical improvement is discrepant.

Neuroimaging studies have revealed a raised density of monoamine oxidase A (MAO-A) receptors. Depression is proposed to be related to a chronic and ongoing depletion of these neurotransmitters as a result of this enzyme's increased activity and its interaction with region-specific monoamine transporter densities. The relative transporter densities in particular regions and how they are affected by the global reduction in monoamine levels are then thought to determine the particular expression of the depressive illness and the predominance of particular symptoms.

Neuroendocrine tests also suggest that the serotonin neurotransmitter system is downregulated. 5-HT₁a and 5-HT₂ receptor subtypes are thought most likely to be involved. Receptor-labelled functional brain scans suggest that dopamine under-activity is related to psychomotor retardation.

Hypothalamo–pituitary–adrenal axis
The administration of exogenous steroids is associated with the onset of depressive symptoms and people with Cushing syndrome often demonstrate depressive episodes. Acute stress, whether physical or psychological, is associated with a rise in serum glucocorticoids. Severe depressive episodes have been linked with hypercortisolaemia (of note is the fact that cortisol is low in ‘atypical’ depression), but whether this is aetiological or secondary to sleep disturbance and weight loss is unknown. This cortisol dysregulation has been associated with impaired glucocorticoid negative feedback, adrenal hyper-responsiveness to adrenocorticotropic hormone (ACTH) and hypersecretion of cortisol-releasing hormone (CRH).
Exposure to the high levels of cortisol is thought to have a direct effect on neuronal plasticity and to lower resistance to neuronal damage. The hippocampus seems especially susceptible, resulting in atrophic changes. This, in turn, has further deleterious effects on wider neuroendocrine function, leading to a self-perpetuating dysregulation that may serve to maintain and/or worsen the illness.

The interplay at this level becomes more complicated, with reduced central and peripheral glucocorticoid receptor sensitivity, hypothalamo–pituitary–adrenal (HPA) axis upregulation, and the release of pro-inflammatory cytokines that may, in turn, explain changes in mood, fatigue, appetite, sensitivity to pain and reduced libido (note that depression is a side-effect of interferon treatment). Additionally, at the cellular level, this affects monoamine transport and causes neuronal apoptosis and dysfunction of glial cells, normally responsible for maintaining neuronal homeostasis.

**Brain-derived neurotrophic factor**

Healthy interactions between neurones and glial cells are maintained by brain-derived neurotrophic factor (BDNF), which is found in its greatest concentration in the hippocampus and cerebral cortex. It promotes cell growth and long-term potentiation (the enhancement of synchronous firing between two neurones). Pro-BDNF, its precursor, promotes the reduction of dendritic spines and apoptosis. BDNF is then involved in the growth and activity of neural networks.

- Animal studies show BDNF is reduced under stressful conditions.
- Adult humans with untreated depressive illness have lower serum concentrations of BDNF when compared with both healthy controls and those that have received antidepressant treatment.
- Low levels normalize with antidepressant treatment.

BDNF therefore has potential as an objective marker of depression and its response to treatment, as well as being a potential target for treatment of the disorder itself.

**Neuroimaging changes**

The use of functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) has revealed a number of abnormalities in the brains of people with major depression. These changes are non-specific but involve regions that are associated with both the emotional and the cognitive abnormalities seen in depression. Increased brain ventricle volume, and orbitofrontal, dorsolateral frontal and anterior cingulate cortex altered activation have been implicated. The hippocampus is smaller in several stress-related neuropsychiatric disorders, including recurrent depression.

**Sleep**

A reduced time between onset of sleep and REM sleep (shortened REM latency), and reduced slow-wave sleep both occur in depressive illness. These abnormalities persist in some
patients when they are not depressed. Families with several sufferers of depressive illness can share these traits, suggesting that sleep patterns may be inherited and may predispose to depression.

**Childhood traumas and personality**

Physical, sexual and emotional abuse and neglect in childhood all predispose adults to depressive illness but the effect is non-specific. Both ‘neurotic’ (emotional) and perfectionist personality traits are risks for depressive illness, and these may be determined as much by genetic factors as childhood environment.

**Social factors**

Some 30% of women will develop a depressive illness after a severe life event or difficulty, such as a divorce, and this is compounded by low self-esteem and a lack of a confiding relationship. Unemployment is a significant risk factor in men.

**An integrated model of aetiology**

Stress is more likely to trigger depressive illness in a person predisposed by lack of social support and/or certain personality traits. Stress, in turn, triggers various brain changes in both stress hormones (such as the release of CRH) and neurotransmitters (e.g. serotonin), which are both known to be altered in depressive illness. This suggests an integrated biopsychosocial model of depressive illness and challenges dualistic ideas that depressive illnesses are either psychological or physical. Depressive illnesses involve both the mind and the body, which are themselves indivisible.

**Management of depressive illness**

The patient needs to know the diagnosis to provide understanding and rationalization of the overwhelming distress inherent in depressive illness. Knowing that self-loathing, guilt and suicidal thoughts are caused by the illness may have an ‘antidepressant’ effect. The further treatment of depressive disorders involves physical, psychological and social interventions *(Box 22.22)*.

**Box 22.22**

**Management of depressive illness**

**Physical**

- Cessation of depressing drugs (alcohol, steroids)
- Regular exercise (good for mild to moderate depression)
- Antidepressants (choice determined by adverse effects, co-morbid illnesses and interactions)
• Adjunctive drugs (e.g. lithium; if no response to two different antidepressants)
• Electroconvulsive therapy (ECT; if depression is life-threatening or non-responsive)

Psychological
• Education and regular follow-up by same professional
• Cognitive behaviour therapy (CBT)
• Other indicated psychotherapies (couple, family, interpersonal)

Social
• Financial: eligible benefits, debt counselling
• Employment: acquiring or changing a job or career
• Housing: adequate, secure tenancy, safe, social neighbours
• Young children: child-care support

Treatments combined
• The most effective treatment is a mixture of CBT and an antidepressant

Patients who are actively suicidal or severely depressed (with or without psychotic symptoms) should be admitted to hospital. Admission is necessary for perhaps 1 in 1000 people with clinical depression in primary care. This provides the patient with a break from self-care, and allows support, listening, observation, the close monitoring of treatments and the prevention of suicide. The pitfall of not treating a depressive illness just because it seems an ‘understandable’ reaction to serious illness or difficult circumstances should be avoided. This is particularly likely to happen if the patient is elderly, or severely or even terminally ill.

Psychological treatments
There is good evidence that mild to moderate depressive episodes respond well to ‘talking therapies’.

Cognitive behaviour therapy
Beck developed cognitive behaviour therapy (CBT) to reverse the negative cognitive triad with which patients regard themselves, their situation and their futures. It involves the identification of the negative automatic thoughts that maintain the negative perceptions that feed depression. These commonly include catastrophizing (e.g. making a ‘mountain out of a molehill’), over-generalizing (e.g. ‘I failed an exam; therefore I am a failure as a person’) and categorical (‘all-or-none’) thinking (e.g. ‘My work is either perfect or abysmal’). CBT then involves identifying the links between these thoughts, consequent behaviour and feeling low, and then testing their logic. This is done by looking at the evidence either in the therapy sessions (e.g. Q: ‘Did you pass the other exams you took?’; A: ‘Yes; I guess I did’) or in behavioural ‘experiments’ (e.g. showing the ‘abysmal’ work to a colleague and asking their
There is good evidence that individual CBT is as effective as antidepressant drugs for mild and moderate depressive illness, and should be offered as first-choice treatment. It is also effective in preventing a relapse of clinical depression after therapy has ceased. Individual CBT is more effective than group-delivered therapy, and computer-delivered CBT programs are also helpful when used to supplement therapist involvement. Third-wave CBT therapies, such as mindfulness-based CBT, centred on the use of meditation, can prevent recurrence. Acceptance and commitment therapy (accepting the things that cannot be changed, and committing oneself to things that can be) shows promise.

**Interpersonal psychotherapy**

This psychotherapy is probably as effective as both antidepressants and CBT in mild and moderate clinical depression. The therapist focuses on those interpersonal relationships involved in, or affected by, the patient's illness (especially relationship changes or deficiencies), using problem-solving techniques to help the individual to find solutions.

**Other psychotherapies**

*Couple therapy* is particularly effective when a patient is in a problematic relationship that may be contributing to the depressive illness; both the patient and partner attend therapy.

*Family therapy* is effective not only to treat a family with problems, but also to assist the family to help a patient get better. It may involve understanding one family member's ‘depression’ as a systemic ‘solution’ for a wider problem within the family.

**Physical treatments**

*Exercise and other self-help*

There is good evidence that regular exercise, particularly involving other people, can help relieve depressive illness of mild severity. The benefit is independent of a physical training effect. The role of exercise is unclear but recent evidence suggests that kynurenine is prevented from crossing the blood–brain barrier, thereby reducing neuroactive metabolites. Other self-help and psycho-educational advice (e.g. reduction of alcohol consumption, regular meals and sleep–wake cycle) may be helpful, particularly if supported by bibliotherapy.

**Use of drugs in the treatment of clinical depression**

Moderate and severe episodes of depression can be effectively treated using medication. Antidepressants are designed to provide an acute increase in monoamine activity. They do this through either prevention of reuptake or enzymatic degradation. This occurs acutely and, although an equally rapid *depletion* of monoamines has an acute mood-lowering effect, the mood-elevating benefits of these drugs require weeks of continuous administration. The benefits are therefore unlikely to be due to this mechanism alone.

The effects of chronic administration of monoamine reuptake inhibitors are various.
Examples include an increase in the synthesis of binding proteins necessary for serotonin receptor activity and increases in cyclic adenine monophosphate activation, which, in turn, increases BDNF synthesis, enhances glucocorticoid receptor sensitivity and inhibits cytokine signalling. These effects may be secondary to the acute restoration of monoamine levels but rely upon transcriptional and translational changes that alter neuronal plasticity. It is this protein synthesis-dependent process that is thought to be the final pathway responsible for the clinical effect of the drugs.

As the neurobiology for depressive illness becomes clearer, so too are novel approaches to its treatment; some of the novel targets under active investigation are listed in **Box 22.23**.

---

**Box 22.23**

**Potential targets for novel antidepressant agents**

- Brain-derived neurotrophic factor (BDNF)
- Tumour necrosis factor-alpha (TNF-α)
- Interleukin-1 beta (IL-1β)
- Glucocorticoid receptors
- Corticotrophin-releasing hormone
- Melatonin-concentrating hormone
- Alpha-melanocyte stimulating hormone
- Ghrelin
- Leptin
- Orexins
- Neuropeptide Y
- Nesfatin-1

A general approach to the prescription of antidepressants is outlined in **Box 22.24**.

---

**Box 22.24**

**A general approach to the prescription of antidepressants**

- Any drugs that may contribute to or exacerbate depression, e.g. corticosteroids, should be stopped
- An ECG should be performed prior to institution of antidepressants
- Patient education should be provided (e.g. 80% of the UK public wrongly believe that antidepressants are addictive)
- Regular follow-up (especially weeks 1–6) should accompany the prescription of
antidepressants to increase adherence

- All antidepressants have similar efficacy and speed of onset
- Selective serotonin reuptake inhibitors (SSRIs) are considered first-line agents
- Choice of agent will depend on safety and adverse effects, which can be used to positive effect (sedating drugs given at night to enhance sleep)
- The rate of improvement is greatest in weeks 1–2
- An alternative agent should be considered at week 4 in the absence of any response
- With resolution of symptoms, antidepressants should be continued for 6–9 months after a single episode but for at least 2 years in the case of multiple prior episodes
- Some 50% of patients who stop antidepressants immediately on recovery relapse in the next 6 months

Drug choices in specific circumstances

- **Recurrent episodes.** Maintenance treatment with the antidepressant at the dose that obtained remission should be continued for at least 2 years. Maintenance treatment beyond this point should be re-evaluated, taking into account age, co-morbidities and risk factors.

- **Refractory depressive illness.** Whilst 50% may show a response, as few as 30% of individuals (outpatients) experience complete remission with the first choice of antidepressant agent. Strategies available at this point are switching drug classes or augmenting with other agents. This should be overseen by a specialist.

- **Psychotic depression.** This needs either a combination of an antidepressant and an antipsychotic drug, or electroconvulsive therapy.

- **Depressive episodes in bipolar affective disorder.** Monotherapy with quetiapine has been proposed as the treatment of choice. Other drugs include mood stabilizers or olanzapine, either alone or in combination with an SSRI antidepressant (see p. 914).

Selective serotonin reuptake inhibitors

Selective serotonin reuptake inhibitors (SSRIs) selectively inhibit the reuptake of the monoamine serotonin (5-HT) within the synapse (Fig. 22.3). Citalopram and its laevo-isomer, escitalopram, fluvoxamine, fluoxetine, paroxetine and sertraline have the advantage of causing less serious adverse effects than tricyclic antidepressants. For instance, SSRIs do not usually lead to significant weight gain. Because of their long half-lives, they can also be given just once a day, normally in the morning after breakfast. For these reasons, patients adhere better to treatment and therefore SSRIs are now first-line treatments for depressive disorders.
The effect of drugs used in the treatment of depression on central nervous system serotonergic and adrenergic functioning. (a) The majority of released serotonin 5-HT and noradrenaline (NA; norepinephrine) is rapidly removed from the synapse by reuptake into the neurone (yellow circles). (b) There is a range of antidepressants, which vary in their abilities to inhibit the reuptake of serotonin or noradrenaline, thus enhancing the synapse concentrations of these transmitters. (c) Stimulation of presynaptic α₂-adrenoceptors reduces monoamine release; mirtazapine blocks these presynaptic autoreceptors, and increases the release and transmission of noradrenaline and serotonin. (d) Other drugs act by significantly blocking postsynaptic receptors that are upregulated in depression. βAR, β-adrenoceptor; MAO, monoamine oxidase; MAOI, monoamine oxidase inhibitor; NA, noradrenaline; NRI, (selective) noradrenaline reuptake inhibitor; SNRI, serotonin and noradrenaline reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, ‘classic’ tricyclic antidepressant. (From Waller DG, Sampson AP, Renwick A, Hillier K. Medical Pharmacology and Therapeutics. Edinburgh: Saunders; 2014, with permission.)

The most common adverse effects of SSRIs resemble a ‘hangover’ and include nausea, vomiting, headache, diarrhoea and dry mouth. Insomnia and paradoxical agitation can occur when first starting the drugs. Adolescents, in particular, may develop suicidal thoughts with SSRIs; for this reason, only fluoxetine is licensed in the UK for adolescents. Further studies suggest that this is a small risk, if present, and no study has shown a significant increased risk of suicide itself. One in five patients also has sexual adverse effects, such as erectile
dysfunction and loss of libido. Uncommon adverse effects include restless legs syndrome (see p. 852) and hyponatraemia.

A **risk of bleeding** is associated with SSRIs and is thought to be due to the inhibition of serotonin uptake by platelets as part of normal aggregation in response to vascular injury. To date, much of the reported incidence relates to gastrointestinal bleeding, and any patient with one or more risk factors for upper gastrointestinal bleeding, such as taking an NSAID, should be given gastro-protection with a proton pump inhibitor or advised to stop the NSAID. A risk of intra- and postoperative bleeding has also been reported. Whilst antidepressants are certainly not a reason to withhold a surgical intervention, there is certainly an added risk, of which the surgeon and anaesthetist should be aware.

‘**Serotonin syndrome**’ is a toxic hyper-serotonergic state, which can be caused by the ingestion of two or more drugs that increase serotonin levels, e.g. an SSRI combined with a monoamine oxidase inhibitor, a dopaminergic drug (e.g. selegiline) or a tricyclic antidepressant. Symptoms include agitation, confusion, tremor, diarrhoea, tachycardia and hypertension; hyperthermia is characteristic. This is a medical emergency and treatment may require admission to hospital.

**Discontinuation syndrome**, a specific withdrawal syndrome, has also been reported with SSRIs, and may occur with any antidepressant if stopped suddenly. The syndrome is characterized by shivering, anxiety, dizziness, ‘electric shocks’, headache and nausea. Patients should be warned not to omit a dose and to reduce SSRIs gradually when stopping them.

A **prolonged QTc interval** has been noted, particularly with high doses of citalopram and escitalopram.

**Tricyclic antidepressants**

Tricyclic antidepressants (TCAs) potentiate the action of the monoamines, noradrenaline (norepinephrine) and serotonin, by inhibiting their reuptake into nerve terminals (*Fig. 22.3*). Other tricyclics in common use include nortriptyline, doxepin and clomipramine. Dosulepin, imipramine and amitriptyline are the three most commonly used TCAs in the UK, but many related compounds have been introduced, some having fewer autonomic and cardiotoxic effects (e.g. lofepramine).

TCAs have a number of adverse effects (*Box 22.25*). In long-term treatment or prophylaxis, weight gain is most troublesome. Because of their toxicity in overdose, it is wisest not to prescribe them to outpatients who have suicidal thoughts without monitoring or giving the drugs to a reliable family member to look after.

---

*Box 22.25*

**Adverse effects of tricyclic antidepressants**

**Antimuscarinic effects**

- Dry mouth
- Constipation
- Tremor
- Blurred vision
- Urinary retention

**Cardiovascular effects**
- QT prolongation
- Arrhythmias
- Postural hypotension

**Convulsant activity**
- Lowered seizure threshold

**Other effects**
- Weight gain
- Sedation
- Mania (rarely)

---

**Serotonergic and noradrenergic antidepressants**

These antidepressants block a number of different neurotransmitter receptors both at the synapse and elsewhere. Their different receptor profiles cause different adverse effects.

- **Dual-acting agents (serotonin and noradrenaline reuptake inhibitors, SNRIs).**
  
  Venlafaxine is a potent blocker of both serotonin and noradrenaline (norepinephrine) reuptake. At higher doses, it also affects dopamine transmission. It has negligible affinity for other neurotransmitter receptor sites and so produces less sedation and fewer antimuscarinic effects. It can be given in slow-release form with the advantage of once-daily dosage. Nausea is the most common side-effect and patients should be monitored for hypertension. It should not be prescribed in those with uncontrolled hypertension or cardiac arrhythmias. Duloxetine works in a similar way to venlafaxine and has been found to be especially helpful with chronic pain.

- **Tetracyclics.** Trazodone is a tetracyclic compound that acts as a serotonin antagonist (except at 5-HT1A receptors, where it acts as a partial agonist) and reuptake inhibitor. It is used in the treatment of anxiety and depressive disorders, and also for insomnia due to its sedative effects. It has low cardiotoxic and antimuscarinic effects. However, dizziness and postural hypotension can be problems for some patients, and blood pressure should be monitored during the initial titration.

- **Mirtazapine** is a 5-HT2 and 5-HT3 receptor antagonist and a potent α2-adrenergic blocker. The consequent effect is to increase both noradrenaline and selective serotonin transmission: an NSSA. It can be given at night to aid sleep and rarely causes sexual adverse effects.
Mirtazapine can be sedating in low dose and can cause weight gain. An uncommon adverse effect is agranulocytosis.

- **Noradrenaline (norepinephrine) reuptake inhibitors (NRIs).** Reboxetine is an NRI that is an effective antidepressant but has also demonstrated benefit in the treatment of panic disorder and attention deficit disorder. It can cause insomnia in some patients in addition to antimuscarinic adverse effects.

**Monoamine oxidase inhibitors**

Monoamine oxidase inhibitors (MAOIs) act by irreversibly inhibiting the intracellular enzymes monoamine oxidase A and B, leading to an increase of noradrenaline (norepinephrine), dopamine and 5-HT in the brain (see Fig. 22.3). Because of their adverse effects and restrictions placed on patients taking them, they are rarely used by non-psychiatrists. MAOIs also produce a dangerous hypertensive reaction with foods containing tyramine or dopamine and therefore a restricted diet is prescribed. Tyramine is present in cheese, pickled herrings, yeast extracts, certain red wines, and any food, such as game, that has undergone partial decomposition. Dopamine is present in broad beans. MAOIs interact with drugs such as pethidine and can also cause liver damage occasionally.

**Reversible inhibitors of monoamine oxidase A**

An example of a reversible inhibitor of monoamine oxidase A (RIMA) is moclobemide; the usual dose is 300 mg daily. These drugs appear to have fewer adverse effects than the MAOIs (insomnia and headache, but some sexual problems) and constitute a low risk in overdose. Patients prescribed such antidepressants should be told that they can eat a normal diet, but should be careful to avoid excessive amounts of food rich in tyramine (see above).

**Selective irreversible inhibitors of monoamine oxidase B**

Selegiline is a selective irreversible inhibitor of MAO-B. At higher doses, it loses its specificity and also inhibits MAO-A. It is more frequently used in the treatment of Parkinson's disease (see p. 854) than in depression, as it prolongs the activity of levodopa because dopamine is a substrate of MAO-B.

**Melatonin receptor agonist and serotonin receptor antagonist (see Box 22.23)**

Agomelatine is the only drug in this class. It is an agonist at both the melatonin MT₁ and MT₂ receptors. It is a weak antagonist at 5-HT₂C receptors. It does not affect the uptake of serotonin, noradrenaline (norepinephrine) or dopamine. Agomelatine has the same antidepressant efficacy as the SSRIs.

**Antidepressant augmentation**

If two trials of antidepressants have failed, adding a second concomitant drug, such as lithium, an atypical antipsychotic or tri-iodothyronine, can be helpful.
**Antidepressant use in general medicine**

- **Cardiac disease.** In people with cardiac disease, SSRIs, lofepramine and trazodone are preferred over more quinidine-like compounds.

- **Epilepsy.** MAOIs and mirtazapine do not affect epileptic thresholds.

- **Drug interactions.** SSRIs are metabolized by the cytochrome P450 system, unlike venlafaxine, mirtazapine and reboxetine; the latter therefore have fewer drug interactions.

- **Herbal medicine.** Care should be taken not to prescribe antidepressants while a patient is taking the herbal antidepressant St John's wort, which interacts with serotonergic drugs in particular.

- **Elderly.** Doses of antidepressants should initially be halved in the elderly and in people with renal or hepatic failure.

- **Pregnancy.** Antidepressants should be avoided if possible in pregnancy and breast-feeding. If other treatments are ineffective, the risks of drug therapy should be balanced against those of taking no treatment, since depression can affect fetal progress and future mother–child bonding. TCAs are generally believed to be safe in pregnancy, with no significant increase in congenital malformations in fetuses exposed to them. However, occasionally, their antimuscarinic adverse effects produce jitteriness, sucking problems and hyperexcitability in the newborn. Postpartum plasma levels of babies breast-fed by treated mothers are negligible. SSRIs do not seem to be teratogenic but manufacturers advise against their use in pregnancy until more data are available. Pulmonary hypertension in the newborn is a rare complication. MAOIs should be avoided during pregnancy because of the possibility of a hypertensive reaction in the mother.

**Combining antidepressants with psychotherapy**

Historically, the understanding has been that combining psychotherapy with antidepressants provided no additive benefit. Recently, however, a well-designed randomized controlled trial has suggested that an additive effect can be achieved with this approach (specifically, with CBT). However, this is both a modest and a specific effect. Patients with more severe and non-chronic episodes attain this benefit, whilst those with milder forms of the disorder, chronic depression and co-morbid personality disorders do not, when compared to antidepressants alone. Individuals who obtained benefit from the combined treatment also experienced fewer adverse effects from the antidepressants prescribed.

**Electroconvulsive therapy**

Electroconvulsive therapy (ECT) is the treatment of choice in severe, life-threatening depressive illness, particularly when psychotic symptoms are present. It is sometimes essential treatment when the patient is dangerously suicidal or refusing to eat and drink, and when a rapid resolution is required, such as in postpartum depressive illness, when returning baby to mother as soon as it is safe to do so forms part of the treatment.

The treatment is performed under general anaesthetic and involves the passage of an electric
current across two electrodes applied to the anterior temporal areas of the scalp, in order to induce a seizure. The motoric seizure is less significant than its electrophysiological evidence (spike-and-wave activity on an EEG), without which benefit is unlikely to be seen. Treatments are normally given twice a week for 3–6 weeks.

ECT is a controversial treatment, yet it is free of serious adverse effects. Most adverse effects are due to the general anaesthetic. Post-ictal confusion and headache are not uncommon, while transient and short-term retrograde amnesia and a temporary defect in new learning can occur during the weeks of treatment, but these are typically short-lived effects. The frequency with which defects in autobiographical memory occur during the time of treatment should be noted. These are discrete and, in most instances, not recognized by the patient, unless the particular memory is actively sought. It is necessary to warn patients of its possibility beforehand.

**Uncommonly used physical treatments**

**Transcranial magnetic stimulation (TMS)** shows moderate efficacy, but is uncommonly used. *Psychosurgery* is very occasionally considered in people with severe intractable depressive illness, when all other treatments have failed (see p. 920). A third of them improve remarkably, while a further third improve somewhat.

**Vagal nerve and deep brain stimulation** may represent major advances in the management of chronic and treatment-refractory depressive disorders, but definitive trials are not available.

**Social treatments**

Many people with clinical depression have associated social problems (see Box 22.22). Assistance with these can make a significant contribution to clinical recovery. Other social interventions include the provision of group support, social clubs, occupational therapy and referral to a social worker. Educational programmes, self-help groups, and informed and supportive family members can help improve outcome.

**Prognosis**

Depression is one of the leading causes of disease burden worldwide. People with major depressive illness are between 1.5 and 2 times more likely to die than non-depressed people in the next 16 years, and the risks encompass not only suicide, but also cardiovascular disorders. Depression produces greater disability than angina, arthritis, asthma and diabetes, which makes effective treatment and prevention imperative.

The majority of patients have recovered by 6 months in primary care and 12 months in secondary care. About a quarter of patients attending hospital with depressive illnesses will have a recurrence within 1 year, and three-quarters will have a recurrence within 10 years. People with recurrent depressive illnesses should be offered prevention. This may involve CBT that concentrates on relapse prevention, other forms of psychotherapy, prolonged antidepressant use, and advice on lifestyle activities such as regular exercise. Full-dose
Antidepressants are the most effective prophylaxis in recurrent depressive disorders.

**Mania, hypomania and bipolar disorder**

Mania and hypomania almost always occur as part of a bipolar disorder. The clinical features of mania include a marked elevation of mood, characterized by euphoria, over-activity and disinhibition (*Box 22.26*). Hypomania lasts a shorter time and is less severe, with no psychotic features and less disability. Hypomania can be distinguished from normal happiness by its persistence, non-reactivity (not provoked by good news and not affected by bad news) and social disability.

**Box 22.26**

**Clinical features of mania**

<table>
<thead>
<tr>
<th>Characteristic</th>
<th>Clinical feature</th>
</tr>
</thead>
<tbody>
<tr>
<td>Mood</td>
<td>Elevated or irritable</td>
</tr>
<tr>
<td>Talk</td>
<td>Fast, pressurized, flight of ideas</td>
</tr>
<tr>
<td>Energy</td>
<td>Excessive</td>
</tr>
<tr>
<td>Ideas</td>
<td>Grandiose, self-confident, delusions of wealth, power, influence or of religious significance, sometimes persecutory</td>
</tr>
<tr>
<td>Cognition</td>
<td>Disturbance of registration of memories</td>
</tr>
<tr>
<td>Physical</td>
<td>Insomnia, mild to moderate weight loss, increased libido</td>
</tr>
<tr>
<td>Behaviour</td>
<td>Disinhibition, increased sexual activity, excessive drinking or spending</td>
</tr>
<tr>
<td>Hallucinations</td>
<td>Fleeting auditory</td>
</tr>
</tbody>
</table>

The social disability of mania can be severe, with disinhibited behaviour leading to significant debts (from overspending), lost relationships (from promiscuity or irritability), social ostracism and lost employment (from reckless or disinhibited behaviour).

Some patients have a **rapid-cycling** illness, with frequent swings from one mood state to another. A **mixed affective state** occurs when features of mania and depressive illness are seen in the same episode. **Cyclothymia** is a personality trait with spontaneous swings in mood that are not sufficiently severe or persistent to warrant another diagnosis.
**Differential diagnosis**

Acute intoxication with recreational drugs such as amphetamines, amphetamine derivatives (MDMA: ecstasy), and cocaine can mimic mania. Up to a quarter of people with Cushing syndrome develop mania. Similarly, corticosteroids can induce mania less commonly than depressive illness. Dopamine agonists (e.g. bromocriptine) are also known to induce mania sometimes.

**Epidemiology**

The lifetime prevalence of bipolar affective disorder is 1% across the world. Unlike unipolar depressive illness, it is equally common in men and women, supporting its different aetiology. There is no variation by socioeconomic class or race. The mean age of onset is 21, earlier than unipolar depression. The higher prevalence found in divorced people is probably a consequence of the condition.

**Aetiology**

**Genetic factors**

There is strong evidence for a genetic aetiology in this disorder. There is a 60–80% concordance rate in monozygotic twins, compared to 15% in dizygotic twins, suggesting a high rate of heritability. Studies in adoptive twins show similar rates, so this high rate is probably genetic and not due to the family environment. Linkage studies have so far proved disappointing, with several polymorphism associations being found, similar to polymorphisms associated with schizophrenia.

**Biochemical changes**

Brain monoamines, such as serotonin, are increased in mania. Dexamethasone tends not to suppress cortisol levels in people with mania, suggesting a similar pattern of non-suppression to that seen in severe depressive illness.

**Psychological factors**

The effect of life events is weaker in bipolar compared with unipolar illnesses, most effects being apparent at first onset. Similarly, personality does not seem to be a major influence, in contrast to unipolar depression, although there is some evidence of a link with the creativity and divergent thinking that is an advantage in the right occupation.

**Management**

Acute mania or hypomania
Treatment is summarized in Box 22.27. Acute mania is treated with an atypical antipsychotic (neuroleptic), sodium valproate or lithium.

- The atypical antipsychotics aripiprazole, olanzapine, quetiapine and risperidone are particularly recommended, especially with behavioural disturbance. Doses are similar to those used in schizophrenia. The behavioural excitement and overactivity are usually reduced within days, but elation, grandiosity and associated delusions often take longer to respond.
- Lithium may be used in instances where compliance is likely to be good; however, the screening necessary prior to its prescription (see below) may prohibit its use in these circumstances as a first-line agent.
- Valproic acid is also helpful in hypomania or in rapid-cycling illnesses (see below).

<table>
<thead>
<tr>
<th>Box 22.27</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Treatment options in acute mania or hypomania</strong></td>
</tr>
<tr>
<td>Choice of agent is determined largely by clinical judgement, contraindications and prior response</td>
</tr>
</tbody>
</table>
- Stop antidepressant medication

**If the patient is NOT on antimanic medication, then start**

- Antipsychotic, e.g. aripiprazole 15 mg daily
- *Or* Valproate 750 mg daily
- *Or* Lithium 0.4 mg daily to serum lithium of 0.4–1.0 mmol/L
  - If response is inadequate:
    - Antipsychotic + valproate or lithium

**If the patient is already ON antimanic medication**

- If taking an antipsychotic: check dose and compliance; increase if possible, or add valproate or lithium
- If taking valproate: check plasma levels and increase dose, aiming for a serum concentration of 125 mg/L as tolerated and/or add an antipsychotic (this should be done if mania is severe)
- If taking lithium: check plasma levels and increase dose to gain a level of 1.0–1.2 mmol/L if necessary (*Note*: higher than usual reference range) or add an antipsychotic (this should be done if mania is severe)
- If taking carbamazepine: add an antipsychotic if appropriate
  - A short-acting benzodiazepine may be added to assist with agitation in all patients

**Prevention in bipolar disorders**

Since bipolar illnesses tend to be relapsing and remitting, prevention of recurrence is the
major therapeutic challenge in management. A patient who has experienced more than two episodes of affective disorder within a 5-year period is likely to benefit from preventive treatments. Recommendations include lithium, olanzapine and valproic acid (so long as the patient is not a woman at risk of pregnancy).

**Lithium**

Lithium (carbonate or citrate) is one of the two main agents used for prophylaxis in people with repeated episodes of bipolar illness (the other being valproic acid). It is rapidly absorbed from the gastrointestinal tract and more than 95% is excreted by the kidneys; small amounts are found in the saliva, sweat and breast milk. Renal clearance of lithium correlates with renal creatinine clearance. Lithium is a mood-stabilizing drug that prevents mania more than depression. It lowers the frequency and severity of relapses by half and significantly reduces the likelihood of suicide. Its mode of action is unknown, but lithium is known to act on the serotonergic system. Poor response to lithium is associated with a negative family history, an unstable premorbid personality and a rapid-cycling illness. Pharmacogenetic work suggests that certain polymorphisms may predict response.

**Plasma levels**

These should be monitored weekly, with blood drawn 12 h after the last dose (a ‘trough’ level) until a steady state is reached and at 3-monthly intervals thereafter. The minimum level for prophylaxis is 0.4 mmol/L, with an optimum range of between 0.6 and 0.75 mmol/L. Levels higher than this may afford further protection against manic episodes but the relationship with depression is less clear. For this reason, the therapeutic range is typically quoted as 0.5–1.0 mmol/L. Fluctuations in plasma levels increase the risk of relapse.

**Screening** prior to starting lithium and at 6-monthly intervals thereafter includes:

- **Thyroid function** (free T₄, TSH and thyroid autoantibodies). Lithium interferes with thyroid function and can produce frank hypothyroidism. The presence of thyroid autoantibodies increases the risk.
- **Parathyroid function.** Serum calcium and parathyroid hormone levels are higher in 10% of patients.
- **Renal function** (serum urea and creatinine, eGFR and 24-h urinary volume). Long-term treatment with lithium causes two renal problems: nephrogenic diabetes insipidus (p. 1234) and reduced glomerular function. The best screen for diabetes insipidus is to ask the patient about polyuria and polydipsia.

**Toxicity**

Patients should carry a lithium card with them at all times, be advised to avoid dehydration, and be warned of drug interactions, such as with NSAIDs and diuretics. As with all medications, it is vital to discuss adverse effects and signs of toxicity (these are listed in **Box. 22.28**).
Pregnancy

As a rule, lithium is not advised during pregnancy, particularly in the first trimester, because of an increased risk of fetal malformation (Ebstein's anomaly). About 25% of women with a history of bipolar disorder relapse within 2 weeks of delivery. Restarting lithium within 24 h of delivery (if the mother is prepared to forgo breast-feeding) markedly reduces the risk of relapse.

Other mood stabilizers

**Valproic acid** (as the semisodium salt) is recommended in both prophylaxis and treatment of manic states. Second-line treatments include **carbamazepine** and **lamotrigine**. Some patients who do not respond to lithium may respond to these anticonvulsants or a combination of both. People with rapid-cycling illnesses show a better response to anticonvulsants than to lithium. For antimanic treatment, dosage in the initial stage of treatment will be 200 mg twice daily of carbamazepine, increasing to a normal dose of 800–1000 mg.

Other drugs that appear to exert a prophylactic mood-stabilizing effect include **olanzapine** and **risperidone**.

Both carbamazepine and valproate can be teratogenic (neural tube defects) and should be avoided in pregnancy. Other adverse effects of these drugs are given on page 850.

Prognosis

The mean duration of a manic episode is 2 months, with 95% making a full recovery in time. Recurrence is the rule in bipolar disorders, up to 90% relapsing within 10 years.
**Further reading**

**Suicide and Self-Harm**

(See also p. 63.) Suicide accounts for 2% of male deaths and 1% of female deaths in England and Wales each year, equivalent to a rate of 8 per 100,000. The rate increases with age, peaking for women in their sixties and for men in their seventies. Suicide is the second most common cause of mortality in 15- to 34-year-olds. Meta-analyses of relevant studies suggest that the lifetime risk of suicide is 7% in alcohol dependence, 6% in affective disorders and 4% in schizophrenia.

The highest rates of suicide have been reported in rural southern India (148/100,000 in young women and 58/100,000 in young men) and in Eastern Europe (30–40/100,000), while the lowest are found in Spain (4/100,000) and Greece (3/100,000), but such variations may reflect differences in reporting, which may be related to religion, as much as genuine differences. The provision of mental health care to suicidal individuals varies greatly around the world; a World Health Organization (WHO) study suggests that most receive no treatment at all. Factors that increase the risk of suicide are indicated in **Box 22.29**.

### Box 22.29

**Factors that increase the risk of suicide**

- Male sex
- Older age
- Living alone
• Immigrant status
• Recent bereavement, separation or divorce
• Unemployment or retirement
• Living in a socially disorganized area
• Family history of affective disorder, suicide or alcohol misuse
• Previous history of affective disorder, alcohol or drug misuse
• Previous suicide attempt
• Addiction to alcohol or drugs
• Severe depression or early dementia
• Incapacitating painful physical illness

A distinction must be drawn between those who attempt suicide – self-harm (SH) – and those who succeed (suicide):
• The majority of cases of SH occur in people under 35 years of age.
• The majority of suicides occur in people aged over 60.
• Suicides are more common in men, while SH is more common in women.
• Suicides are more common in older men, although rates are falling. Rates in young men are rising fast throughout the UK and Europe.
• Suicides in women are slowly falling in the UK.
• Approximately 90% of cases of SH involve self-poisoning.
• A formal psychiatric diagnosis can be made retrospectively in 90% of suicides but is unusual in SH.

There is, however, an overlap between SH and suicide. Between 1% and 2% of people who attempt suicide will kill themselves in the year following SH. The risk of suicide stays elevated in those with SH, with 0.5% per annum committing suicide in the following 20 years. Following the guidelines for the assessment of such patients (Box 22.30) will help ensure that the risk factors relating to suicide are assessed. Indications for referral to a psychiatrist before discharge from hospital are also given.

Box 22.30

Guidelines for the assessment of patients who harm themselves

Questions to ask: of concern if positive answer
• Was there a clear precipitant/cause for the attempt?
• Was the act premeditated or impulsive?
• Did the patient leave a suicide note?
• Had the patient taken pains not to be discovered?
• Did the patient make the attempt in strange surroundings (i.e. away from home)?
• Would the patient do it again?

**Other relevant factors**

• Has the precipitant or crisis resolved?
• Is there a continuing suicidal intent?
• Does the patient have any psychiatric symptoms?
• What is the patient's social support system?
• Has the patient inflicted self-harm before?
• Has anyone in the family ever taken their life?
• Does the patient have a physical illness?

**Indications for referral to a psychiatrist**

**Absolute indications**

• Clinical depression
• Psychotic illness of any kind
• Clearly pre-planned suicidal attempt that was not intended to be discovered
• Persistent suicidal intent (the more detailed the plans, the more serious the risk)
• A violent method used

**Other common indications**

• Alcohol and drug misuse
• Patients over 45 years, especially if male, and young adolescents
• Those with a family history of suicide in first-degree relatives
• Those with serious (especially incurable) physical disease
• Those living alone or otherwise unsupported
• Those in whom there is a major unresolved crisis
• Persistent suicide attempts
• Any patients who give you cause for concern

In general, it is worth trying to interview a family member or close friend and checking these points with them. Requests for immediate re-prescription on discharge should be denied, except in cases of essential medication. In such cases, however, only 3 days' supply of medication should be given, and the patient should be requested to report to their general practitioner or to their psychiatric outpatient clinic for further supplies. Occasionally, involuntary admission to hospital may be required (see pp. 929–930).

Anxiety Disorders

These are conditions in which anxiety dominates the clinical symptoms. They are classified according to whether the anxiety is persistent (general anxiety) or episodic, with the episodic conditions classified according to whether the episodes are regularly triggered by a cue (phobia) or not (panic disorder). The differential diagnoses of anxiety disorders are given in *Box 22.31*. A patient with one anxiety disorder may well develop others in time.

**Box 22.31**

**Anxiety disorders: the differential diagnosis**

**Psychiatric disorders**

- Depressive illness
- Obsessive–compulsive disorder
- Pre-senile dementia
- Alcohol dependence
- Drug dependence
- Benzodiazepine withdrawal

**Endocrine disorders**

- Hyperthyroidism
- Hypoglycaemia
- Phaeochromocytoma

**General anxiety disorder**

General anxiety disorder (GAD) occurs in 4–6% of the population and is more common in women. Symptoms are persistent and often chronic. GAD and the related panic disorder are differential diagnoses for functional somatic syndromes, owing to the many physical symptoms that are caused by these conditions.
**Clinical features**

The physical and psychological symptoms are outlined in **Box 22.32**. The patient looks worried, and has a tense posture, restless behaviour, a pale and sweaty skin, or neck and chest intermittent flushing. The patient takes time to go to sleep; once asleep, they wake intermittently with worry dreams. Associated conditions include hyperventilation, which is even more common in panic disorders (**Box 22.33**). The patient will either breathe rapidly and shallowly or sigh deeply, particularly when talking about the stresses in their life.

**Box 22.32**

</table>

**Box 22.33**

**The hyperventilation syndrome**

**Clinical features**

• Panic attacks – fear, terror and impending doom – accompanied by some or all of the following:
  – Dyspnoea (trouble getting a good breath in)
  – Palpitations
  – Chest pain or discomfort
– Suffocating sensation
– Dizziness
– Paraesthesiae in hands and feet
– Perioral paraesthesiae
– Sweating
– Carpopedal spasms

**Aetiology**

• Over-breathing leading to a decrease in $P_a CO_2$ and an increase in arterial pH, causing relative hypocalcaemia

**Diagnosis**

• A provocation test – voluntary overbreathing for 1 minute – provokes similar symptoms; rebreathing from a large paper bag relieves them

**Management**

• Explanation and reassurance is given
• The patient is trained in relaxation techniques and slow, controlled breathing
• The patient is asked to breathe into a closed paper bag

---

**Mixed anxiety and depressive disorder**

This disorder is the most common mood disorder in primary care (7% point prevalence), in which there are equal elements of both anxiety and depression, showing how closely associated these two abnormal mood states are.

**Panic disorder**

Panic disorder is diagnosed when the patient has repeated, sudden attacks of overwhelming anxiety, accompanied by severe physical symptoms, usually related to both hyperventilation (see Box 22.33) and sympathetic nervous system overactivity (palpitations, tremor, restlessness and sweating). The lifetime prevalence is 5%. People with a panic disorder often have catastrophic illness beliefs during the panic attack, such as the conviction that they are about to die from a stroke or heart attack. The fear of a stroke is related to dizziness and headache. Fear of a heart attack accompanies chest pain (atypical chest pain). The occasional patient with longstanding attacks may no longer feel anxious and simply notices the physical symptoms.

**Aetiology**

General anxiety and panic disorders occur four times more commonly in first-degree relatives
of affected patients. Sympathetic nervous system overactivity, increased muscle tension and hyperventilation are the common pathophysiological associations. Anxiety is the emotional response to the threat of a loss, whereas depression is the response to the loss itself. There is some evidence that being bullied, with the explicit threats involved, leads to anxiety disorders in adolescents.

### Phobic (anxiety) disorders

Phobias are common conditions in which intense fear is triggered by a stimulus, or group of stimuli, that are predictable and normally cause no particular concern to others (e.g. agoraphobia, claustrophobia, social phobia). This leads to avoidance of the stimulus (Box 22.34). The patient knows that the fear is irrational but cannot control it. The prevalence of all phobias is 8%, with many patients having more than one. Many phobias of ‘medical’ stimuli exist (e.g. of doctors, dentists, hospitals, vomit, blood and injections), which affect the patient's ability to receive adequate healthcare.

#### Box 22.34

**Phobias**

- A phobia is an abnormal fear and avoidance of an object or situation
- Phobias are common (the incidence varies from 3.5% to 12.8% worldwide), disabling and treatable with behaviour therapy

#### Aetiology

Phobias may be caused by classical conditioning, in which a response (fear and avoidance) becomes conditioned to a previously benign stimulus (e.g. a lift), often after an initiating emotional shock (e.g. being stuck in a lift). In children, phobias can arise through imagined threats (e.g. stories of ghosts told in the playground). Women have twice the prevalence of phobias than men. Phobias aggregate in families, with increasing evidence of the importance of genetic factors being published.

**Agoraphobia**

Translated as ‘fear of the marketplace’, this common phobia (4% prevalence) presents as a fear of being away from home, with travelling, walking down a road and going to supermarkets being common cues. This can be a very disabling condition, since the patient often avoids leaving home, particularly when unaccompanied. It is often associated with **claustrophobia**, a fear of enclosed spaces.

**Social phobia**
This is the fear and avoidance of social situations: crowds, strangers, parties and meetings. Public speaking would be the sufferer's worst nightmare. It is suffered by 2% of the population.

**Simple phobias**

The most common is the phobia of spiders (arachnophobia), particularly in women. The prevalence of simple phobias is 7% in the general population. Other common phobias include insects, moths, bats, dogs, snakes, heights, thunderstorms and the dark. Children are particularly phobic about the dark, ghosts and burglars, but the large majority grow out of these fears.

### Management of anxiety disorders

**Psychological management**

For many people with brief episodes, discussion with a doctor concerning the nature of anxiety and its precipitants is sufficient.

- **Relaxation techniques** can be effective in mild/moderate anxiety. Relaxation can be achieved in many ways, including complementary techniques such as meditation and yoga. Conventional relaxation training involves a slowing down of the rate of breathing, muscle relaxation and mental imagery.

- **Anxiety management** training involves two stages. In the first stage, verbal cues and mental imagery are used to arouse anxiety to demonstrate the link with symptoms. In the second stage, the patient is trained to reduce this anxiety by relaxation, distraction and reassuring self-statements.

- **Biofeedback** is useful for showing patients that they are not relaxed, even when they fail to recognize it, having become so used to anxiety. Biofeedback involves feeding back to the patient a physiological measure that is abnormal in anxiety. These measures may include electrical resistance of the skin of the palm, heart rate, muscle electromyography or breathing pattern. The effect tends not to generalize to everyday life away from the feedback.

- **Behaviour therapies** are treatments that are intended to change behaviour and thus symptoms. The most common and successful behaviour therapy (with 80% success in some phobias) is graded exposure, otherwise known as systematic desensitization. First, the patient rates the phobia into a hierarchy or ‘ladder’ of worsening fears (e.g. in agoraphobia: walking to the front door with a coat on; walking out into the garden; walking to the end of the road). Second, the patient practises exposure to the least fearful stimulus until no fear is felt. The patient then moves ‘up the ladder’ of fears until they are cured.

- **Cognitive behaviour therapy** (CBT; see p. 909) is the treatment of choice for panic disorder and general anxiety disorder because the therapist and patient need to identify the mental cues (thoughts and memories) that may subtly provoke exacerbations of anxiety or panic attacks. CBT also allows identification and alteration of the patient’s ‘schema’, or way of looking at themselves and their situation, which feeds anxiety.
Drug treatments

Initial ‘drug’ treatment should involve advice for gradual cessation of anxiogenic recreational drugs such as caffeine and alcohol (which can cause a rebound anxiety and withdrawal). Prescribed drugs used in the treatment of anxiety can be divided into two groups: those that act primarily on the central nervous system, and those that block peripheral autonomic receptors.

• **Benzodiazepines** are centrally acting anxiolytic drugs. They are agonists of the inhibitory transmitter γ-aminobutyric acid (GABA). Diazepam (5 mg twice daily, up to 10 mg three times daily in severe cases), alprazolam (250–500 µg three times daily) and chlordiazepoxide have relatively long half-lives (20–40 h) and are used as anti-anxiety drugs in the short term. Adverse effects include sedation and memory problems, and patients should be advised not to drive while on treatment. They can cause dependence and tolerance within 4–6 weeks, particularly in those with dependent personalities. A withdrawal syndrome (Box 22.35) can occur after just 3 weeks of continuous use and is particularly severe when high doses have been given for a longer time. Thus, if a benzodiazepine drug is prescribed for anxiety, it should be given in as low a dose as possible, preferably on an ‘as necessary’ basis, and for not more than 2–4 weeks. A withdrawal programme from chronic use includes changing the drug to the long-acting diazepam, followed by a very gradual reduction in dosage.

• **Most SSRIs** (e.g. fluoxetine, paroxetine, sertraline, escitalopram, citalopram) are useful symptomatic treatments for general anxiety and panic disorders, as well as some phobias (social phobia), although doses higher than those used in depression are often required. Duloxetine, mirtazapine, venlafaxine and pregabalin are alternative treatments for GADs, with the added benefit of possibly preventing the subsequent development of depression. Treatment response is often delayed several weeks; a trial of treatment should last 3 months.

• **Antipsychotics**, such as aripiprazole or olanzapine, can be effective for more severe or
refractory cases.

- **Beta-blockers** are effective in reducing peripheral symptoms, as many of the symptoms of anxiety are due to an increased or sustained release of adrenaline (epinephrine) and noradrenaline (norepinephrine) from the adrenal medulla and sympathetic nerves. Beta-blockers, such as propranolol (20–40 mg two or three times daily), can reduce peripheral symptoms such as palpitations, tremor and tachycardia, but they do not help central symptoms such as anxiety.

## Acute stress reactions and adjustment disorders

### Acute stress reaction

This occurs in individuals in response to exceptional physical and/or psychological stress. While severe, such a reaction usually subsides within days. The stress may be an overwhelming traumatic experience (e.g. accident, battle, physical assault, rape) or a sudden change in the social circumstances of the individual, such as a bereavement. Individual vulnerability and coping capacity play a role in the occurrence and severity of an acute stress reaction, as evidenced by the fact that not all people exposed to exceptional stress develop symptoms. Symptoms usually include an initial state of feeling ‘dazed’ or numb, with inability to comprehend the situation. This may be followed either by further withdrawal from the situation, or by anxiety and overactivity. No treatments beyond reassurance and support are normally necessary.

### Adjustment disorder

This disorder can follow an acute stress reaction and is common in the general hospital. This is a more prolonged (up to 6 months) emotional reaction to a significant life event, with low mood joining the initial shock and consequent anxiety, but not of sufficient severity or persistence to fulfil a diagnosis of a depressive or anxiety disorder. Supportive counselling is usually a successful treatment, allowing facilitation of unexpressed feelings, elucidation of unspoken fears, and education about the likely future.

### Normal grief

Normal grief immediately follows bereavement, is expressed openly, and allows a person to go through the social ceremonies and personal processes of bereavement. The three stages are, first, shock and disbelief; second, the emotional phase (anger, guilt and sadness); and, third, acceptance and resolution. This normal process of adjustment may take up to a year, with movement between all three stages occurring in a sometimes haphazard fashion.

### Pathological (abnormal) grief

This is a particular kind of adjustment disorder. It can be characterized as excessive and/or prolonged grief, or even absent grieving with abnormal denial of the bereavement. Usually, a
relative will be stuck in grief, with insomnia and repeated dreams of the dead person, anger at doctors or even the patient for dying, consequent guilt in equal measure, and an inability to ‘say good-bye’ to the loved person by dealing with their effects. **Guided mourning** uses cognitive and behavioural techniques to allow the relative to stop grieving and move on in life.

### Post-traumatic stress disorder

Post-traumatic stress disorder (PTSD) is a protracted response to a stressful event or situation of an exceptionally threatening nature, likely to cause pervasive distress in almost anyone. Causes include natural or human disasters, war, serious accidents, witnessing the violent death of others, and being the victim of sexual abuse, rape, torture, terrorism or hostage-taking. Predisposing factors, such as personality, previously unresolved traumas or a history of psychiatric illness, may prolong the course of the syndrome. These factors are neither necessary nor sufficient to explain its occurrence, which is mostly related to the intensity of the trauma, the proximity of the patient to the traumatic event, and its prolonged or repeated nature. Functional brain scan research suggests a possible neurophysiological relationship with obsessive–compulsive disorder (see pp. 919–920).

#### Clinical features

The typical symptoms of PTSD include:

- **‘flashbacks’**, repeated vivid reliving of the trauma in the form of intrusive memories, often triggered by a reminder of the trauma
- **insomnia**, usually accompanied by nightmares, the nocturnal equivalent of flashbacks
- **emotional blunting**, emptiness or ‘numbness’, alternating with **intense anxiety** on exposure to events that resemble an aspect of the traumatic event, including anniversaries of the trauma
- **avoidance** of activities and situations reminiscent of the trauma
- **emotional detachment** from other people
- **hypervigilance**, with autonomic hyperarousal and an enhanced startle reaction.

This clinical picture represents the severe end of a spectrum of emotional reactions to trauma, which might alternatively take the form of an adjustment or mood disorder. The course is often fluctuating but recovery can be expected in two-thirds of cases at the end of the first year. Complications include depressive illness and alcohol misuse. In a small proportion of cases, the condition may follow a chronic course over many years and a transition to an enduring personality change.

### Management and prevention

Compulsory **psychological debriefing** immediately after a trauma does not prevent PTSD and may be harmful. Prevention is better achieved by the support offered by others who were also
involved. Trauma-focused CBT is often effective. *Eye movement desensitization and reprocessing* (EMDR) is an equally effective treatment and may require fewer sessions. SSRIs and venlafaxine have a place in the management of chronic PTSD but dropout from pharmacotherapy is common.

### The adult consequences of childhood abuse

Estimates of the prevalence of childhood sexual abuse vary, depending on definition, but there is reasonable evidence that 20% of women and 10% of men suffered significant, coercive and inappropriate sexual activity in childhood. The abuser is usually a member of the family or known to the child in social care homes. The likelihood of long-term consequences is determined by:

- an earlier age of onset
- the severity of the abuse
- the repeated nature and duration of the period of abuse
- the association with physical abuse.

Consequent adult psychiatric disorders include depressive illness, substance misuse, eating disorders, borderline personality disorder and deliberate self-harm. Other negative outcomes include a decline in socioeconomic status, sexual problems, prostitution and difficulties in forming adult relationships.

Repeated childhood physical and emotional abuse or neglect may also affect emotional and personality development, predisposing the adult to similar psychiatric disorders. Those who have undergone repeated abuse are more likely to have long-term physical stress related consequences, such as hypothalamic–pituitary–adrenal axis downregulation and smaller brain hippocampal sizes.

### Management

**Psychodynamic psychotherapy**

Psychodynamic psychotherapy is derived from psychoanalysis and is based on a number of key analytical concepts. These include Freud’s ideas about psychosexual development, defence mechanisms, free association as the method of recall, and the therapeutic techniques of interpretation, including that of transference, defences and dreams. Such therapy usually involves once-weekly sessions, the length of treatment varying between 3 months and 2 years. The long-term aim of such therapy is twofold: symptom relief and personality change. Psychodynamic psychotherapy is classically indicated in the treatment of unresolved conflicts in early life, as might be found in non-psychotic and personality disorders, but there is no convincing evidence concerning its superiority over alternative forms of treatment.

**Cognitive analytical therapy**
Cognitive analytical therapy is an integration of CBT and psychodynamic therapy. It is a short-term therapy that involves the patient and therapist recognizing the origins of a recurrent problem, reformulating how it continues to occur, and revising other ways of coping and internalizing it, using both the transference of the patient–therapist relationship and behavioural experiments.

**Obsessive–compulsive disorder**

Obsessive–compulsive disorder (OCD) is characterized by obsessional ruminations and compulsive rituals. It is particularly associated with, and/or secondary to, both depressive illness and *Tourette syndrome* (see p. 857). The prevalence is between 1% and 2% in the general population, and patients uncommonly seek help. There is an equal distribution by gender, and the mean age of onset ranges from 20 to 40 years.

**Clinical features**

The obsessions and compulsions are time-consuming and intrusive, so that they affect functioning and cause considerable distress. Ruminations are often unpleasant repetitive thoughts, out of character, such as being dirty or violent. This can lead to a constant need to check that everything and everyone is all right and that things have been done correctly, and reassurance cannot remove the doubt that persists. Some rituals are derived from superstitions, such as actions repeated a fixed number of times, with the need to start again if interrupted. When severe and primary, OCD can last for many years and may be resistant to treatment. However, obsessional symptoms commonly occur in other disorders, most notably depressive illness, and remit with the resolution of the primary disorder.

Minor degrees of obsessional symptoms and compulsive rituals or superstitions are common in people who are not ill or in need of treatment, particularly in times of stress and in children, who usually grow out of it. The mildest grade is that of obsessional personality traits, such as over-conscientiousness, tidiness, punctuality, and other attitudes and behaviours indicating a strong tendency towards conformity and inflexibility. Such individuals are *perfectionists* who are intolerant of shortcomings in themselves and others, and take pride in their high standards. When such traits are so marked that they dominate other aspects of the personality, in the absence of clear-cut OCD, the diagnosis is obsessional (anankastic) personality (see p. 929).

**Aetiology**

**Genetic factors**

OCD is found in 5–7% of the first-degree relatives. Twin studies showed 80–90% concordance in monozygotic twins and about 50% in dizygotic twins. Genetic factors account for more of the variance in childhood-onset cases than in those who develop it as an adult.
Biological model

Neuroimaging studies suggest dysfunction in the orbito-striatal area (including the caudate nucleus) and dorsolateral prefrontal cortex, combined with abnormalities in serotonergic (underactive) and glutamatergic (overactive) neurotransmission. Further support for this model comes from an association with a number of neurological disorders involving dysfunction of the striatum, including Parkinson's disease, Huntington's disease, Tourette syndrome and Sydenham's chorea. The latter has also been associated with OCD and tic disorders in the paediatric autoimmune neuropsychiatric disorder associated with streptococcal infection (PANDAS). This is a rare condition in children that follows group A haemolytic streptococcal infection. OCD also can follow head trauma.

Cognitive behavioural model

Most people have the occasional intrusive thoughts, but would ordinarily dismiss these as meaningless and not focus upon them further. These develop into an obsession when they assume great significance to the individual, causing greater anxiety. This anxiety motivates suppression of these thoughts, and ritual behaviours are developed to reduce anxiety further.

Management

Psychological management

CBT focusing on exposure and response prevention is reasonably effective. This involves confronting the anxiety-provoking stimulus in a controlled environment and not performing the associated ritual. The aim is for the individual to habituate to the stimulus, thus reducing anxiety. Since it provokes anxiety, the dropout rate is often high.

Physical management

**Tricyclic antidepressants (TCAs) and serotonin reuptake inhibitors (SSRIs)**

Clomipramine (a TCA) and the SSRIs are the mainstay of drug treatment. Their efficacy is independent of their antidepressant action but the doses required are usually some 50–100% higher than those effective in depression. Although many sufferers respond, relapse rates on discontinuation are high. Three months' treatment with maximum tolerated doses may be necessary for a positive response; in those who fail to respond, the addition of an antipsychotic significantly improves outcome, especially when tics occur co-morbidly. Positive correlations between reduced severity of OCD and decreased orbitofrontal and caudate metabolism following behavioural and SSRI treatments have been demonstrated in a number of studies.

**Deep brain stimulation**

This is a non-ablative, and therefore potentially reversible, surgical technique that involves the electrical stimulation of the basal ganglia by implanted electrodes, creating a ‘functional
lesion' (Fig. 22.4). Although this has had success, often impressively so in intractable cases, issues still remain regarding subject selection and the optimum anatomical targets.

**Psychosurgery**

This is very occasionally recommended in cases of chronic and severe OCD that has not responded to other treatments. The development of stereotactic techniques has led to the replacement of the earlier, crude leucotomies with more precise surgical interventions such as subcaudate tractotomy and cingulotomy, with small yttrium radioactive implants, which induce lesions in the cingulate area or the ventromedial quadrant of the frontal lobe.

**Prognosis**

Two-thirds of cases improve within a year. The remainder run a fluctuating or persistent course. The prognosis is worse when the personality is obsessional or anankastic and the OCD is primary and severe.

**Further reading**

**Alcohol Misuse and Dependence**
A wide range of physical, social and psychiatric problems are associated with excessive drinking. Alcohol misuse occurs when a patient is drinking in a way that regularly causes problems to the patient or others.

- **The problem drinker** is one who causes or experiences physical, psychological and/or social harm as a consequence of drinking alcohol. Many problem drinkers, while heavy drinkers, are not physically addicted to alcohol.

- **Heavy drinkers** are those who drink significantly more in terms of quantity and/or frequency than is safe in the long term.

- **Binge drinkers** are those who drink excessively in short bouts, usually 24–48 h long, separated by often quite lengthy periods of abstinence. Their overall monthly or weekly alcohol intake may be relatively modest.

- **Alcohol dependence** is defined by a physical dependence on or addiction to alcohol. The term ‘alcoholism’ is a confusing one and has off-putting connotations of vagrancy, ‘meths’ drinking and social disintegration. It has been replaced by the term ‘alcohol dependence syndrome’.

### Epidemiology

A total of 20% of men and 10% of women drink more than double the recommended limits of 3 units a day of alcohol for men, and 2 units for women in the UK. The amount of alcohol consumed in the UK has doubled over the last 50 years. Some 4% of men and 2% of women report alcohol withdrawal symptoms, suggesting dependence. Approximately 1 in 5 male admissions to acute medical wards is directly or indirectly due to alcohol. People with serious drinking problems have a two to three times increased risk of dying compared with members of the general population of the same age and sex.

**Box 22.36** provides an approximate estimate of what can be expected in an average individual in the way of behavioural impairment resulting from a particular blood alcohol level. The amount of alcohol is measured for convenience in units that contain about 8 g of absolute alcohol and raise the blood alcohol concentration by about 15–20 mg/dL, the amount that is metabolized in 1 h. One unit of alcohol is found in half a pint of ordinary beer (3.5% alcohol by volume, ABV) and 125 mL of 9% wine. However, some beers and most lagers are now 5% ABV (3 units per pint). Wine is often 13% ABV and sold in 175 mL glasses (2–3 units per glass).

**Box 22.36**

**Behavioural effects of alcohol**
### Diagnosis

Alcohol misuse should be suspected in any patient presenting with one or more of the physical problems commonly associated with excessive drinking (see pp. 217–218). Alcohol misuse may also be associated with a number of psychiatric symptoms/disorders and social problems (Box 22.37).

### Box 22.37

#### Common alcohol-related psychological and social problems

**Psychological**
- Depression
- Anxiety
- Memory problems
- Delirium tremens
- Attempted suicide
- Suicide
- Pathological jealousy

**Social**
- Domestic violence
- Marital and sexual difficulties
- Child abuse
- Employment problems
- Financial difficulties
- Accidents at home, on the roads, at work
- Delinquency and crime
- Homelessness

The patient's frequency of drinking and the quantity drunk during a typical week should be established:

• Up to 21 units of alcohol a week for men and 14 units for women: this carries no long-term health risk.
• 21–35 units a week for men and 14–24 units for women: there is unlikely to be any long-term health damage, provided the drinking is spread throughout the week.
• Over 36 units a week for men and 24 for women: damage to health becomes increasingly likely.
• Above 50 units a week for men and 35 for women: this is a definite health hazard.

Diagnostic markers of alcohol misuse

Laboratory parameters indicating alcohol misuse in recent weeks include elevated γ-glutamyl transpeptidase (γ-GT) and mean corpuscular volume (MCV). Blood or breath alcohol tests are useful in anyone suspected of very recent drinking.

Alcohol dependence syndrome

Dependence is a pattern of repeated self-administration that causes tolerance, withdrawal and compulsive drug-taking, the essential element of which is the continued use of the substance despite significant substance-related problems. Symptoms of alcohol dependence in a typical order of occurrence are shown in Box 22.38. Diagnostic criteria for alcohol withdrawal syndrome are shown in Box 22.39.

### Box 22.38

**Symptoms of alcohol dependence**

• Inability to keep to a drink limit
• Difficulty in avoiding getting drunk
• Spending a considerable time drinking
• Missing meals
• Memory lapses, blackouts
• Restlessness without drink
• Organizing the day around drink
• Trembling after drinking the day before
• Morning retching and vomiting
• Sweating excessively at night
• Withdrawal fits
• Morning drinking
- Increased tolerance
- Hallucinations, frank delirium tremens

**Diagnostic criteria for alcohol withdrawal syndrome**

Any three of the following:
- Tremor of outstretched hands, tongue or eyelids
- Sweating
- Nausea, retching or vomiting
- Tachycardia or hypertension
- Anxiety
- Psychomotor agitation
- Headache
- Insomnia
- Malaise or weakness
- Transient visual, tactile or auditory hallucinations or illusions
- Grand mal convulsions

**Course**

About 25% of all cases of alcohol misuse will lead to chronic alcohol dependence. This most commonly ends in social incapacity, death or abstinence. Alcohol dependence syndrome usually develops after 10 years of heavy drinking (3–4 years in women). In some individuals who use alcohol to alter consciousness, obliterate conscience and defy social mores, dependence and loss of control may appear in only a few months or years.

**Delirium tremens**

Delirium tremens (DTs) is the most serious withdrawal state and occurs 1–3 days after alcohol cessation, so is commonly seen 1–2 days after admission to hospital. Patients are disorientated and agitated, and have a marked tremor and visual hallucinations (e.g. insects or small animals coming menacingly towards them). Signs include sweating, tachycardia, tachypnoea and pyrexia. Complications include dehydration, infection, hepatic disease or the Wernicke–Korsakoff syndrome (see p. 885).

**Aetiology of alcohol dependence**

**Genetic factors**
Sons of alcohol-dependent people who are adopted by other families are four times more likely to develop drinking problems than are the adopted sons of non-alcohol misusers. Genetic markers include the serotonin transported gene, dopamine-2 receptor allele A1, alcohol dehydrogenase subtypes and monoamine oxidase B activity, but they are not specific.

Environmental factors
Childhood maltreatment increases the risk of subsequent alcohol dependence and this rises if there is also a history of parental alcohol dependence or other substance misuse.

Biochemical factors
Several factors have been suggested, including abnormalities in alcohol dehydrogenase, neurotransmitter substances and brain amino acids, such as GABA. There is no conclusive evidence that these or other biochemical factors play a causal role.

Psychiatric illness
This is an uncommon cause of addictive drinking but it is a treatable one. Some depressed patients drink excessively in the hope of raising their mood. People with anxiety states or phobias are also at risk.

Excess consumption in society
The prevalence of alcohol dependence and problems correlates with the general level (per capita consumption) of alcohol use in a society. This, in turn, is determined by factors that may control overall consumption, including price, licensing laws, availability, and the societal norms concerning the use and misuse of alcohol.

Management

Psychological management of problem drinking
Successful identification at an early stage can be a helpful intervention in its own right. It should lead to:

• the provision of information concerning safe drinking levels
• a recommendation to cut down where indicated
• simple support and advice concerning associated problems.

Such a brief intervention is effective in its own right. Successful alcohol misuse treatment involves motivational enhancement (motivational therapy), feedback, education about the adverse effects of alcohol, and agreed drinking goals. A motivational approach is based on five stages of change: pre-contemplation, contemplation, determination, action and maintenance. The therapist uses motivational interviewing and reflective listening to allow the patient to persuade himself along the five stages to change.

This technique, CBT and 12-step facilitation (as used by Alcoholics Anonymous, AA) have
all been shown to reduce harmful drinking. With addictive drinking, self-help group therapy, which involves long-term support by fellow members of the group (e.g. AA), is helpful in maintaining abstinence. Family and marital therapy involving both the alcohol misuser and spouse may also be helpful. Families of drinkers find meeting others in a similar situation helpful (Al-Anon).

Drug treatments for problem drinking

Alcohol withdrawal and DTs

Addicted drinkers often experience considerable difficulty when they attempt to reduce or stop their drinking. Withdrawal symptoms are a particular problem and delirium tremens needs urgent treatment (Box 22.40). In the absence of DTs, alcohol withdrawal can be treated on an outpatient basis, using one of the fixed schedules in Box 22.40, so long as the patient attends daily for medication and monitoring, and has good social support. Outpatient schedules are sometimes given over 5 days. Long-term treatment with benzodiazepines should not be prescribed in those patients who continue to misuse alcohol. Some alcohol misusers add dependence on diazepam to their problems.

Box 22.40
Management of delirium tremens (DTs)

General measures

• Admit the patient to a medical bed.
• Correct electrolyte abnormalities and dehydration.
• Treat any co-morbid disorder (e.g. infection).
• Give parenteral thiamine slowly (250 mg daily for 3–5 days) in the absence of Wernicke–Korsakoff syndrome.
• Give parenteral thiamine slowly (500 mg daily for 3–5 days) with Wernicke–Korsakoff encephalopathy. Note: Beware anaphylaxis.
• Give prophylactic phenytoin or carbamazepine, if there is a previous history of withdrawal fits.

Specific drug treatment

• Give one of the following orally:
  – Diazepam 10–20 mg
  – Chlordiazepoxide 30–60 mg
• Repeat 1 h after the last dose, depending on response.

Fixed-schedule regimens
Drugs for prevention of alcohol dependence

*Naltrexone*, the opioid antagonist (50 mg per day), reduces the risk of relapse into heavy drinking and the frequency of drinking. *Acamprosate* (1–2 g/day) acts on several receptors, including those for GABA, noradrenaline (norepinephrine) and serotonin. There is reasonable evidence that it reduces drinking frequency. Neither drug seems particularly helpful in maintaining abstinence. The effects of both drugs are enhanced by combining them with counselling, but their moderate efficacy precludes regular use.

Drugs such as *disulfiram* react with alcohol to cause unpleasant acetaldehyde intoxication and histamine release. A daily maintenance dose means that the patient must wait until the disulfiram is eliminated from the body before drinking safely. There is mixed evidence of efficacy.

Oral thiamine (300 mg/day) can prevent Wernicke–Korsakoff syndrome (see p. 885) in heavy drinkers.

**Prognosis**

Research suggests that 30–50% of alcohol-dependent drinkers are abstinent or drinking very much less up to 2 years following traditional intervention. The long-term outcome of patients treated with the latest psychological and pharmacological therapies remains uncertain.

**Further reading**

**Drug Misuse and Dependence**

In addition to alcohol and nicotine, there are a number of psychotropic substances that are taken for their effects on mood and other mental functions (*Box 22.41*).

**Box 22.41**

Commonly used drugs of misuse and dependence

**Stimulants**

• Methylphenidate
Phenmetrazine
Phencyclidine (‘angel dust’)
Cocaine
Amfetamine derivatives
Ecstasy (MDMA)

**Hallucinogens**
- Cannabis preparations
- Solvents
- Lysergic acid diethylamide (LSD)
- Mescaline

**Narcotics**
- Morphine
- Heroin
- Codeine
- Pethidine
- Methadone

**Tranquillizers**
- Barbiturates
- Benzodiazepines

---

**Aetiology of drug misuse**

There is no single cause of drug misuse and/or dependence. Three factors appear commonly, in a similar way to alcohol problems:

- the availability of drugs
- a vulnerable personality
- social pressures, particularly from peers.

Once regular drug-taking is established, pharmacological factors determine dependence.

---

**Drugs of misuse and their effects**

**Inhaled substances**

Some 1% of adolescents in the UK sniff solvents such as glue for their intoxicating effects. Tolerance develops over weeks or months. Intoxication is characterized by euphoria, excitement, a floating sensation, dizziness, slurred speech and ataxia. Acute intoxication can
cause amnesia and visual hallucinations.

Nitric oxide (laughing gas) is also popular in the UK.

**Amfetamines and related substances**

These have temporary stimulant and euphoriant effects that are followed by fatigue and depression, the latter sometimes prolonged for weeks. Psychological rather than true physical dependence occurs with amphetamine sulphate (‘speed’). Methyl amphetamine, also known as ‘methamphetamine’ or ‘crystal meth’, is another amphetamine psychostimulant. The particularly high potential for abuse is associated with the activation of neural reward mechanisms involving nucleus accumbens dopamine release.

In addition to a manic-like presentation, amphetamines can produce a paranoid psychosis indistinguishable from schizophrenia.

‘Ecstasy’ (also known as E, white burger or white dove) is the street name for 3,4-methylenedioxy-metamfetamine (MDMA), a psychoactive phenylisopropylamine, synthesized as an amphetamine derivative. It is a psychedelic drug, which is often used as a ‘dance drug’. It has a brief duration of action (4–6 h). Deaths have been reported from malignant hyperpyrexia and dehydration. Acute renal and liver failure can occur.

**Cocaine**

Cocaine (see pp. 73–74) is a central nervous system stimulant (with similar effects to amphetamines), derived from *Erythroxylon coca* trees grown in the Andes. In purified form, it may be taken by mouth, or snorted or injected. If cocaine hydrochloride is converted to its base (‘crack’), it can be smoked. This causes an intense stimulating effect, and ‘free-basing’ is common. Compulsive use and dependence occur more frequently among users who are free-basing. Dependent users take large doses and alternate between withdrawal phenomena of depression, tremor and muscle pains, and the hyper-arousal produced by increasing doses. Prolonged use of high doses produces irritability, restlessness, paranoid ideation and, occasionally, convulsions. Persistent sniffing of the drug can cause perforation of the nasal septum. Overdoses cause death through myocardial infarction, cerebrovascular disease, hyperthermia and arrhythmias (see pp. 73–74).

**Hallucinogenic drugs**

Hallucinogenic drugs, such as lysergic acid diethylamide (LSD) and mescaline, produce distortions and intensifications of sensory perceptions, as well as frank hallucinations in acute intoxication. Psychosis is a long-term complication.

**Cannabis**

Cannabis (also known as grass, pot, skunk, spliff or marijuana) is a widely used drug in some sub-cultures. It is derived from the dried leaves and flowers of the plant *Cannabis sativa*. It can cause tolerance and dependence. Hashish is the dried resin from the flower tops, whilst marijuana refers to any part of the plant. The drug, when smoked, seems to exaggerate the pre-
existing mood, be it depression, euphoria or anxiety. It has specific analgesic properties. Cannabis use, especially of the more potent ‘skunk’, has increased in the UK. An amotivational syndrome with apathy and memory problems has been reported with chronic daily use. Cannabis may, of itself, sometimes cause psychosis in the right circumstances (see below).

Tranquillizers

Drugs that cause dependence include barbiturates and benzodiazepines. Benzodiazepine dependence is common and may be iatrogenic, when the drugs are prescribed and not discontinued. Discontinuing treatment with benzodiazepines may cause withdrawal symptoms (see Box 22.35). For this reason, withdrawal should be supervised and gradual.

Opiates

Physical dependence occurs with morphine, heroin and codeine, as well as with synthetic and semi-synthetic opiates such as methadone, pethidine and fentanyl. These substances display cross-tolerance – the withdrawal effects of one are reduced by administration of another. The psychological effects of opiates are a calm, slightly euphoric mood associated with freedom from physical discomfort and a flattening of emotional response. This is believed to be due to the attachment of morphine and its analogues to endorphin receptors in the central nervous system. Tolerance to this group of drugs is rapidly developed and marked, but is quickly lost following abstinence. The opiate withdrawal syndrome consists of a constellation of signs and symptoms (Box 22.42) that reaches peak intensity on the second or third day after the last dose of the opiate. These rapidly subside over the next 7 days. Withdrawal is dangerous in people with heart disease or other chronic debilitating conditions.

Box 22.42

Opiate withdrawal syndrome

12–16 h after last dose of opiate

- Yawning
- Rhinorrhea
- Lacrimation
- Pupillary dilatation
- Sweating
- Piloerection
- Restlessness

24–72 h after last dose of opiate

- Muscular twitches
- Aches and pains
- Abdominal cramps
- Vomiting
- Diarrhoea
- Hypertension
- Insomnia
- Anorexia
- Agitation
- Profuse sweating
Opiate addicts have a relatively high mortality rate, owing to both the ease of accidental overdose and the blood-borne infections associated with shared needles. Heart disease (including infective endocarditis), tuberculosis and AIDS are common causes of death, while the complications of hepatitis B and C are also common.

**Management of chronic misuse**

Blood and urine screening for drugs is required in circumstances where drug misuse is suspected (see Box 22.41). When a patient with an opiate addiction is admitted to hospital for another health problem, advice should be sought from a psychiatrist or drug misuse clinic regarding management of their addiction while an inpatient.

The treatment of chronic dependence is directed towards helping the patient either to live without drugs, or to regularize and control use, and to prevent secondary ill-health. Patients need help and advice in order to avoid a withdrawal syndrome. Some people with opiate addiction who cannot manage abstinence may be maintained on oral methadone. In the UK, only specially licensed doctors may legally prescribe heroin and cocaine to an addict for maintenance treatment of addiction. An overdose should be treated immediately with the opioid antagonist naloxone. Injectable diacetylmorphine, the active ingredient in heroin, has been proposed as a more effective alternative to methadone but adverse effects (accidental overdose and seizures) remain a potential concern.

**Drug-induced psychosis**

Drug-induced psychosis has been reported with amphetamines and its derivatives, and with cocaine and hallucinogens. It can occur acutely after drug use but is more usually associated with chronic misuse. Psychoses are characterized by vivid hallucinations (usually auditory, but often occurring in more than one sensory modality), misidentifications, delusions and/or ideas of reference (often of a persecutory nature), psychomotor disturbances (excitement or stupor) and an abnormal affect. For diagnosis, ICD-10 requires the condition to occur within 2 weeks and usually within 48 h of drug use, and to persist for more than 48 h but not more than 6 months.

Cannabis use can result in anxiety, depression or hallucinations. Manic-like psychoses occurring after long-term cannabis use have been described but seem more likely to be related to the toxic effects of heavy ingestion. Evidence suggests that the risk of psychosis is significantly raised in those using cannabis at an early age (before, as compared to after, 15 years) and on a daily basis. High-potency cannabis (‘skunk’) is associated with an increased risk. A meta-analysis suggests that daily cannabis use doubles the risk of psychosis, and that 14% of schizophrenia in the UK would be prevented if cannabis use ceased.

Degenhardt L, Hall W. Extent of illicit drug use and dependence, and their contribution to

---

**Schizophrenia**

The group of illnesses conventionally referred to as ‘schizophrenia’ is diverse in nature and covers a broad range of perceptual, cognitive and behavioural disturbances. The point prevalence of the condition is 0.5% throughout the world, with equal gender distribution. A non-psychiatrist primarily needs to know how to recognize schizophrenia, what problems it might present with in the general hospital, and how it is treated.

---

**Aetiology**

No single cause has been identified. Schizophrenia is likely to be a disease of neurodevelopmental disconnection caused by an interaction of genetic and multiple environmental factors that affect brain development. It is likely that daily cannabis use is a risk factor. The genetic aetiology is likely to be polygenic and non-mendelian; a recent very large study suggests there are about 100 single nucleotide polymorphisms that are associated. Schizophrenia has a heritability of about 60%. Functional neuroimaging studies and histology point towards alterations in prefrontal and, less consistently, temporal lobe function, with enlarged lateral ventricles and disorganized cytoarchitecture in the hippocampus, supporting the neurodevelopmental theory of aetiology. Dopamine excess (D₂) is the oldest and most widely accepted neurochemical hypothesis, although this may explain only one group of symptoms (the positive ones). The cognitive impairments in schizophrenia may be related to dopamine D₁ abnormalities. The interaction between serotonergic and dopaminergic systems is likely to play a role, although direct evidence is lacking. Additional hypotheses involving glutamate (NMDA) and GABA systems are under scrutiny.
Clinical features

The illness can begin at any age but is rare before puberty. The peak age of onset is the early twenties. The symptoms that are diagnostic of the condition have been termed **first-rank symptoms** and were described by the German psychiatrist Kurt Schneider. They consist of:

- **auditory hallucinations** in the third person and/or voices commenting on the patient's behaviour
- **thought withdrawal**, insertion and broadcast
- **primary delusion** (arising out of nothing)
- **delusional perception**
- **somatic passivity and feelings** – patients believe that their thoughts, feelings or acts are controlled by others.

The more of these symptoms a patient has, the more likely it is that the diagnosis is schizophrenia, but these symptoms may also occur in other psychoses.

Other symptoms of **acute schizophrenia** include behavioural disturbances, other hallucinations, secondary (usually persecutory) delusions and blunting of mood. Schizophrenia is sometimes divided into ‘positive’ (type 1) and ‘negative’ (type 2) types:

- **Positive schizophrenia** is characterized by acute onset, prominent delusions and hallucinations, normal brain structure, a biochemical disorder involving dopaminergic transmission, a good response to neuroleptics, and a better outcome.
- **Negative schizophrenia** is characterized by a slow, insidious onset, a relative absence of acute symptoms, the presence of apathy, social withdrawal, lack of motivation, underlying brain structure abnormalities and poor neuroleptic response.

**Chronic schizophrenia** is characterized by its long duration and by the ‘negative’ symptoms of underactivity, lack of drive, social withdrawal and emotional emptiness.

Differential diagnosis

Schizophrenia should be distinguished from:

- organic mental disorders (e.g. partial complex epilepsy)
- mood (affective) disorders (e.g. mania)
- drug psychoses (e.g. amphetamine psychosis)
- personality disorders (schizotypal).

In older patients, any acute or chronic brain syndrome can present in a schizophrenia-like manner. A helpful diagnostic point is the fact that altered consciousness and disturbances of memory do not occur in schizophrenia, and visual hallucinations are unusual.

A **schizoaffective psychosis** describes a clinical presentation in which clear-cut affective and schizophrenic symptoms coexist in the same episode.
Management

The best results are obtained by combining drug and social treatments.

Antipsychotic (neuroleptic) drugs

These act by blocking the $\text{D}_1$ and $\text{D}_2$ groups of dopamine receptors. Such drugs are most effective against acute, positive symptoms and are least effective in the management of chronic, negative symptoms. Complete control of positive symptoms can take up to 3 months, and premature discontinuation of treatment can result in relapse.

As antipsychotic drugs block both $\text{D}_1$ and $\text{D}_2$ dopamine receptors, they usually produce extrapyramidal adverse effects. This limits their use in the maintenance therapy of many patients. They also block adrenergic and muscarinic receptors and thereby cause a number of unwanted effects (Box 22.43).

Box 22.43

Unwanted effects of antipsychotic drugs

Motor
- Acute dystonia
- Parkinsonism
- Akathisia (motor restlessness)
- Tardive dyskinesia

Autonomic
- Hypotension
- Failure of ejaculation

Antimuscarinic
- Dry mouth
- Urinary retention
- Constipation
- Blurred vision

Metabolic
- Weight gain

Others
- Precipitation of glaucoma
- Galactorrhoea (due to hyperprolactinaemia)
• Amenorrhoea
• Cardiac arrhythmias
• QTc interval prolongation
• Seizures
• Leucopenia
• Cholestatic jaundice
• Skin reactions
• Hypersensitivity

The frequency and type of side effects will depend upon the choice of antipsychotic agent and its dose.

**Neuroleptic malignant syndrome**
This is an infrequent but potentially dangerous adverse effect. Neuroleptic malignant syndrome is a medical emergency and should be managed by medical admission. It occurs in 0.2% of patients on neuroleptic drugs, particularly the potent dopaminergic antagonists, such as haloperidol. Symptoms occur a few days to a few weeks after starting treatment and consist of hyperthermia, muscle rigidity, autonomic instability (tachycardia, labile blood pressure, pallor) and a fluctuating level of consciousness. Investigations show a raised creatine kinase, raised white cell count and abnormal liver biochemistry. The more severe consequences include acute kidney injury, pulmonary embolus and death. Treatment consists of stopping the drug and general resuscitation measures, such as temperature reduction. Bromocriptine enhances dopaminergic activity and dantrolene will reduce muscle tone but no treatment has proven benefit.

**Pregnancy**
Data on the potential teratogenicity of antipsychotic (neuroleptic) medications are still limited. The disadvantages of not treating during pregnancy have to be balanced against possible developmental risks to the fetus. The butyrophenones (e.g. haloperidol) are probably safer than the phenothiazines, such as chlorpromazine. Subsequent management decisions relating to dosage will depend primarily on the ability to avoid adverse effects, since the antiparkinsonian agents are still believed to be teratogenic and should be avoided.

**Typical or first-generation antipsychotics**
**Phenothiazines** were the first group of antipsychotics to be developed but are used less frequently now. Chlorpromazine (100–1000 mg daily) is the drug of choice when a more sedating drug is required. Trifluoperazine is used when sedation is undesirable. Fluphenazine decanoate is used as a long-term prophylactic to prevent relapse, as a depot injection (25–100 mg i.m. every 1–4 weeks). **Butyrophenones** (e.g. haloperidol 2–15 mg daily) are also powerful antipsychotics, and are used in the treatment of acute schizophrenia and mania. They
are likely to cause a dystonia and/or extrapyramidal adverse effects, but are much less sedating than the phenothiazines.

**Atypical antipsychotics or serotonin dopamine antagonists**

Atypical antipsychotics or serotonin dopamine antagonists (SDAs), also referred to as the ‘second-generation antipsychotics’, are ‘atypical’ in that they block D₂ receptors less than D₁, and thus cause fewer extrapyramidal adverse effects and less tardive dyskinesia. They are now recommended as first-line drugs for newly diagnosed schizophrenia and for patients taking typical antipsychotics who are experiencing significant adverse effects.

*Risperidone* is a benzisoxazole derivative with combined dopamine D₂ receptor and 5-HT₂A-receptor blocking properties. Dosage ranges from 6 to 10 mg/day. The drug is not markedly sedative and the overall incidence and severity of extrapyramidal adverse effects is lower than with more conventional antipsychotics. Hyperprolactinaemia can be problematic and prolactin levels should be monitored. Paliperidone is an active metabolite of risperidone, available in oral and depot (4-weekly) preparations.

*Olanzapine* has affinity for 5-HT₂, D₁, D₂, D₄ and muscarinic receptor sites. Clinical studies indicate that it has a lower incidence of extrapyramidal adverse effects. The apparent better compliance with the drug may be related to its lower side-effect profile and its once-daily dosage of 5–15 mg. Weight gain is a problem with long-term treatment and there is an increased risk of type 1 diabetes mellitus with this and other atypical drugs.

**Other atypical antipsychotics** include amisulpride, lurasidone, sulpiride, zotepine, ziprasidone and quetiapine, the latter causing less hyperprolactinaemia. Those taking atypical antipsychotics should have regular monitoring of their body mass index, cholesterol levels, blood sugar and QTc interval on ECG. No more than one antipsychotic should be prescribed routinely. Neither risperidone nor olanzapine seems as specific a treatment for intractable chronic schizophrenia as clozapine.

*Clozapine* is used in patients who have intractable schizophrenia and have failed to respond to at least two conventional antipsychotic drugs; alternatively, it may be used as first-line therapy. This drug is a dibenzodiazepine with a relative high affinity for D₄ dopamine receptors, as compared with D₁, D₂, D₃ and D₅, in addition to muscarinic and α-adrenergic receptors. It acts additionally as a partial agonist at 5-HT₁A receptors, which may be of benefit in treating the ‘negative’ symptoms of psychosis. Functional brain scans have shown that clozapine selectively blocks limbic dopamine receptors more than striatal ones, which is probably why it causes considerably fewer extrapyramidal adverse effects. Clozapine exercises a strong therapeutic effect on both intractable positive and negative symptoms. However, it is expensive and produces severe agranulocytosis in 1–2% of patients. Therefore, in the UK, for example, it can only be prescribed to registered patients by doctors and pharmacists registered with a patient-monitoring service. The starting dose is 25 mg per day with a maintenance dose of 150–300 mg daily. White cell counts should be monitored weekly for 18 weeks and then 2-weekly for the length of treatment. In addition to its antipsychotic
actions, clozapine may also help reduce aggressive and hostile behaviour and the risk of suicide. It can cause considerable weight gain and sialorrhoea. There is an increased risk of diabetes mellitus, and gastrointestinal hypomotility resulting in a functional obstruction has also been reported.

**Psychological management**

This consists of reassurance, support and a good doctor–patient relationship. Psychotherapy of an intensive or exploratory kind is contraindicated. In contrast, individual CBT may have some efficacy, particularly in those who decline drug treatment.

**Social management**

Social treatment involves attention being paid to the patient's environment and social functioning. Family education can help relatives and partners to provide the optimal amount of emotional and social stimulation, so that not too much emotion is expressed (a risk for relapse). Over 90% of patients are unemployed but sheltered employment can be helpful. Assertive outreach mental health teams will follow up those adhering poorly to treatment.

**Medical presentations related to treatment**

The motor adverse effects of neuroleptics are the most common reason for a patient with schizophrenia to present to a physician, followed by self-harm. *Acute dystonia* normally arises in patients newly started on neuroleptics, causing torticollis. *Extrapyramidal adverse effects* are common and present in the same way as Parkinson's disease. They remit once the drug is stopped and on use of antimuscarinic drugs, such as procyclidine. *Akathisia* is motor restlessness, most commonly affecting the legs. It is similar to the restless legs syndrome but is apparent during the day. *Amenorrhoea* and *galactorrhoea* can be caused by dopamine antagonists. Postural hypotension can affect the elderly, and neuroleptics can be the cause of delirium in this age group, if their antimuscarinic effects are prominent.

Long-term benefits outweigh the risks in most cases, and long-term treatment is associated with a lower mortality rate when compared with no treatment. In this respect, the atypical antipsychotics are preferable to the typical antipsychotics and clozapine is the class leader.

**Prognosis**

The prognosis of schizophrenia is variable: 15–25% of people with schizophrenia recover completely, about 70% will have relapses and may develop mild to moderate negative symptoms, and about 20% will remain seriously disabled. There is some evidence that early drug treatment improves prognosis.

**Further reading**

Organic Mental Disorders

Organic brain disorders result from structural pathology, as in dementia (see pp. 874–879), or from disturbed central nervous system function, as in fever-induced delirium.

Delirium

Delirium, also termed toxic confusional state and acute organic psychosis, is an acute or subacute brain failure in which impairment of attention is accompanied by abnormalities of perception and mood. It is the most common psychosis seen in the general hospital setting, where it occurs in 14–24% of patients. This figure rises in specialist populations such as intensive care patients. Agitation is usually worse at night, with consequent sleep reversal, so that the patient is asleep in the day and awake all night. In addition to an agitated, ‘hyperactive’ presentation, a hypoactive variant is also recognized and is thought to represent a worse prognosis in the elderly. Most cases will demonstrate a fluctuation between these two psychomotor forms. During the acute phase, thought and speech are incoherent, memory is impaired and misperceptions occur. Episodic visual hallucinations (or illusions) and persecutory delusions occur. As a consequence, the patient may be frightened, suspicious, restless and uncooperative.

A developing, deteriorating or damaged brain predisposes a patient to develop delirium (Box 22.44). A large number of diseases may cause delirium, particularly in elderly patients, such that it is wise to assess for delirium in patients over 65 years who are admitted to hospital. Some causes of delirium are listed in Box 22.45. Delirium tremens should be considered in the differential diagnosis (see p. 921), as well as Lewy body dementia (pp. 877–878). Diagnostic criteria are given in Box 22.46.

Box 22.44

Predisposing factors in delirium

- Extremes of age (developing or deteriorating brain)
- Damaged brain:
  - Any dementia (most common predisposition)
  - Previous head injury
  - Alcohol brain damage
  - Previous stroke
- Dislocation to an unfamiliar environment (e.g. hospital admission)
- Sleep deprivation
- Sensory extremes (overload or deprivation)
- Immobilization
- Visual or hearing impairment

**Box 22.45**

**Some common causes of delirium**

- **Systemic infection:**
  - Any infection, particularly with high fever (e.g. malaria, septicaemia)
- **Metabolic disturbance:**
  - Hepatic failure
  - Chronic kidney disease
  - Disorders of electrolyte balance, dehydration
  - Hypoxia
- **Vitamin deficiency:**
  - Thiamine (Wernicke–Korsakoff syndrome, beriberi)
  - Nicotinic acid (pellagra)
  - Vitamin B<sub>12</sub>
- **Endocrine disease:**
  - Hypothyroidism
  - Cushing syndrome
- **Intracranial causes:**
  - Trauma
  - Tumour
  - Abscess
  - Subarachnoid haemorrhage
  - Epilepsy
- **Drug intoxication:**
  - Anticonvulsants
  - Antimuscarinics
  - Anxiolytics/hypnotics
  - Tricyclic antidepressants
  - Dopamine agonists
  - Digoxin
- **Drug/alcohol withdrawal**
- **Postoperative states**
Box 22.46

**Delirium: diagnostic criteria**

- Disturbance of consciousness:
  - ↓Clarity of awareness of environment
  - ↓Ability to focus, sustain or shift attention
- Change in cognition:
  - Memory deficit, disorientation, language disturbance, perceptual disturbance
- Disturbance develops over a short period (hours or days)
- Fluctuation over the course of a day

*Derived from Diagnostic and Statistical Manual of the American Psychiatric Association, 5th edn: text revision (DSM-5).*

**Management**

History should be taken from a witness. Examination may reveal the cause. Investigation and treatment of the underlying physical disease should be undertaken (see Box 22.45). The patient should be carefully nursed and rehydrated in a quiet single room with a window that does not allow exits. If a high fever is present, the patient's temperature should be reduced. All current drug therapy should be reviewed and, where possible, stopped. If they are needed, ensure that patients have hearing aids, glasses and dentures. Psychoactive drugs should be avoided if possible (because of their own risk of exacerbating delirium). In severe delirium, haloperidol is an effective choice, the daily dose usually ranging between 1.5 mg (in the elderly) and 20 mg per day. Benzodiazepines should not be used as first-line medication and may prolong confusion. If necessary, the first dose can be administered intramuscularly. Olanzapine is an effective alternative, especially if given at night for insomnia.

**Prognosis**

Delirium usually clears within a week or two, but brain recovery usually lags behind recovery from the causative physical illness. The prognosis depends not only on the successful treatment of the causative disease, but also on the underlying state of the brain. Some 25% of the elderly with delirium will have an underlying dementia; 15% of patients do not survive their underlying illness; 40% are in institutional care at 6 months. Mortality rates are raised in patients with delirium in the 18 months after admission and this is greatest in those who present to emergency departments with the diagnosis.

**Further reading**
Eating Disorders

Obesity
Obesity is the most common eating disorder (see pp. 206–212) and has become epidemic in many developed countries. It is usually caused by a combination of constitutional and social factors, but a binge eating disorder and psychological determinants of ‘comfort eating’ should be excluded.

Anorexia nervosa
Case register data suggest an incidence rate of 19/100 000 females aged between 15 and 34 years. Surveys have suggested a prevalence rate of approximately 1% among schoolgirls and university students. However, many more young women have amenorrhoea accompanied by less weight loss than the 15% required for the diagnosis of anorexia nervosa. The condition is much less common among men (ratio of 1:10).

Clinical features
The main clinical criteria for diagnosis are shown in Box 22.47. Clinical features include the following:

- Onset is usually in adolescence.
- There is a previous history of faddish eating.
- The patient generally eats little, yet is obsessed by food.
- Exercising is excessive.

Box 22.47
Clinical criteria for anorexia nervosa

- Body weight >15% below the standard weight or a body mass index <17.5 kg/m² (ICD-10)
- Self-induced weight loss: avoidance of fattening foods, vomiting, purging, exercise or
appetite suppressants

- Distortion of body image, i.e. patients regard themselves as fat when they are thin
- Morbid fear of fatness
- Amenorrhea in women

ICD-10, *Classification of Mental and Behavioural Disorders*, 10th edn.

The physical consequences of anorexia include sensitivity to cold, constipation, hypotension and bradycardia. In most cases, amenorrhea is secondary to the weight loss. In those who also binge and vomit or abuse purgatives, there may be hypokalaemia and alkalosis.

## Aetiology

### Biological factors

#### Genetic

Some 6–10% of female siblings of affected women suffer from anorexia nervosa. There is an increased concordance amongst monozygotic twins, suggesting a genetic predisposition.

#### Hormonal

The reductions in sex hormones and downregulation of the hypothalamic–pituitary–adrenal axis are secondary to malnutrition and usually reversed by refeeding.

### Psychological factors

#### Individual

Anorexia nervosa has often been seen as an escape from the emotional problems of adolescence and a regression into childhood. Patients will often have had dietary problems in early life. Perfectionism and low self-esteem are common antecedents. Studies suggest that survivors of childhood sexual or other abuse are at greater risk of developing an eating disorder, usually anorexia nervosa, in adolescence.

#### Family

Family problems are most commonly secondary to the stress of coping with a family member with the illness.

#### Social and cultural factors

There is a higher prevalence in higher social classes, Westernized families, certain occupational groups (e.g. ballet dancers and nurses) and societies where cultural value is placed on thinness.
Management

Treatment can be conducted on an outpatient basis, unless the weight loss is severe and accompanied by marked cardiovascular signs and/or electrolyte and vitamin disturbances. Hospital admission may then be unavoidable and may need to be on a medical ward initially. Uncommonly, the patient's weight loss may be so severe as to be life-threatening. If the patient cannot be persuaded to enter hospital, compulsory admission may have to be used. Inpatient treatment goals include:

• establishing a therapeutic relationship with both the patient and her family
• restoring the weight to a level between the ideal body weight and the patient's ideal weight
• providing a balanced diet, aimed at gaining 0.5–1 kg weight per week
• eliminating purgative and/or laxative use and vomiting.

Outpatient treatment should include cognitive behavioural or interpersonal psychotherapies. Setting up a therapeutic alliance is vital. Family therapy is more effective than individual psychotherapy in adolescents and those still at home, and less effective in those who have left home. Motivational enhancement techniques are being used with some success.

Drug treatment has met with limited success, and those drugs that increase the QTc interval should be avoided. Vitamins and minerals may need replacement.

Prognosis

The condition runs a fluctuating course, with exacerbations and partial remissions. Long-term follow-up suggests that about two-thirds of patients maintain normal weight and that the remaining one-third are split between those who are moderately underweight and those who are seriously underweight. Indicators of a poor outcome include:

• a long initial illness
• severe weight loss
• older age at onset
• bingeing and purging
• personality difficulties
• difficulties in relationships.

Suicide has been reported in 2–5% of people with chronic anorexia nervosa. The mortality rate per year is 0.5% from all causes. The illness can quickly cause osteopenia, and later osteoporosis. More than one-third have recurrent affective illness, and various family, genetic and endocrine studies have found associations between eating disorders and depression.

Bulimia nervosa

This refers to episodes of uncontrolled excessive eating, which are also termed 'binges',
accompanied by means to lose weight. There is a preoccupation with food and habitual behaviours to avoid the fattening effects of periodic binges. These behaviours include:

- self-induced vomiting
- misuse of drugs – laxatives, diuretics, thyroid extract or anorectics.

Additional clinical features are shown in **Box 22.48.**

**Box 22.48**

**Clinical features of bulimia nervosa**

- Physical complications of vomiting:
  - Cardiac arrhythmias
  - Renal impairment
  - Muscular paralysis
  - Tetany – from hypokalaemic alkalosis
  - Swollen salivary glands – from vomiting
  - Eroded dental enamel
- Associated psychiatric disorders:
  - Depressive illness
  - Alcohol misuse
- Fluctuations in body weight within normal limits
- Menstrual function – periods irregular but amenorrhoea is rare
- Personality – perfectionism and/or low self-esteem present premorbidly

The lifetime prevalence of bulimia ranges between 3% and 7% for women. Bulimia is sometimes associated with anorexia nervosa. A premorbid history of dieting is common. The prognosis for bulimia nervosa is better than that for anorexia nervosa.

**Management**

Individual CBT is more effective than both interpersonal psychotherapy and drug treatments. SSRIs (e.g. fluoxetine) are also an effective treatment, even in the absence of a depressive illness, but may require high doses.

**Atypical eating disorders**

These include eating disorders that do not conform clinically to the diagnostic criteria for anorexia nervosa or bulimia nervosa. **Binge eating disorders (BEDs)** consist of bulimia without the vomiting and other weight-reducing strategies. The new DSM-5 considers binge eating disorder as a separate diagnosis, characterized by discrete episodes of significant over-
eating combined with a sense of having no control over eating during these episodes. Periods of binging need to be present at least once a week over a period of 3 months or more. ICD-10 continues to consider the diagnosis as an otherwise undefined eating disorder. Management strategies include self-help programmes and CBT, which are often combined with an SSRI.

**Sexual Disorders**

Sexual disorders can be divided into sexual dysfunctions and deviations, and gender role disorders (*Box 22.49*).

---

**Box 22.49**

**Classification of sexual disorders**

**Sexual dysfunction**

*Affecting sexual desire*

- Low libido

*Impaired sexual arousal*

- Erectile dysfunction
- Failure of arousal in women

*Affecting orgasm*

- Premature ejaculation
- Retarded ejaculation
- Orgasmic dysfunction in women

**Sexual deviations**

*Variations of the sexual ‘object’*

- Fetishism
- Transvestism
- Paedophilia
- Bestiality
- Necrophilia
Variations of the sexual act
- Exhibitionism
- Voyeurism
- Sadism
- Masochism
- Frotteurism

Disorders of the gender role
- Transsexualism

Sexual dysfunction
Sexual dysfunction in men refers to the repeated inability to achieve normal sexual intercourse, whereas in women it refers to a repeatedly unsatisfactory quality of sexual satisfaction. Problems of sexual dysfunction can usefully be classified into those affecting sexual desire, arousal and orgasm.

Among men presenting for treatment of sexual dysfunction, erectile dysfunction is the most frequent complaint. The prevalence of premature ejaculation is low, except in young men, while ejaculatory failure is rare.

Common female problems include reduced libido, vaginismus and anorgasmia.

Sexual drive is affected by constitutional factors, ignorance of sexual technique, anxiety about sexual performance, medical and psychiatric conditions, and certain drugs (Boxes 22.50 and 22.51).

Box 22.50
Medical conditions affecting sexual performance

Endocrine
- Diabetes mellitus
- Hyperthyroidism
- Hypothyroidism

Cardiovascular
- Angina pectoris
- Previous myocardial infarction
- Disorders of peripheral circulation

Hepatic
• Cirrhosis, particularly alcohol-related

**Renal**
• Chronic kidney disease

**Neurological**
• Neuropathy
• Spinal cord lesions

**Respiratory**
• Asthma
• Chronic obstructive pulmonary disease

**Psychiatric**
• Depressive illness
• Substance misuse

---

**Box 22.51**

**Drugs affecting sexual arousal**

**Male arousal**
• Alcohol
• Benzodiazepines
• Neuroleptics
• Cimetidine
• Opiate analgesics
• Methyldopa
• Clonidine
• Spironolactone
• Antihistamines
• Metoclopramide
• Diuretics
• Beta-blockers
• Cannabis

**Female arousal**
• Alcohol
• Central nervous system depressants
• Antidepressants (SSRIs)
• Oral combined contraceptives
• Methyldopa
• Clonidine

*Alcohol increases the desire but diminishes the performance. SSRIs, selective serotonin reuptake inhibitors.

The treatment of sexual dysfunction involves careful assessment of both physical and psychosocial factors, the participation (where appropriate) of the patient's partner, sex education, and specific therapeutic techniques, including relaxation, behavioural therapy and couple therapy. The introduction of phosphodiesterase type 5 inhibitors (e.g. sildenafil) has provided an effective therapy for the treatment of erectile dysfunction (see p. 1217).

### Sexual deviation

Sexual deviations are regarded as unusual forms of behaviour rather than as an illness. Doctors are only likely to be involved when the behaviour involves breaking the law (e.g. paedophilia) and when there is a question of an associated mental or physical disorder. Men are more likely than women to have sexual deviations.

### Gender role disorders

Transsexualism involves a disturbance in gender identity in which the patient is convinced that their body is the wrong gender. A person's gender identity refers to the individual's sense of masculinity or femininity, as distinct from sex. There is increasing evidence that transsexualism is biologically determined, perhaps by prenatal endocrine influences, and functional brain imaging shows specific differences from normal controls.

For males, treatment includes oestrogen administration and, if surgery is to be recommended, a period of living as a woman as a trial beforehand. In the case of female transsexuals, treatment involves surgery and the use of methyltestosterone.

### Personality Disorders

These disorders comprise enduring patterns of behaviour that manifest themselves as inflexible responses to a broad range of personal and social situations. Personality disorders are developmental conditions that appear in childhood or adolescence and continue into adult life. Their prevalence is about 15% in the population. They are not secondary to another psychiatric disorder or brain disease, although they may precede or coexist with other disorders. In contrast, personality change is acquired, usually in adult life, following severe or prolonged stress, extreme environmental deprivation, serious psychiatric disorder or brain injury or
Personality disorders are usually subdivided according to clusters of traits that correspond to the most frequent or obvious behavioural manifestations, but many will show the characteristics of more than one category. The main categories of personality disorder are described in Box 22.52.

The main categories of personality disorder
<table>
<thead>
<tr>
<th>Category</th>
<th>Description</th>
</tr>
</thead>
</table>
| Borderline (emotionally unstable) | Impulsive actions  
Intense, short-lived emotional attachments  
Chronic internal emptiness  
Frequent self-harm  
Transient ‘pseudo’-psychotic features  
Strong family history of mood disorders |
| Paranoid                         | Extreme sensitivity  
Suspicion  
Litigiousness  
Self-importance  
Preoccupation with conspiracy theories |
| Schizoid                         | Emotional coldness and detachment  
Limited capacity to express emotions  
Indifference to praise or criticism  
Preference for solitary activities  
Lack of close friendships  
Marked insensitivity to social norms |
| Antisocial                       | Callous unconcern for the feelings of others  
Incapacity to maintain enduring relationships  
Very low tolerance of frustration  
Incapacity to experience guilt and to learn from experience  
Tendency to blame others |
| Histrionic                       | Self-dramatization, theatricality, suggestibility  
Shallow and labile emotions  
Continual seeking for excitement and appreciation  
Inappropriately seductive appearance and behaviour |
| Narcissistic                     | Inflated sense of self-importance  
Need to be admired  
Self-referential nature  
Arrogance |
| Anankastic (obsessional)         | Feelings of excessive doubt and caution  
Preoccupation with details, rules and order  
Perfectionism  
Excessive conscientiousness, scrupulousness, pedantry and rigidity |
| Dependent                        | Encouragement of others to make their personal decisions  
Subordination of their needs to others  
Unwillingness to make demands on others  
Feelings of inability to care for themselves  
Preoccupation with fears of being abandoned |

**Involuntary Detention or Commitment**

Involuntary detention in hospital is typically used as a last resort and treatment on an outpatient basis is preferable in most cases. The term describes the practice of *admitting or keeping a patient in hospital against their will*. This is done in compliance with the mental health legislation relevant to a particular country. Application for such a course of action may be made by a doctor (typically, but not always, a psychiatrist), social worker, psychologist or, in some instances, a police officer.

Mental health laws differ between countries and, in the case of the USA, also between states. However, in broad terms, the principles remain the same and are summarized in Box 22.53.
The basis of mental health laws for detention or commitment

1. The individual to be detained must be suffering from a defined mental disorder.
2. Detention is for the purposes of observation and refinement of the diagnosis and/or to actively treat the disorder (i.e. detention is a means to an end).
3. Attempts to treat the individual on an outpatient basis have failed.
4. The offer of a voluntary admission to hospital has been refused or is impractical.
5. Treatment in hospital is necessary:
   – because it will benefit the outcome of the illness
   – to protect the patient from harm (in terms of physical health, mental health, and abuse or manipulation at the hands of others)
   – to protect others from harm that the patient might cause them passively (neglect) or actively.

The potential for abuse of such ‘powers’ is a constant focal point for the review of such legislation. Although this is thankfully uncommon, the detention of individuals as a means to suppress dissent against regimes is well known.

Mental Capacity Act

Mental capacity is the ability to make decisions about all aspects of one's life, including, but not exclusively, healthcare. All doctors need to be able to assess mental capacity. In England and Wales, a new act was passed in 2005, which, for the first time, formally protects patients who lack capacity (see Boxes 1.4 and 22.54). Some 3% of people in the UK are thought to lack capacity due to conditions affecting brain function, such as dementia. However, the assessment of capacity is specific to an individual decision, so it is possible to have capacity to make one decision but not another. The assessment of capacity is outlined in Box 22.54. Capacity is assumed unless there is evidence to the contrary. In the absence of capacity, it is best to act in the best interests of the patient and provide the least restrictive management, after consulting the nearest relative or an independent advocate.

Assessment of mental capacity to make a decision

The patient has a demonstrated impairment or disturbance of their mind/brain and a demonstrated inability to do any of the following:

• Understand relevant information
• Retain that information for sufficient time to make the decision
• Use or weigh that information
• Communicate their decision

Anatomy, Physiology and Embryology of the Heart

Myocardial cells constitute 75% of the heart mass but only about 25% of the cell number. They are designed to perform two fundamental functions: initiation and conduction of electrical
impulses and contraction. Although most myocardial cells are able to perform both these functions, the vast majority are predominantly contractile cells (myocytes) and a small number are specifically designed as electrical cells. The latter, collectively known as the conducting system of the heart, are not nervous tissue but modified myocytes lacking in myofibril components. They have the ability to generate electrical impulses, which are then conducted to the myocytes, leading to contraction by a process known as excitation–contraction coupling. The rate of electrical impulse generation and the force of myocardial contraction are modified by numerous factors, including autonomic input and stretch.

Three epicardial coronary arteries supply blood to the myocardium, and a more complex network of veins is responsible for drainage. In the face of continuous arterial pressure fluctuations, blood vessels, especially in the cerebral circulation, maintain constant tissue perfusion by a process known as ‘autoregulation’; blood vessel control is, however, complex, involving additional local and central mechanisms.

The conduction system of the heart

The sinus node (sinoatrial node)

The sinus node is a complex, spindle-shaped structure that lies in the lateral and epicardial aspects of the junction between the superior vena cava and the right atrium (Fig. 23.1). Physiologically, it generates impulses automatically by spontaneous depolarization of its membrane at a rate quicker than any other cardiac cell type. It is therefore the natural pacemaker of the heart.

![The conducting system of the heart](image)

A number of factors are responsible for the spontaneous decay of the sinus node cell membrane potential (‘the pacemaker potential’), the most significant of which is a small influx of sodium ions into the cells. This small sodium current has two components: the background
inward ($I_b$) current and the ‘funny’ ($I_f$) current (or pacemaker current) (Fig. 23.2). The term ‘funny’ current denotes ionic flow through channels activated in hyperpolarized cells (−60 mV or greater), unlike other time- and voltage-dependent channels activated by depolarization. The rate of depolarization of the sinus node membrane potential is modulated by autonomic tone (i.e. sympathetic and parasympathetic input), stretch, temperature, hypoxia and blood pH and responds to other hormonal influences (e.g. tri-iodothyronine and serotonin).

Atrial and ventricular myocyte action potentials

Action potentials in the sinus node trigger depolarization of the atrial, and subsequently the ventricular, myocytes. These cells have a different action potential from that of sinus node cells (Fig. 23.2). Their resting membrane potential is a consequence of a small flow of potassium ions into the cells through open ‘inward rectifier’ channels ($I_{Kr}$); at this stage, sodium and calcium channels are closed. The arrival of adjacent action potentials triggers the opening of voltage-gated, fast, self-inactivating sodium channels, resulting in a sharp depolarization spike. This is followed by a partial repolarization of the membrane due to activation of ‘transient outward’ potassium channels.

The plateau phase that follows is unique to myocytes and results from a small, but sustained, inward calcium current through L-type calcium channels ($I_{CaL}$) lasting 200–400 ms. This calcium influx is caused by a combined increase in permeability of the cell, especially the sarcolemmal membranes to calcium (Fig. 23.3). This plateau (or refractory) phase in myocyte action potential prevents early reactivation of the myocytes and directly determines the strength of contraction. The gradual inactivation of the calcium channels activates delayed rectifier potassium channels ($I_K$), repolarizing the membrane. Atrial tissue is activated like a ‘forest fire’, but the activation peters out when the insulating layer between the atrium and the ventricle – the annulus fibrosus – is reached. Controversy exists about whether impulses from the sinoatrial (SA) node travel over specialized conducting ‘pathways’ or over ordinary atrial myocardium.
FIGURE 23.3 The ‘complete’ cardiac cell. (a) Spontaneous depolarization in sinus node cells, due to sodium (Na) influx through the ‘funny’ current, generates the ‘pacemaker’ potential. (b) This activates other atrial and ventricular myocytes, triggering action potentials and activating L-type calcium (Ca) channels in the surface and transverse tubule membranes (at the top and bottom of the figure). (c) The resulting Ca influx acts on Ca-induced Ca release channels (RyR2) on the sarcoplasmic reticulum (SR); this causes the release of stored Ca, which acts on actin and myosin fibrils, leading to contraction. Ca reuptake pumps in the SR, regulated by phospholamban, replenish the stores; various exchange pumps also expel Ca from the cell. (d) Autonomic input has either a positive chronotropic/inotropic effect ($\beta_1$ receptors) or a negative chronotropic/inotropic effect (muscarinic receptors). AMP, adenosine monophosphate; ATPase, adenosine triphosphatase.

The atrioventricular node, His bundle and Purkinje fibres

The depolarization continues to conduct slowly through the atrioventricular (AV) node. This is a small, bean-shaped structure that lies beneath the right atrial endocardium within the lower interatrial septum. The AV node continues as the His bundle, which penetrates the annulus fibrosus and conducts the cardiac impulse rapidly towards the ventricle. The His bundle reaches the crest of the interventricular septum and divides into the right bundle branch and the main left bundle branch.

The right bundle branch continues down the right side of the interventricular septum to the apex; from here, it radiates and divides to form the Purkinje network, which spreads throughout the sub-endocardial surface of the right ventricle. The main left bundle branch is a short structure, which fans out into many strands on the left side of the interventricular septum. These strands can be grouped into an anterior superior division (the anterior hemi-bundle) and a posterior inferior division (the posterior hemi-bundle). The anterior hemi-bundle supplies the sub-endocardial Purkinje network of the anterior and superior surfaces of the left ventricle, and the inferior hemi-bundle supplies the inferior and posterior surfaces. Impulse conduction through the AV node is slow and depends on action potentials largely produced by slow transmembrane calcium flux. In the atria, ventricles and His–Purkinje system, conduction is rapid and is due to action potentials generated by rapid transmembrane sodium diffusion.

The cellular basis of myocardial contraction – excitation–contraction coupling
Each myocyte, approximately 100 µm long, branches and interdigitates with adjacent cells. An intercalated disc permits electrical conduction to adjacent cells. Myocytes contain bundles of parallel myofibrils. Each myofibril is made up of a series of sarcomeres (Fig. 23.4). A sarcomere (which is the basic unit of contraction) is bound by two transverse Z lines, to each of which is attached a perpendicular filament of the protein actin. The actin filaments from each of the two Z bands overlap with thicker parallel protein filaments known as myosin. Actin and myosin filaments are attached to each other by cross-bridges that contain adenosine triphosphatase (ATPase), which breaks down adenosine triphosphate (ATP) to provide the energy for contraction.

![Figure 23.4](image)

**FIGURE 23.4** The structure of a myofibril within a myocyte. The myofibrils are made up of a series of sarcomeres joined at the Z line.

Two chains of actin molecules form a helical structure, with another molecule, tropomyosin, in the grooves of the actin helix; a further molecule, troponin, is attached to every seven actin molecules. During cardiac contraction, the length of the actin and myosin monofilaments does not change. Rather, the actin filaments slide between the myosin filaments when ATPase splits a high-energy bond of ATP. To supply the ATP, the myocyte (which cannot stop for a rest) has a very high mitochondrial density (35% of the cell volume). As calcium ions bind to troponin C, the activity of troponin I is inhibited, which induces a conformational change in tropomyosin. This event unlocks the active site between actin and myosin, enabling contraction to proceed.
Calcium is made available during the plateau phase of the action potential when calcium ions enter the cell and are mobilized from the sarcoplasmic reticulum (SR) through the ryanodine receptor (RyR2) calcium-release channel (see p. 1039). RyR2 activity is regulated by the protein calstabin 2 and nitric oxide. The force of cardiac muscle contraction (‘inotropic state’) is thus regulated by the influx of calcium ions into the cell through calcium channels (Fig. 23.3). T (transient) calcium channels open when the muscle is more depolarized, whereas L (long-lasting) calcium channels require less depolarization. The extent to which the sarcomere can shorten determines the stroke volume of the ventricle. It is maximally shortened in response to powerful inotropic drugs or severe exercise.

**Starling's law of the heart**

The contractile function of an isolated strip of cardiac tissue can be described by the relationship between the velocity of muscle contraction, the load that is moved by the contracting muscle, and the extent to which the muscle is stretched before contracting. As with all other types of muscle, the velocity of contraction of myocardial tissue is reduced by increasing the load against which the tissue must contract. However, in the non-failing heart, pre-stretching of cardiac muscle improves the relationship between the force and velocity of contraction (Fig. 23.5).

This phenomenon was described in the intact heart as an increase of stroke volume (ventricular performance) with an enlargement of the diastolic volume (preload), and is known as ‘Starling’s law of the heart’ or the ‘Frank–Starling relationship’. It has been transcribed into more clinically relevant indices. Thus, stroke work (aortic pressure × stroke volume) is increased as ventricular end-diastolic volume is raised. Alternatively, within certain limits, cardiac output rises as pulmonary capillary wedge pressure increases. This clinical relationship is described by the ventricular function curve (Fig. 23.5), which also shows the effect of sympathetic stimulation.
Nerve supply of the myocardium

Adrenergic nerves supply atrial and ventricular muscle fibres, as well as the conduction system. Beta$_1$-receptors predominate in the heart with both adrenaline (epinephrine) and noradrenaline (norepinephrine) having positive inotropic and chronotropic effects. Cholinergic nerves from the vagus supply mainly the SA and AV nodes via M$_2$ muscarinic receptors. The ventricular myocardium is sparsely innervated by the vagus. Under basal conditions, vagal inhibitory effects predominate over the sympathetic excitatory effects, resulting in a slow heart rate.

Adrenergic stimulation and cellular signalling

Beta$_1$-adrenergic stimulation enhances Ca$^{2+}$ flux in the myocyte and thereby strengthens the force of contraction (see Fig. 23.3). Binding of catecholamines, such as noradrenaline, to the myocyte β$_1$-adrenergic receptor stimulates membrane-bound adenylate kinases. These enzymes enhance production of cyclic adenosine monophosphate (cAMP), which activates intracellular protein kinases; these, in turn, phosphorylate cellular proteins, including L-type calcium channels within the cell membrane. Beta$_1$-adrenergic stimulation of the myocyte also enhances myocyte relaxation.

The return of calcium from the cytosol to the SR is regulated by phospholamban (PL), a low-molecular-weight protein in the SR membrane. In its dephosphorylated state, PL inhibits Ca$^{2+}$ uptake by the SR ATPase pump (see Fig. 23.3). However, β$_1$-adrenergic activation of protein kinase phosphorylates PL and blunts its inhibitory effect. The subsequently greater uptake of Ca$^{2+}$ ions by the SR hastens Ca$^{2+}$ removal from the cytosol and promotes myocyte relaxation.

The increased cAMP activity also results in phosphorylation of troponin I, an action that inhibits actin–myosin interaction and further enhances myocyte relaxation.

The cardiac cycle

The cardiac cycle (Fig. 23.6) consists of precisely timed rhythmic electrical and mechanical events that propel blood into the systemic and pulmonary circulations. The first event in the cardiac cycle is atrial depolarization (a P wave on the surface electrocardiogram (ECG)), followed by right atrial and then left atrial contraction. Ventricular activation (the QRS complex on the ECG) follows after a short interval (the PR interval). Left ventricular contraction starts and, shortly thereafter, right ventricular contraction begins. The increased ventricular pressures exceed the atrial pressures, and close first the mitral and then the tricuspid valves.
Until the aortic and pulmonary valves open, the ventricles contract with no change of volume (isovolumetric contraction). When ventricular pressures rise above the aortic and pulmonary artery pressures, the pulmonary valve and then the aortic valve open and ventricular ejection occurs. As the ventricles begin to relax, their pressures fall below the aortic and pulmonary arterial pressures, and aortic valve closure is followed by pulmonary valve closure. Isovolumetric relaxation then occurs. After the ventricular pressures have fallen below the right atrial and left atrial pressures, the tricuspid and mitral valves open. The cardiac cycle can be depicted graphically as the relationship between the pressure and volume of the ventricle. This is shown in *Figure 23.7*, which illustrates the changing pressure–volume relationships in response to increased contractility and to exercise.
The coronary circulation

The coronary arterial system (Fig. 23.8) consists of the right and left coronary arteries. These arteries branch from the aorta, arising immediately above two cusps of the aortic valve. The right and left coronary arteries are unique in that they fill during diastole, when not occluded by valve cusps and when not squeezed by myocardial contraction. The right coronary artery arises from the right coronary sinus and courses through the right side of the AV groove, giving off vessels that supply the right atrium and the right ventricle. The vessel usually continues as the posterior descending coronary artery, which runs in the posterior interventricular groove and supplies the posterior part of the interventricular septum and the posterior left ventricular wall.
Within 2.5 cm of its origin from the left coronary sinus, the left main coronary divides into the left anterior descending artery and the circumflex artery. The left anterior descending artery runs in the anterior interventricular groove and supplies the anterior septum and the anterior left ventricular wall. The left circumflex artery travels along the left AV groove and gives off branches to the left atrium and the left ventricle (marginal branches).

The sinus node and the AV node are supplied by the right coronary artery in about 60% and 90% of people, respectively. Therefore, disease in this artery may cause sinus bradycardia and AV nodal block. The majority of the left ventricle is supplied by the left coronary artery and disease in this vessel can cause significant myocardial dysfunction.

Some blood from the capillary beds in the wall of the heart drains directly into the cavities of the heart via tiny veins, but the majority returns by veins that accompany the arteries, to empty into the right atrium via the coronary sinus. An extensive lymphatic system drains into vessels that travel along the coronary vessels and then into the thoracic duct.

**Blood vessel control and functions of the vascular endothelium**

In functional terms, the tunica intima with the vascular endothelium and the smooth-muscle-cell-containing tunica media are the main constituents of blood vessels. These two structures are closely interlinked by a variety of mechanisms to regulate vascular tone. The central control of blood vessels is achieved via the neuroendocrine system. Sympathetic vasoconstrictor and parasympathetic vasodilator nerves regulate vascular tone in response to daily activity. Where neural control is impaired or in various pathological states, such as haemorrhage, endocrine control of blood vessels, mediated through adrenaline (epinephrine),
angiotensin and vasopressin, takes over.

At a local level, tissue perfusion is maintained automatically and by the effect of various factors synthesized and/or released in the immediate vicinity. In the face of fluctuating arterial pressures, blood vessels vasoconstrict independently of nervous input when blood pressure drops and vice versa. This process of autoregulation is a consequence of:

- the Bayliss myogenic response – the ability of blood vessels to constrict when distended
- the vasodilator washout effect – the vasoconstriction triggered by a decrease in the concentration of tissue metabolites.

The vascular endothelium is a cardiovascular endocrine organ, which occupies a strategic interface between blood and other tissues. It produces various compounds (e.g. nitric oxide (NO), prostacyclin (PGI₂), endothelin, endothelial-derived hyperpolarizing factor (EDHF), adhesion molecules, vascular endothelial growth factor (VEGF)) and has enzymes located on the surface, controlling the levels of circulating compounds such as angiotensin, bradykinin and serotonin. It has many regulatory roles:

**Vasomotor control**

- **Nitric oxide** is a diffusible gas with a very short half-life; it is produced in endothelial cells from the amino acid L-arginine via the action of the enzyme NO synthase (NOS), which is controlled by cytoplasmic calcium/calmodulin ([Fig. 23.9](#)). It is produced in response to various stimuli ([Box 23.1](#)), triggering vascular smooth muscle relaxation through activation of guanylate cyclase; this leads to an increase in the intracellular levels of cyclic 3,5-guanine monophosphate (cGMP). Its cardiovascular effects protect against atherosclerosis, high blood pressure, heart failure and thrombosis. NO is also the neurotransmitter in various ‘nitrergic’ nerves in the central and peripheral nervous systems and may play a role in the central regulation of vascular tone. The class of drugs used to treat erectile dysfunction, the phosphodiesterase (PDE₅) inhibitors, prevent the breakdown of cGMP and promote vasodilatation.
FIGURE 23.9  The stimulus for production and function of nitric oxide (NO). Various stimuli lead to the production of NO via cytoplasmic calcium/calmodulin. NO triggers smooth muscle relaxation via the activation of guanylyl cyclase. cGMP, cyclic guanine monophosphate; ER, endoplasmic reticulum; GTP, guanine triphosphate; IP3, inositol triphosphate; ROC, receptor-operated Ca\textsuperscript{2+} channel; SAC, stretch-activated Ca\textsuperscript{2+} channel.

ICAM, intracellular adhesion molecule; IL, interleukin; PECAM, platelet/endothelial cell adhesion molecule; TNF, tumour necrosis factor; VCAM, vascular cell adhesion molecule; WBC, white blood cell.

- **PGI₂** is synergistic to NO and also plays a role in the local regulation of vasomotor tone.
- **Endothelin** is a 21-amino-acid peptide that counteracts the effects of NO. Its production is inhibited by shear stress – that is, the stress exerted on the vessel wall by the flowing blood – and it causes profound vasoconstriction and vascular smooth muscle hypertrophy. It is thought to play a role in the genesis of hypertension and atheroma.
- **Angiotensin-converting enzyme**, located on the endothelial cell membrane, converts circulating angiotensin I (synthesized by the action of renin on angiotensinogen) to angiotensin II, which has vasoconstrictor properties and leads to aldosterone release (see Fig. 20.6). Aldosterone promotes sodium absorption from the kidney and, together with the angiotensin-induced vasoconstriction, provides haemodynamic stability.
- **Other factors** that influence vasomotor tone include histamine (released by mast cells), bradykinin (synthesized from kininogen by the action of coagulation factor XIIa) and serotonin (released by platelets).

**Anti- and prothrombotic mechanisms**
PGI₂, produced from arachidonic acid in the endothelial cell membrane by the action of the enzyme cyclo-oxygenase, inhibits platelet aggregation. Low-dose aspirin prevents activation of the cyclo-oxygenase pathway in platelets but only to a degree that does not affect PGI₂ synthesis, unlike higher doses. Other antithrombotic agents, such as clopidogrel (an adenosine diphosphate (ADP) receptor antagonist) and glycoprotein IIb/IIIa inhibitors, achieve their effects by acting directly on platelet receptors. The antithrombotic effect of PGI₂ is aided by NO, affecting platelets via activation of guanylate cyclase. The endothelial cell membrane also produces other anticoagulant molecules, such as thrombomodulin, heparin sulphate and various fibrinolytic factors. Clinically used, fast-acting heparin preparations are identical to this naturally occurring molecule.

In addition to their ability to prevent clotting, endothelial cells also aid thrombosis. They are responsible for the production of von Willebrand factor through a unique organelle called the Weibel–Palade body, which not only acts as a carrier for factor VIII but also promotes platelet adhesion by binding to exposed collagen (see p. 565).

Modulation of immune responses

In response to various inflammatory mediators, the vascular endothelium expresses various so-called ‘adhesion molecules’, which promote leucocyte attraction, adhesion and infiltration into the blood vessel wall (see p. 133).

Regulation of vascular cell growth

The endothelial cells are also responsible for the development of new blood vessels (‘angiogenesis’) in the placenta, wound healing, tissue repair and tumour growth. This process is facilitated by VEGF.

Clinical Approach to the Patient with Heart Disease

Clinical features of heart disease

The following symptoms occur with heart disease:

- chest pain
- dyspnoea (breathlessness)
- palpitations
- syncope
- fatigue
- peripheral oedema.

The severity of cardiac symptoms or fatigue is classified according to the New York Heart
Association (NYHA) grading of cardiac status (see Box 23.21). The differential diagnosis of chest pain is given in Box 23.2.

**Box 23.2**

**Differential diagnosis of chest pain**

**Central**

**Cardiac**
- Ischaemic heart disease (infarction or angina)
- Coronary artery spasm
- Pericarditis/myocarditis
- Mitral valve prolapse
- Aortic aneurysm/dissection

**Non-cardiac**
- Pulmonary embolism
- Oesophageal disease (see Box 13.11)
- Mediastinitis
- Costochondritis (Tietze disease)
- Trauma (soft tissue, rib)

**Lateral/peripheral**

**Pulmonary**
- Infarction
- Pneumonia
- Pneumothorax
- Lung cancer
- Mesothelioma

**Non-pulmonary**
- Bornholm disease (epidemic myalgia)
- Herpes zoster
- Trauma (ribs/muscular)

**Central chest pain**

This is the most common symptom associated with heart disease. The pain of angina pectoris and myocardial infarction is due to myocardial hypoxia.

Types of pain include:
• retrosternal heavy or gripping sensation with radiation to the left arm or neck that is provoked by exertion and eased with rest or nitrates – **angina** (see pp. 993–997)
• similar pain at rest – **acute coronary syndrome** (see pp. 997–1006)
• severe, tearing chest pain radiating through to the back – **aortic dissection** (see pp. 1053–1054)
• sharp, central chest pain that is worse with movement or respiration but relieved with sitting forward – **pericarditis pain** (see pp. 1043–1044)
• sharp, stabbing, left sub-mammary pain associated with anxiety – **da Costa syndrome**.

**Dyspnoea**

Left ventricular failure causes dyspnoea due to oedema of the pulmonary interstitium and alveoli. This makes the lungs stiff (less compliant), thus increasing the respiratory effort required to ventilate them. **Tachypnoea** (increased respiratory rate) is often present owing to stimulation of pulmonary stretch receptors.

**Orthopnoea** refers to breathlessness on lying flat. Blood is redistributed from the legs to the torso, leading to an increase in central and pulmonary blood volume. The patient uses an increasing number of pillows to sleep.

**Paroxysmal nocturnal dyspnoea (PND)** is when a patient is woken from sleep fighting for breath. It is caused by the same mechanisms as orthopnoea. However, as sensory awareness is reduced whilst asleep, the pulmonary oedema can become quite severe before the patient is awoken.

**Hyperventilation** with alternating episodes of apnoea (**Cheyne–Stokes respiration**) occurs in severe heart failure.

If hypopnoea occurs rather than apnoea, the phenomenon is termed ‘periodic breathing’, but the two variations are known together as **central sleep apnoea syndrome (CSAS)**. This occurs due to malfunctioning of the respiratory centre in the brain, caused by poor cardiac output with concurrent cerebrovascular disease. The symptoms of CSAS, such as daytime somnolence and fatigue, are similar to those of obstructive sleep apnoea syndrome (OSAS; see pp. 1085–1086) and there is considerable overlap with the symptoms of heart failure. CSAS is believed to lead to myocardial hypertrophy and fibrosis, deterioration in cardiac function and complex arrhythmias, including non-sustained ventricular tachycardia, hypertension and stroke. Patients with CSAS have a worse prognosis than similar patients without CSAS.

**Palpitations**

These represent an increased awareness of the normal heart beat or the sensation of slow, rapid or irregular heart rhythms. The most common arrhythmias felt as palpitations are premature ectopic beats and paroxysmal tachycardias. A useful trick is to ask patients to tap out the rate and rhythm of their palpitations, as the different arrhythmias have different characteristics:

• **Premature beats (ectopics)** are felt by the patient as a pause followed by a forceful beat.
This is because premature beats are usually followed by a pause before the next normal beat, as the heart resets itself. The next beat is more forceful, as the heart has had a longer diastolic period and therefore is filled with more blood before this beat.

- **Paroxysmal tachycardias** (see pp. 963–964) are felt as a sudden, racing heart beat.
- **Bradycardias** (see p. 964) may be appreciated as slow, regular, heavy or forceful beats. Most often, however, they are simply not sensed. All palpitations can be graded by the NYHA cardiac status (see *Box 23.21*).

## Syncope

Syncope is a transient loss of consciousness due to inadequate cerebral blood flow. The cardiovascular causes are listed in *Box 23.3*.

### Box 23.3

**Cardiovascular causes of syncope**

**Vascular**
- Neurocardiogenic (vasovagal)
- Postural hypotension
- Postprandial hypotension
- Micturition syncope
- Carotid sinus syncope

**Obstructive**
- Aortic stenosis
- Hypertrophic cardiomyopathy
- Pulmonary stenosis
- Tetralogy of Fallot
- Pulmonary hypertension/embolism
- Atrial myxoma/thrombus
- Defective prosthetic valve

**Arrhythmias**
- Rapid tachycardias
- Profound bradycardias (Stokes–Adams)
- Significant pauses (in rhythm)
- Artificial pacemaker failure
Vascular

- A vasovagal attack is a simple faint and is the most common cause of syncope. The mechanism begins with peripheral vasodilatation and venous pooling of blood, leading to a reduction in the amount of blood returned to the heart. The near-empty heart responds by contracting vigorously, which, in turn, stimulates mechanoreceptors (stretch receptors) in the inferoposterior wall of the left ventricle. These, in turn, trigger reflexes via the central nervous system, which act to reduce ventricular stretch (i.e. further vasodilatation and sometimes profound bradycardia), but this causes a drop in blood pressure and therefore syncope. These episodes are usually associated with a prodrome of dizziness, nausea, sweating, tinnitus, yawning and a sinking feeling. Recovery occurs within a few seconds, especially if the patient lies down.

- Postural (orthostatic) hypotension is a drop in systolic blood pressure of ≥20 mmHg or more on standing from a sitting or lying position. Usually, reflex vasoconstriction prevents a drop in pressure, but if this is absent or the patient is fluid-depleted or on vasodilating or diuretic drugs, hypotension occurs.

- Postprandial hypotension is a drop in systolic blood pressure of ≥20 mmHg, or the systolic blood pressure drops from >100 mmHg to <90 mmHg within 2 hours of eating. The mechanism is unknown but may be due to pooling of blood in the splanchnic vessels. In normal subjects, this elicits a homeostatic response via activation of baroreceptors and the sympathetic system, peripheral vasoconstriction and an increase in cardiac output.

- Micturition syncope refers to loss of consciousness whilst passing urine.

- Carotid sinus syncope occurs when there is an exaggerated vagal response to carotid sinus stimulation, provoked by wearing a tight collar, looking upwards or turning the head.

Obstructive

The obstructive cardiac causes listed in Box 23.3 all lead to syncope due to restriction of blood flow from the heart into the rest of the circulation, or between the different chambers of the heart.

Arrhythmias

Stokes–Adams attacks (see p. 966) are a sudden loss of consciousness unrelated to posture and caused by intermittent high-grade AV block, profound bradycardia or ventricular standstill. The patient falls to the ground without warning, and is pale and deeply unconscious. The pulse is usually very slow or absent. After a few seconds, the patient flushes brightly and recovers consciousness as the pulse quickens. Often there are no sequelae, but patients may injure themselves during falls. Occasionally, a generalized convulsion may occur if the period of cerebral hypoxia is prolonged, leading to a misdiagnosis of epilepsy.

Fatigue

Fatigue may be a symptom of inadequate systemic perfusion in heart failure. It is due to poor
sleep; is a direct side-effect of medication, particularly beta-blockers; is due to electrolyte imbalance caused by diuretic therapy; or is a systemic manifestation of infection, such as endocarditis.

**Peripheral oedema**

Heart failure results in salt and water retention due to renal under-perfusion and consequent activation of the renin–angiotensin–aldosterone system (see pp. 727–728). This leads to dependent pitting oedema.

Examination of the cardiovascular system

**General examination**

General features of the patient's wellbeing should be noted, as well as the presence of conjunctival pallor, obesity, jaundice and cachexia.

- **Clubbing** (see p. 1067) is seen in congenital cyanotic heart disease, particularly Fallot's tetralogy, and also in 10% of patients with sub-acute infective endocarditis.

- **Splinter haemorrhages** are small, sub-ungual linear haemorrhages that are frequently due to trauma, but also seen in infective endocarditis.

- **Cyanosis** is a dusky blue discoloration of the skin (particularly at the extremities) or of the mucous membranes when the capillary oxygen saturation is <85%. **Central cyanosis** (see p. 1067) is seen with shunting of deoxygenated venous blood into the systemic circulation, as in the presence of a right-to-left heart shunt. **Peripheral cyanosis** is seen in the hands and feet, which are cold. It occurs in conditions associated with peripheral vasoconstriction and stasis of blood in the extremities, leading to increased peripheral oxygen extraction. Such conditions include congestive heart failure, circulatory shock, exposure to cold temperatures and abnormalities of the peripheral circulation, such as Raynaud's (see p. 1054).

**The arterial pulse**

The first pulse to be examined is the right radial pulse. A delayed femoral pulsation occurs
because of a proximal stenosis, particularly of the aorta (coarctation).

**Rate**
The pulse rate should be between 60 and 80 beats per minute (b.p.m.) when an adult patient is lying quietly in bed.

**Rhythm**
The rhythm is regular, except for a slight quickening in early inspiration and a slowing in expiration (sinus arrhythmia).

- **Premature beats** occur as occasional or repeated irregularities superimposed on a regular pulse rhythm. Similarly, intermittent heart block is revealed by occasional beats dropped from an otherwise regular rhythm.
- **Atrial fibrillation** produces an ‘irregularly irregular’ pulse. This irregular pattern persists when the pulse quickens in response to exercise, in contrast to pulse irregularity due to ectopic beats, which usually disappears on exercise.

**Character**

- **Carotid pulsations** are not normally apparent on inspection of the neck but may be visible (Corrigan's sign) in conditions associated with a large-volume pulse, including high-output states (such as thyrotoxicosis, anaemia or fever), and in aortic regurgitation.
- **A ‘collapsing’ or ‘water hammer’ pulse (Fig. 23.10)** is a large-volume pulse characterized by a short duration with a brisk rise and fall. This is best appreciated by palpating the radial artery with the palmar aspect of four fingers while elevating the patient's arm above the level of the heart. A collapsing pulse is characteristic of aortic valvular regurgitation or a persistent ductus arteriosus.
• **A small-volume pulse** is seen in cardiac failure, shock, and obstructive valvular or vascular disease. It may also be present during tachyarrhythmias.

• **A plateau pulse** (*Fig. 23.10*) is small in volume and slow in rising to a peak; it is due to aortic stenosis.

• **An alternating pulse (pulsus alternans)** (*Fig. 23.10*) is characterized by regular alternate beats that are weak and strong. It is a feature of severe myocardial failure and is due to the prolonged recovery time of damaged myocardium; it indicates a very poor prognosis. It is easily noticed when taking the blood pressure because the systolic pressure may vary from beat to beat by as much as 50 mmHg.

• **A bigeminal pulse (pulsus bigeminus)** (*Fig. 23.10*) is caused by a premature ectopic beat following every sinus beat. The rhythm is not regular because every weak pulse is premature.

• **Pulsus bisferiens** (*Fig. 23.10*) is found in hypertrophic cardiomyopathy and in mixed aortic valve disease (regurgitation combined with stenosis). The first systolic wave is the ‘percussion’ wave, produced by the transmission of the left ventricular pressure in early systole. The second peak is the ‘tidal’ wave, caused by recoil of the vascular bed. This normally happens in diastole (the dicrotic wave), but when the left ventricle empties slowly or is obstructed and cannot empty completely, the tidal wave occurs in late systole. The result
is a palpable double pulse.

- **A dicrotic pulse** *(Fig. 23.10)* results from an accentuated dicrotic wave. It occurs in sepsis and hypovolaemic shock, and after aortic valve replacement.

- **Paradoxical pulse** is a misnomer, as it is actually an exaggeration of the normal pattern. In normal subjects, the systolic pressure and the pulse pressure (the difference between the systolic and diastolic blood pressures) fall during inspiration. The normal fall of systolic pressure is $<10$ mmHg, and this can be measured using a sphygmomanometer. It is due to increased pulmonary intravascular volume during inspiration. In severe airflow limitation (especially severe asthma), there is an increased negative intrathoracic pressure on inspiration, which enhances the normal fall in blood pressure. In patients with cardiac tamponade, the fluid in the pericardium increases the intrapericardial pressure, thereby impeding diastolic filling of the heart. The normal inspiratory increase in venous return to the right ventricle is at the expense of the left ventricle, as both ventricles are confined by the accumulated pericardial fluid within the pericardial space. Paradox can occur via a similar mechanism in constrictive pericarditis but is less common.

**Blood pressure**

The peak systemic arterial blood pressure is produced by transmission of left ventricular systolic pressure. Vascular tone and an intact aortic valve maintain the diastolic blood pressure. Instructions for taking the blood pressure are outlined in **Box 23.4**.

---

**Box 23.4**

**Taking the blood pressure**

*Use a properly calibrated machine.*

1. Take the blood pressure in the (right) arm with the patient relaxed and comfortable.
2. Wrap the sphygmomanometer cuff around the upper arm and place the inflation bag over the brachial artery.
3. Inflate the cuff until the pressure exceeds the arterial pressure – when the radial pulse is no longer palpable.
4. Position the diaphragm of the stethoscope over the brachial artery just below the cuff.
5. Slowly reduce the cuff pressure until sounds (Korotkoff sounds) can be heard (phase 1). This is the systolic pressure.
6. Allow the pressure to fall further until the Korotkoff sounds suddenly become muffled (phase 4).
7. Allow the pressure to fall still further until the sounds disappear (phase 5).
8. The diastolic pressure is usually taken as phase 5 because this phase is more reproducible and nearer to the intravascular diastolic pressure. The Korotkoff sounds may disappear (phase 2) and reappear (phase 3) between the systolic and diastolic pressures. Do not mistake phase 2 for the diastolic pressure or phase 3 for the
systolic pressure.

Jugular venous pressure

There are no valves between the internal jugular vein and the right atrium. Observation of the column of blood in the internal jugular system is therefore a good measure of right atrial pressure. The external jugular cannot be relied upon because of its valves and because it may be obstructed by the fascial and muscular layers through which it passes; it can only be used if typical venous pulsation is seen, indicating no obstruction to flow.

Measurement of jugular venous pressure

See Box 23.5.

**Box 23.5**

**Measurement of jugular venous pressure (JVP)**

- The patient is positioned at about 45° to the horizontal (between 30° and 60°), wherever the top of the venous pulsation can be seen in a good light.
- The JVP is measured as the vertical distance between the manubriosternal angle and the top of the venous column.
- The normal JVP is usually <3 cmH₂O, which is equivalent to a right atrial pressure of 8 cmH₂O when measured with reference to a point midway between the anterior and posterior surfaces of the chest.
- The venous pulsations are not usually palpable (except for the forceful venous distension associated with tricuspid regurgitation).
- Compression of the right upper abdomen causes a temporary increase in venous pressure and makes the jugular venous pulse more visible (hepatojugular reflux).

Elevation of the jugular venous pressure (JVP) occurs in **heart failure**. An elevated JVP also occurs in constrictive pericarditis and cardiac tamponade (increases in inspiration – **Kussmaul's sign**), renal disease with salt and water retention, over-transfusion or excessive infusion of fluids, congestive cardiac failure and superior vena cava obstruction.

A reduced JVP occurs in hypovolaemia.

The jugular venous pressure wave

This consists of three peaks and two troughs (**Fig. 23.11**). The peaks are described as a, c and v waves and the troughs are known as x and y descents:

- **The a wave** is produced by atrial systole and is increased with right ventricular hypertrophy secondary to pulmonary hypertension or pulmonary stenosis. Giant cannon waves occur in complete heart block and ventricular tachycardia.
• **The x descent** occurs when atrial contraction finishes.

• **The c wave** occurs during the x descent and is due to transmission of right ventricular systolic pressure before the tricuspid valve closes.

• **The v wave** occurs with venous return filling the right atrium. Giant v waves occur in tricuspid regurgitation.

• **The y descent** follows the v wave when the tricuspid valve opens. A steep y descent is seen in constrictive pericarditis and tricuspid incompetence.

![Diagram of Jugular Venous Waveforms](image)

**FIGURE 23.11** Jugular venous waveforms.

**The precordium**

• With the patient at 45°, the cardiac apex is located in the fifth intercostal space mid-clavicular line. Left ventricular dilatation will displace the apex downwards and laterally. It may be impalpable in patients with emphysema, obesity, or pericardial or pleural effusions.

• **A tapping apex** is a palpable first sound and occurs in mitral stenosis.

• **A vigorous apex** may be present in diseases with volume overload, e.g. aortic regurgitation.

• **A heaving apex** may occur with left ventricular hypertrophy – aortic stenosis, systemic hypertension and hypertrophic cardiomyopathy.

• **A double pulsation** may occur in hypertrophic cardiomyopathy.

• **A sustained left parasternal heave** occurs with right ventricular hypertrophy or left atrial enlargement.
• A palpable thrill may be felt overlying an abnormal cardiac valve, e.g. systolic thrill with aortic stenosis.

**Auscultation**

The *bell* of the stethoscope is used for low-pitched sounds (heart sounds and mid-diastolic murmur in mitral stenosis). The *diaphragm* is used for high-pitched sounds (systolic murmurs, aortic regurgitation, ejection clicks and opening snaps). The areas of auscultation are shown in **Figure 23.12**. Left-sided valve murmurs may be more prominent in expiration and right-sided in inspiration. Mitral murmurs may be more audible with the patient reclining to the left.

**First heart sound (S1)**

This is due to mitral and tricuspid valve closure. A loud S1 occurs in thin people, hyperdynamic circulation, tachycardias and mild to moderate mitral stenosis. A soft S1 occurs in obesity, emphysema, pericardial effusion, severe calcific mitral stenosis, mitral or tricuspid regurgitation, heart failure, shock, bradycardias and first-degree block.

**Second heart sound (S2)**

This is due to aortic and pulmonary valve closure. Physiological splitting of S2 occurs during
Inspiration in children and young adults.

**Third and fourth heart sounds**
These are pathological:

- **A third heart sound** is due to rapid ventricular filling and is present in heart failure.
- **A fourth heart sound** occurs in late diastole and is associated with atrial contraction.
  
  Singly or together, they will produce a gallop rhythm.

**Heart murmurs**

These are due to turbulent blood flow and occur in hyperdynamic states or with abnormal valves. (Listen online on Student Consult.) Innocent or flow murmurs are soft, early systolic, short and non-radiating. They are heard frequently in children and young adults. Heart murmurs can be graded on the following scale:

- 1/6 very faint; not always heard in all positions
- 2/6 quiet but not difficult to hear
- 3/6 moderately loud
- 4/6 loud ± thrills
- 5/6 very loud ± thrills; heard with the stethoscope partly off the chest
- 6/6 ± thrills; heard with the stethoscope completely off the chest.

The individual murmurs are discussed under valve disease (see pp. 1006–1017).

**Cardiac investigations**

**Blood tests**

These include routine haematology, urea/creatinine and electrolytes, liver biochemistry, cardiac enzymes, thyroid function and brain natriuretic peptides (BNP).

**Chest X-ray**

Ideally, this is taken in the postero-anterior (PA) direction at maximum inspiration with the heart close to the X-ray film to minimize magnification with respect to the thorax. A lateral view may give additional information if the PA film is abnormal. The cardiac structures and great vessels that can be seen on these X-rays are indicated in Figure 23.13. An antero-posterior (AP) view is taken only in an emergency.
Heart size

Heart size can be reliably assessed only from the PA chest film. The maximum transverse diameter of the heart is compared with the maximum transverse diameter of the thorax measured from the inside of the ribs (the cardiothoracic ratio, CTR). The CTR is usually <50%, except in neonates, infants, athletes, and patients with skeletal abnormalities such as scoliosis and funnel chest. A transverse cardiac diameter >15.5 cm is abnormal. Pericardial effusion or cardiac dilatation causes an increase in the ratio.

A pericardial effusion produces a globular heart (see Fig. 23.121). This enlargement may occur quite suddenly and, unlike in heart failure, there is no associated change in the pulmonary vasculature. The echocardiogram is more specific (see Fig. 23.122).

Certain patterns of specific chamber enlargement may be seen on the chest X-ray:

• **Left atrial dilatation** leads to prominence of the left atrial appendage and a straightening or convex bulging of the upper left heart border, a double atrial shadow to the right of the sternum, and splaying of the carina because a large left atrium elevates the left main bronchus (Fig. 23.14). On a lateral chest X-ray, an enlarged left atrium bulges backwards, impinging on the oesophagus.
Figure 23.14 A plain postero-anterior chest X-ray of a patient with mixed mitral valve disease. The left atrium (a) is markedly enlarged. Note the large bulge on the left heart border (left atrium). The ‘double shadow’ (border of the right and left atria, (b)) is on the right side of the heart. There is cardiac (left ventricular) enlargement due to mitral regurgitation.

- **Left ventricular enlargement** causes an increase in the CTR and a smooth elongation and increased convexity of the left heart border.
- **Right atrial enlargement** results in the right border of the heart projecting into the right lower lung field.
- **Right ventricular enlargement** causes an increase in the CTR and an upward displacement of the apex of the heart because the enlarging right ventricle pushes the left ventricle leftwards, upwards and eventually backwards. Differentiation of left from right ventricular enlargement may be difficult using the shape of the left heart border alone, but the lateral view shows enlargement anteriorly for the right ventricle and posteriorly for the left ventricle.
- **Ascending aortic dilatation or enlargement** is seen as a prominence of the aortic shadow to the right of the mediastinum between the right atrium and superior vena cava.
- **Dissection of the ascending aorta** is seen as a widening of the mediastinum on chest X-ray but an ultrasound/magnetic resonance imaging (MRI) should be performed.
- **Enlargement of the pulmonary artery** in pulmonary hypertension, pulmonary artery stenosis and left-to-right shunts produces a prominent bulge on the left-hand border of the mediastinum below the aortic knuckle.

**Calcification**

Calcification in the cardiovascular system occurs because of tissue degeneration. Calcification is visible on a lateral or a penetrated PA film, but is best studied with computed tomography (CT) scanning.
Lung fields

- **Pulmonary plethora** results from left-to-right shunts (e.g. atrial or ventricular septal defects). It is seen as a general increase in the vascularity of the lung fields and as an increase in the size of hilar vessels (e.g. in the right lower lobe artery), which normally should not exceed 16 mm diameter.

- **Pulmonary oligaemia** is a paucity of vascular markings and a reduction in the width of the arteries. It occurs in situations where there is reduced pulmonary blood flow, such as pulmonary embolism, severe pulmonary stenosis and Fallot's tetralogy.

- **Pulmonary hypertension** may result from pulmonary embolism, chronic lung disease or chronic left heart disease, e.g. left ventricular failure or mitral valve disease such as shunts due to a ventricular septal defect or mitral valve stenosis. In addition to the X-ray features of these conditions, the pulmonary arteries are prominent close to the hila but are reduced in size (pruned) in the peripheral lung fields. This pattern is usually symmetrical. Normal pulmonary capillary pressure is 5–14 mmHg at rest. Mild pulmonary capillary hypertension (15–20 mmHg) produces isolated dilatation of the upper zone vessels.

- **Interstitial oedema** occurs when the pressure is between 21 and 30 mmHg. This manifests as fluid collections in the interlobar fissures, interlobular septa (Kerley B lines) and pleural spaces. This gives rise to indistinctness of the hilar regions and haziness of the lung fields.

- **Alveolar oedema** occurs when the pressure exceeds 30 mmHg, appearing as areas of consolidation and mottling of the lung fields (*Fig. 23.15*) and pleural effusions. Patients with longstanding elevation of the pulmonary capillary pressure have reactive thickening of the pulmonary arteriolar intima, which protects the alveoli from pulmonary oedema. Thus, in these patients, the pulmonary venous pressure may increase to well above 30 mmHg before frank pulmonary oedema develops.
Acute pulmonary oedema: chest X-rays taken before and after treatment.

A. The X-ray taken when the oedema was present demonstrates hilar haziness, Kerley B lines, upper lobe venous engorgement, and fluid in the right horizontal interlobar fissure.

B. These abnormalities are resolved on the film taken after successful treatment.
Electrocardiography

The electrocardiogram (ECG) is a recording of the electrical activity of the heart. It is the vector sum of the depolarization and repolarization potentials of all myocardial cells (see Fig. 23.2). At the body surface, these generate potential differences of about 1 mV, and the fluctuations of these potentials create the familiar P-QRS-T pattern. At rest, the intracellular voltage of the myocardium is polarized at −90 mV compared with that of the extracellular space. This diastolic voltage difference occurs because of the high intracellular potassium concentration, which is maintained by the sodium potassium pump despite the free membrane permeability to potassium. Depolarization of cardiac cells occurs when there is a sudden increase in the permeability of the membrane to sodium. Sodium rushes into the cell and the negative resting voltage is lost (phase 0 on Fig. 23.39). The depolarization of a myocardial cell causes the depolarization of adjacent cells and, in the healthy heart, the entire myocardium is depolarized in a coordinated fashion. During repolarization, cellular electrolyte balance is slowly restored (phases 1, 2 and 3). Slow diastolic depolarization (phase 4) follows until the threshold potential is reached. Another action potential then follows.

The ECG is recorded from two or more simultaneous points of skin contact (electrodes). When cardiac activation proceeds towards the positive contact, an upward deflection is produced on the ECG. Correct representation of a three-dimensional spatial vector requires recordings from three mutually perpendicular (orthogonal) axes. The shape of the human torso does not make this easy, so the practical ECG records 12 projections of the vector, called ‘leads’ (Fig. 23.16).

![Figure 23.16: The connections or directions that comprise the 12-lead electrocardiogram.](image)

Six of the leads are obtained by recording voltages from the limbs (I, II, III, AVR, AVL and AVF). The other six leads record potentials between points on the chest surface and an average
of the three limbs: RA, LA and LL. These are designated V₁–V₆ and aim to select activity from the right ventricle (V₁–V₂), interventricular septum (V₃–V₄) and left ventricle (V₅–V₆). Note that leads AVR and V₁ are oriented towards the cavity of the heart, leads II, III and AVF face the inferior surface, and leads I, AVL and V₆ face the lateral wall of the left ventricle. A V₄ on the right side of the chest (V₄R) is occasionally useful (e.g. for the diagnosis of right ventricular infarction).

Most ECG machines are simultaneous three-channel recorders with output given either as a continuous strip or with automatic channel switching. Many ECG machines also analyse the recordings and print the analysis on the record. Usually, the machine interpretation is correct but many arrhythmias still defy automatic analysis.

The ECG waveform

The shape of the normal ECG waveform (Fig. 23.17) has similarities, whatever the orientation. The first deflection is caused by atrial depolarization; it is a low-amplitude, slow deflection called a P wave. The QRS complex reflects ventricular activation or depolarization, and is sharper and larger in amplitude than the P wave. An initial downward deflection is called the Q wave. An initial upward deflection is called an R wave. The S wave is the last part of ventricular activation. The T wave is another slow and low-amplitude deflection that results from ventricular repolarization.

![The waves and elaboration of the normal electrocardiogram.](image)

The PR interval is the length of time from the start of the P wave to the start of the QRS complex. It is the time taken for activation to pass from the sinus node, through the atrium, AV node and His–Purkinje system, to the ventricle.

The QT interval extends from the start of the QRS complex to the end of the T wave. This interval represents the time taken to depolarize and repolarize the ventricular myocardium. The
QT interval varies greatly with heart rate and is often represented as a corrected QT interval (or QTc) for a given heart rate. There are a number of formulae for derivation of QTc, but the most widely accepted are Bazett's formula and Fridericia's correction (Box 23.6).

**Box 23.6**

</tbody>
</table>

An abnormally prolonged QTc can predispose to a risk of dangerous ventricular arrhythmias. Prolongation of the QT interval may be congenital or can occur in many acquired conditions (see Box 23.15).

The **ST segment** is the period between the end of the QRS complex and the start of the T wave. In the normal heart, all cells are depolarized by this phase of the ECG; that is, the ST segment represents ventricular repolarization.

A normal 12-lead ECG is shown in **Figure 23.18**, and the normal values for the electrocardiographic intervals are indicated in **Box 23.6**. Leads that face the lateral wall of the left ventricle have predominantly positive deflections, and leads looking into the ventricular cavity are usually negative. Detailed patterns depend on the size, shape and rhythm of the heart and the characteristics of the torso.
Cardiac vectors

At any point in time during depolarization and repolarization, electrical potentials are being propagated in different directions. Most of these cancel each other out and only the net force is recorded. This net force in the frontal plane is known as the cardiac vector.

The mean QRS vector can be calculated from the six standard leads (Fig. 23.19):

- Normal between −30° and +90°
- Left axis deviation between −30° and −90°
- Right axis deviation between +90° and +150°.
FIGURE 23.19  Cardiac vectors. A. The hexaxial reference system, illustrating the six leads in the frontal plane; for example, lead I is 0°, lead II is +60° and lead III is +120°. B. Calculating the direction of the cardiac vector. In the first column, the QRS complex with zero net amplitude (i.e., when the positive and negative deflections are equal) is seen in lead III. The mean QRS vector is therefore perpendicular to lead III and is either −150° or +30°. Lead I is positive, so the axis must be +30°, which is normal. In left axis deviation (second column), the main deflection is positive (R wave) in lead I and negative (S wave) in lead III. In right axis deviation (third column), the main deflection is negative (S wave) in lead I and positive (R wave) in lead III. The frontal plane QRS axis is normal only if the QRS complexes in leads I and II are predominantly positive.

Calculation of this vector is useful in the diagnosis of some cardiac disorders.

**Exercise electrocardiography**

This is less used than previously (see p. 995) because of its low sensitivity. The ECG is recorded while the patient walks or runs on a motorized treadmill. The test is based on the principle that exercise increases myocardial demand on coronary blood supply, which may be
inadequate during exercise, and at peak stress can result in relative myocardial ischaemia. Most exercise tests are performed according to a standardized method, such as the Bruce protocol. Recording an ECG after exercise is not an adequate form of stress test. Normally, there is little change in the T wave or ST segment during exercise.

The patient's exercise capacity (the total time achieved) will depend on many factors; however, patients who can only exercise for <6 min generally have a poorer prognosis.

Myocardial ischaemia provoked by exertion results in ST segment depression (>1 mm) in leads facing the affected area. The form of ST segment depression provoked by ischaemia is characteristic: it is either planar or shows down-sloping depression (Fig. 23.20). Up-sloping depression is a non-specific finding. The degree of ST segment depression is positively correlated to the degree of myocardial ischaemia.

![Electrocardiographic changes during exercise testing. The upper traces show significant horizontal ST segment depression during exercise. The lower traces show ST elevation during exercise.](image)

ST segment elevation during an exercise test is induced much less frequently than ST depression. When it occurs, it reflects transmural ischaemia caused by coronary spasm or critical stenosis.

Although most abnormalities are detected in lead V₅ (anterior and lateral ischaemia) or AVF (inferior ischaemia), it is best to record a full 12-lead ECG. During an exercise test, the blood pressure and rhythm responses to exercise are also assessed. Exercise normally causes an increase in heart rate and blood pressure. A sustained fall in blood pressure usually indicates severe coronary artery disease. A slow recovery of the heart rate to basal levels has also been reported to be a predictor of mortality.

Frequent premature ventricular depolarizations during the test are associated with a long-term increase in the risk of death from cardiovascular causes, and further testing is required in these patients.

**Twenty-four-hour ambulatory taped electrocardiography**

This records transient changes such as a brief paroxysm of tachycardia, an occasional pause in
the rhythm, or intermittent ST segment shifts (Fig. 23.21). A conventional 12-lead ECG is recorded in less than a minute and usually samples fewer than 20 complexes. In a 24-hour period, over 100,000 complexes are recorded. Such a large amount of data must be analysed by automatic or semi-automatic methods. This technique is called Holter electrocardiography after its inventor.
Event recording is another technique that is used to record less frequent arrhythmias. The patient is provided with a pocket-sized device that can record and store a short segment of the ECG. The device may be kept for several days or weeks until the arrhythmia is recorded. Most units of this kind will also allow transtelephonic ECG transmission so that the physician can determine the need for treatment or the continued need for monitoring.
A very small event recorder, known as an implantable loop recorder (ILR), can also be implanted subcutaneously, triggered by events or a magnet, and interrogated by the physician.

**Other tests**

Non-invasive methods that make use of digitalized Holter recordings to identify increased risk of ventricular arrhythmias include assessment of heart rate variability, signal-averaged ECG and T wave alternans.

- **Heart rate variability (HRV)** can be assessed from a 24-hour ECG. HRV is decreased in some patients following myocardial infarction and represents an abnormality of autonomic tone or cardiac responsiveness. Low HRV is a major risk factor for sudden death and ventricular arrhythmias in patients discharged from hospital following myocardial infarction.

- **Signal-averaged ECG (SAECG)** is a technique that requires amplification and averaging of abnormal low-amplitude signals that occur beyond the end of the QRS complex and extend well into the ST segment. These signals are therefore also known as late potentials and are too small to be detected on a surface ECG. They arise in areas of slow conduction in the myocardium, such as the border zone of an infarct, where re-entrant ventricular arrhythmias can originate.

- **T wave alternans (TWA)** is a valuable technique used as a non-invasive marker of susceptibility to ventricular arrhythmias and sudden cardiac death. TWA represents microvolt level changes in the morphology of the T waves in every other beat and can be detected during acute myocardial ischaemia using amplification techniques. Visible TWA on an ordinary surface ECG is quite a rare phenomenon, except in patients with long QT syndromes, particularly during motion or exercise.

**Tilt testing**

Patients with suspected neurocardiogenic (vasovagal) syncope should be investigated by upright tilt testing. The patient is secured to a table which is tilted to +60° to the vertical for ≥45 minutes. The ECG and blood pressure are monitored throughout. If neither symptoms nor signs develop, isoprenaline may be slowly infused or glyceryl trinitrate inhaled and the tilt repeated. A positive test results in hypotension, sometimes bradycardia (Fig. 23.22) and pre-syncope/syncope, and supports the diagnosis of neurocardiogenic syncope. If symptoms and signs appear, placing the patient flat can quickly reverse them. The effect of treatment can be evaluated by repeating the tilt test, but it is not always reproducible. The overall sensitivity, specificity and reproducibility are low.
FIGURE 23.22  Tilt test. The ECG (top trace) and arterial blood pressure (bottom trace) recorded during a tilt test. After 1 min of tilt, hypotension, bradycardia and syncope occur.

Carotid sinus massage

Carotid sinus massage (Box 23.7) may lead to asystole (>3 s) and/or a fall in systolic blood pressure (>50 mmHg). This hypersensitive response occurs in many of the normal (especially elderly) population, but may also be responsible for loss of consciousness in some patients with carotid sinus syndrome (see p. 940). In one-third of cases, carotid sinus massage is only positive when the patient is standing. Atherosclerosis can cause narrowing and stenosis of carotid arteries. Carotid sinus massage should thus be avoided in patients with carotid bruits.

Box 23.7

Carotid sinus massage

- Explanation and informed consent.
- Ensure there is no significant carotid artery disease (carotid bruits).
- Provide continuous electrocardiographic monitoring.
- Place the patient in the supine position with the head slightly extended.
- Start with right carotid sinus massage.
- Apply firm rotary pressure to the carotid artery at the level of the third cervical vertebra for 5 s.
- Alternatively, apply steady pressure.
- If there is no response, massage the left carotid sinus.
- Generally, right carotid sinus massage decreases the sinus node discharge, and left carotid sinus massage slows atrioventricular conduction.
- Do not massage both carotid sinuses at the same time.
• Single application of carotid sinus pressure may be effective in about 20–30% of patients with paroxysmal supraventricular tachycardias; multiple applications can terminate tachycardia in about 50% of patients.

• Asystole is a potential but rare complication.

Echocardiography

Echocardiography is a non-invasive diagnostic technique that is widely employed in clinical cardiology. It involves the use of ultrasound (either alone or with contrast agent) to assess cardiac structure and function. A physician or technician performs the studies and a comprehensive examination takes 15–45 minutes. The ultrasound machines are either mobile on wheels, or handheld.

Physics

Echocardiography uses transmitted ultrasound wavelengths of ≤1 mm, which correspond to frequencies of approximately ≥2 MHz (≥2 million cycles per second). At such high frequencies, the ultrasound waves can be focused into a ‘beam’ and aimed at a particular region of the heart. The waves are generated in very short bursts or pulses a few microseconds long by a crystal transducer, which also detects returning echoes and converts them into electrical signals.

When the handheld crystal transducer is placed on the body surface, the emitted ultrasound pulses encounter interfaces between various body tissues as they pass through the body. In crossing each interface, some of the wave energy is reflected, and if the beam path is approximately at right angles to the plane of the interface, the reflected waves return to the transducer as an echo. Since the velocity of sound in body tissues is almost constant (1550 m/s), the time delay for the echo to return measures the distance of the reflecting interface. Thus, if a single ultrasound pulse is transmitted, a series of echoes return, the first of which is from the closest interface.

Echocardiographic modalities

M-mode and two-dimensional echocardiography

M-mode echocardiography is a technique that details the changing motion of structures along the ultrasound beam with time. Thus, the motion of the interventricular septum during the cardiac cycle (either towards or away from the transducer placed on the chest wall) can be assessed and quantified. Stationary structures thus generate horizontal straight lines; the distances of these lines from the top of the screen indicate the depth of the structures, and movements, such as those of heart valves, are indicated by zigzag lines (Fig. 23.23C). Alternatively, a series of views from different positions can be obtained in the form of a two-dimensional image (cross-sectional 2-D echocardiography; Fig. 23.23A,B). This method is useful for delineating anatomical structures and for quantifying volumes of the cardiac
chambers. M mode can be used to estimate left ventricular (LV) systolic function by comparing end-diastolic and end-systolic dimensions. For example, the percentage reduction in the left ventricular cavity size (‘shortening fraction’, SF) is given by:

$$SF = \frac{LVDD - LVSD}{LVDD} \times 100\%$$

where LVDD is left ventricular diastolic diameter and LVSD is left ventricular systolic diameter, at the base of the heart. The normal range is 30–45%.
This method is easy to perform, but is an inaccurate measure of ejection fraction (EF) because it does not take account of reduced regional function of the mid or apical myocardium—due to infarction, for example. For this reason, estimation of EF based on the difference in LV volumes from systole to diastole, derived from planimetered measurements of LV area in at least two planes, is more accurate. A normal EF is >55%. This method is helpful in assessing the response of the patient with heart failure to therapy. It also permits estimation of LV mass.

**Three-dimensional echocardiography**

Three-dimensional echocardiography is a novel development in cardiac imaging in which a volumetric dataset is acquired using a multiplane probe rotating around a fixed axis. Clinical uses include accurate volumetric assessment of ventricular function and mass, assessment of mitral and aortic valve disease, and assessment of adult congenital heart disease (*Fig. 23.24*).
**Doppler echocardiography**

Echocardiography imaging utilizes echoes from tissue interfaces. Using high amplification, it is also possible to detect weak echoes scattered by small targets, including those from red blood cells. Blood velocity in the heart chambers is typically much more rapid (>1 m/s) than the movement of myocardial tissue. If the blood is moving in the same direction as the direction of the ultrasound beam, the frequency of the returning echoes will be changed according to the Doppler phenomenon. The Doppler shift frequency is directly proportional to the blood velocity. Blood velocity data can be acquired and displayed in several ways.

**Pulsed-wave Doppler**

Pulsed-wave (PW) Doppler extracts velocity data from the pulse echoes used to form a 2-D image and gives useful qualitative information. PW echoes can be specified from locations within an image identified by a sample volume cursor placed on the screen. Such information from the left ventricular outflow tract (LVOT) and right ventricular outflow tract provides the stroke distance, and is used to estimate cardiac output (CO) and also to quantify intracardiac shunts.

Cardiac output can then be derived using the formula:

\[ CO = \text{stroke volume} \times \text{heart rate} \]

Stroke volume is the stroke distance multiplied by the area of the LVOT, which can also be measured echocardiographically. PW Doppler of the flow across the mitral valve and into the left atrium through the pulmonary veins can be used as an element of the estimation of left ventricular filling pressure.
Colour flow Doppler

Doppler colour flow imaging uses one colour for blood flowing towards the transducer and another colour for blood flowing away. This technique allows the direction, velocity and timing of the flow to be measured with a simultaneous view of cardiac structure and function. Colour flow Doppler is used to help assess valvular regurgitation (Fig. 23.25) and may be helpful in the assessment of coronary blood flow.

![Colour Doppler Image](image)

**FIGURE 23.25** Colour Doppler. Blood is shown flowing away from the echocardiography probe as a blue signal and towards the probe as a red signal. In this patient with tricuspid regurgitation, blood leaks from the right ventricle (RV) to the right atrium (RA) during cardiac systole. LA, left atrium; LV, left ventricle.

Continuous-wave Doppler

Continuous-wave (CW) Doppler collects all the velocity data from the path of the beam and analyses it to generate a spectral display. This is unlike PW Doppler, which provides information from a particular sample volume at one location along a line. Thus, CW Doppler does not provide any depth information.

The outline of the envelope of the spectral display is used to estimate the value of peak velocity throughout the cardiac cycle. CW Doppler is typically used to assess valvular obstruction, which then causes increased velocities. For example, normal flow velocities are of the order of 1 m/s across the normal aortic valve, but if there is a severe obstructive lesion, such as a severely stenotic aortic valve, velocities of 4 m/s or more can occur. These velocities are generated by the pressure gradient that exists across the lesion.

According to the Bernoulli equation, the pressure difference between two chambers is calculated as: 4 multiplied by the square of the CW Doppler velocity between chambers. Thus a velocity of 5 m/s across the aortic valve suggests a peak gradient of $4 \times 5 \times 5 = 100$ mmHg between the ascending aorta and the left ventricle. This equation has been validated in a wide variety of clinical situations, including valve stenoses, ventricular septal defects and intraventricular obstruction (as in hypertrophic cardiomyopathy). It is often clinically unnecessary to resort to invasive methods such as cardiac catheterization to measure...
intracardiac pressure gradients.

Similarly, pulmonary artery (PA) systolic pressure and right ventricular diastolic pressure can be calculated using the Bernoulli equation. In this case, CW Doppler tracing of the tricuspid regurgitant jet is used to estimate the pressure gradient between the right ventricle and the right atrium. The PA systolic pressure is then calculated by adding the estimated right atrial pressure to the pressure gradient between the right ventricle and the right atrium.

**Tissue Doppler**

Tissue Doppler is similar to PW Doppler. It measures myocardial tissue velocities within a particular sample volume placed on the image. Such velocities are of the order of 1 cm/s. Currently, tissue Doppler of the mitral annulus is used as part of the estimation of left ventricular filling pressure.

**Other ultrasound modalities**

Harmonic power Doppler, pulse inversion Doppler and ultraharmonics are used to detect and amplify microsphere-specific signals as part of the echocardiographic assessment of myocardial perfusion.

**Transoesophageal echocardiography**

In transoesophageal echocardiography (TOE), a transducer mounted on a flexible tube is placed into the oesophagus. This involves the use of local anaesthesia and, sometimes, intravenous sedation. High-resolution images can be obtained because of the close proximity of the heart to the transducer in the oesophagus, and also because of the higher frequencies that are used relative to transthoracic imaging. TOE is most commonly used to assess valve structure and function (for reparability of mitral valve prolapse), the features and complications of infective endocarditis, and the aorta (for aortic dissection); and to seek a cardiac source of embolus.

**Wall motion stress echocardiography**

Echocardiography can be used clinically to evaluate the patient for the presence of myocardial scars and reversible ischaemia. Since ultrasound cannot directly detect red blood cells in capillaries, myocardial wall motion is used as a surrogate for perfusion. Myocardial segments that demonstrate a change in function (defined as a change or reduction in thickening) from rest to stress can be assumed to be supplied by a flow-limiting stenosis in the epicardial artery or graft.

Stress for this indication needs to be inotropic to induce true ischaemia. Physiological stress includes treadmill exercise, which is complicated by the difficulty in obtaining reliable images rapidly as the patient comes off the treadmill, before heart rate reduces back to sub-maximal levels. Alternatively, pharmacological stress can be induced with dobutamine at graded doses. This is relatively safe but complications such as ventricular arrhythmia have been reported. This technique can also be used to assess viability of the myocardium, and hibernating or
stunned myocardium (see p. 987).

**Myocardial perfusion echocardiography**

In order to assess myocardial perfusion by echocardiography (MPE), microspheres of similar size to red blood cells are used as an intravenous contrast agent. Microsphere-specific ultrasound modes, such as harmonic power Doppler, can be used for detection. MPE involves the use of intravenous infusion of contrast to fill the myocardium. A pulse of ultrasound destroys microspheres within the capillaries (and not the left ventricular cavity), and the time taken to replenish the capillaries is a measure of myocardial blood flow. The time taken to fill should be significantly shorter at stress than at rest.

**Contrast echo for left ventricular opacification**

Intravenous contrast agents opacify the left ventricle and can define the endocardial border. Their clinical utility has reduced with the advent of harmonic imaging, which has improved image quality in patients who were previously ‘difficult to image’.

**Intravascular (coronary) ultrasound**

Intravascular (coronary) ultrasound probes can be used to obtain images of proximal coronary arteries as part of a percutaneous transluminal coronary angioplasty (PTCA) procedure: for example, to assess adequacy of deployment of intracoronary stents.

**Nuclear imaging**

Nuclear imaging is used to detect myocardial infarction or to measure myocardial function, perfusion or viability, depending on the radiopharmaceutical and the imaging technique chosen. These data are particularly valuable when used in combination. All involve a significant radiation dose (see p. 953).

**Image type**

Gamma cameras produce a planar image in which structures are superimposed, as in a standard radiograph. Single-photon-emission computed tomography (SPECT) imaging uses similar raw data to construct tomographic images, just as a CT image is reconstructed from X-rays. This gives finer anatomical resolution, but is technically demanding. These methods may be used with any of the radiopharmaceuticals.

**Myocardial perfusion and viability**

Thallium-201 is rapidly taken up by the myocardium, so an image taken immediately after injection reflects the distribution of blood flow to the myocardium. Areas of ischaemia or infarction receive less $^{201}$Tl and appear dark. Between 2 and 24 hours after injection, $^{201}$Tl is redistributed so that all cardiac myocytes contain a comparable concentration. Images obtained at this time show dark areas where the myocardium has infarcted, but normal density in ischaemic areas. Comparison of the early and late images is one method of predicting whether
an ischaemic area of myocardium contains enough viable tissue to justify coronary bypass or angioplasty. Technetium-99-labelled tetrofosmin (Fig. 23.26) is also taken up rapidly by cardiac myocytes but does not undergo redistribution. When this substance is injected during exercise, its distribution in the myocardium reflects the distribution of blood at the time of the exercise, even if the image is taken several hours later. This is a sensitive method of detecting myocardial viability. Images produced following injection of $^{99m}$Tc-tetrofosmin during exercise can be compared to images produced following injection at rest to decide which areas of ischaemia are reversible (see p. 987). In patients unable to exercise, the heart can be stressed with drugs, e.g. dipyridamole or dobutamine.

**FIGURE 23.26** Myocardial SPECT study acquired with $^{99m}$Tc-tetrofosmin tracer. *Left panel:* Three short-axis slices and a horizontal and a vertical axis plane of the left ventricle after stress and following a resting re-injection of tracer. The rest images demonstrate normal tracer uptake (orange signal) in the whole of the left ventricle. The stress images demonstrate reduced tracer uptake (arrows; purple-blue signal) in the anterior and septal walls, consistent with a significant stenosis in the left anterior descending artery. *Middle panel:* Polar maps of the whole myocardium can localize the ischaemic territory. *Right panel:* Quantitative analysis can help define the extent and reversibility of the ischaemia.

**Infarct imaging**

Perfusion images produced using compounds labelled with $^{201}$Tl or $^{99m}$Tc-sestamibi show a myocardial infarction as a perfusion defect or ‘cold spot’. These methods are sensitive for detecting and localizing the infarct, but give no information about its age. $^{99m}$Tc-Pyrophosphate
is preferentially taken up by myocardium that has undergone infarction within the previous few days. Images are difficult to interpret because the isotope is also concentrated by bone and cartilage.

**Cardiac computed tomography**

Computed tomography (CT) is useful for the assessment of the thoracic aorta and mediastinum. The development of 64-slice multidetector CT (MDCT) scanners has enabled accurate non-invasive imaging of the coronary arteries.

**Coronary artery calcification**

Calcium is absent in normal coronary arteries, but is present in atherosclerosis and increases with age. Studies have demonstrated a positive correlation between calcification and the presence of coronary artery stenoses, although the relationship is non-linear. Electron beam CT (EBT) and MDCT scanners are used to obtain multiple thin axial slices through the heart and then the calcium score is calculated. The calcium score is based on the X-ray attenuation coefficient or CT number measured in Hounsfield units. Meta-analyses have demonstrated that a higher calcium score is associated with a higher event rate and higher relative risk ratios, although currently no study has shown a net effect on health outcomes of calcium scoring. The current National Institute for Health and Care Excellence (NICE) chest pain guidelines recommend the use of CT calcium scoring in patients with chest pain and a 10–29% likelihood of coronary artery disease (see p. 995).

**CT coronary angiography**

CT coronary angiography (CTCA) is performed with a supine patient connected to a three-lead ECG for cardiac synchronization. The 64-slice MDCT scanners have a temporal resolution of 165–210 ms; image quality is optimal with a slow and steady heart rate (<65–70 b.p.m.), which can be obtained with the use of oral or intravenous beta-blockers. Sublingual nitroglycerin (0.4–0.8 mg dose) may improve visualization of the coronary artery lumen. A volume dataset containing the whole heart is acquired during a single breath-hold with the injection of 60–80 mL of iodinated contrast agent at 4–6 mL/s. The radiation dose during the scan is 11–22 mSv but this can be reduced to 7–11 mSv with ECG-controlled dose modulation; this compares with 2.5–5.0 mSv for diagnostic coronary angiography and 15–20 mSv for SPECT. The volume dataset is then analysed with multiplanar reformatting for the presence of coronary artery stenoses ([Fig. 23.27](#)). Studies have reported high sensitivity (>85%) and specificity (>90%) for the detection of coronary artery disease, with a very high negative predictive value (>95%). CTCA may become part of an acute chest pain service in the emergency medicine department to exclude aortic dissection, pulmonary embolism and coronary artery disease. However, this technique does expose the patient to ionizing radiation.
FIGURE 23.27  Coronary artery stent: multislice computed tomography. A. A volume-rendered image in a patient with coronary artery stent insertion (arrow) in a saphenous vein graft to the native circumflex coronary artery. B. The multiplanar reformatted image demonstrates stent patency (arrow) and insertion of the graft to the circumflex coronary artery.

Cardiovascular magnetic resonance

Cardiovascular magnetic resonance (CMR), a non-invasive imaging technique that does not involve harmful radiation, is increasingly used in the investigation of patients with
cardiovascular disease.

CMR is usually performed with multiple breath-holds to minimize respiratory motion artefacts and cardiac gating to reduce blurring during the cardiac cycle. Several different sequences are used to provide anatomical and functional information. Most sequences do not require a contrast agent but intravenous gadolinium may be needed for magnetic resonance angiography, myocardial perfusion, infarct and fibrosis imaging. The major contraindications are permanent pacemaker or defibrillator, intracerebral clips and significant claustrophobia. Patients with coronary stents and prosthetic valves can be safely scanned.

**Clinical use of CMR**

The current indications for CMR are summarized in [Box 23.8](#).

---

### Box 23.8

**Indications for cardiovascular magnetic resonance (CMR)**

- **Congenital heart disease (CHD):**
  - Anatomical assessment following echocardiography, particularly in patients with complex CHD or following surgical intervention
  - Follow-up/surveillance studies
  - Anomalous pulmonary or systemic venous return
  - Assessment of right or left ventricular function/dilatation
- **Cardiomyopathies/cardiac infiltration/pericardial disease**
- **Disease of the aorta, including aortic dissection, aneurysm, coarctation**
- **Valvular heart disease:**
  - Quantification of stenosis and regurgitation
  - Accurate ventricular dimensions/function
  - Planimetry of valvular stenosis
- **Coronary artery disease:**
  - Left and right ventricular function
  - Wall motion assessment during dobutamine stress
  - Myocardial perfusion during adenosine stress
  - Coronary artery and coronary artery bypass graft imaging
  - Myocardial infarct imaging and viability assessment with dobutamine CMR or delayed enhancement
- **Pulmonary vessels**

---

**Congenital heart disease**

CMR provides additional and complementary information to echocardiography in patients with congenital heart disease. Cine-imaging can accurately assess systemic and non-systemic
ventricular function and mass. Extracardiac conduits, anomalous pulmonary venous return and aortic coarctations before and after repair can be studied by CMR, and the studies repeated for long-term follow-up without the risk of ionizing radiation.

Cardiomyopathies, pericardial disease and cardiac masses

In hypertrophic cardiomyopathy, CMR accurately defines the extent and distribution of myocardial hypertrophy and can be used in patients with sub-optimal echocardiograms. Intravenous gadolinium can be utilized to demonstrate regional myocardial fibrosis, which is associated with an adverse prognosis. In patients with suspected arrhythmogenic right ventricular cardiomyopathy, CMR is the imaging investigation of choice to detect global and regional wall motion abnormalities of the right ventricle and right ventricular outflow tract, and to detect fatty or fibro-fatty infiltration of the right and left ventricles. In constrictive pericarditis and restrictive cardiomyopathy, CMR can demonstrate the effects of the impaired ventricular filling common to both conditions (dilated right atrium and inferior vena cava), and can also determine the thickness of the pericardium (usually 4 mm in normal individuals) (Fig. 23.28). In patients with dilated cardiomyopathy, CMR can accurately quantify biventricular function and, with gadolinium, can demonstrate myocardial fibrosis. In inflammatory and infiltrative conditions of the myocardium, such as myocarditis, sarcoidosis and amyloidosis, CMR is increasingly used as a diagnostic investigation due to different patterns of signal enhancement seen with gadolinium. In patients with thalassaemia, CMR can detect iron deposition within the myocardium and guide chelation therapy. CMR can be useful in patients with cardiac masses to differentiate benign from malignant tumours and to identify thrombus not visualized on echocardiography.

Diseases of the aorta

CMR is an excellent technique for assessing patients with aortic dissection and can detect the clinical features of an aortic dissection: the intimal flap, thrombosis in a false lumen, aortic regurgitation, pericardial effusion and aortic dilatation. As it does not involve radiation or
need contrast, CMR is an ideal method of surveillance of patients with dilated thoracic aortas or repaired coarctation.

Valvular heart disease

Valvular stenosis produces signal void on gradient-echo CMR. CMR can quantify the velocity across a stenosed valve using phase-contrast velocity mapping. Valvular regurgitation can be accurately quantified using phase-contrast velocity mapping across the valve, or by calculating the stroke volumes of the left and right ventricles, which are equal in the absence of significant regurgitation. However, in most patients, transthoracic and transoesophageal echocardiography should provide sufficient information.

Coronary artery disease

CMR can be used to assess coronary artery anatomy, left ventricular function, myocardial perfusion and viability in a ‘one-stop’ approach to the assessment of patients with coronary artery disease. Coronary artery anatomy and stenoses can be identified with ultra-fast breath-hold or respiratory-gated sequences with high accuracies. Global left ventricular function and wall motion abnormalities can be detected with cine-imaging performed at rest and during dobutamine stress. Myocardial perfusion can be assessed with gadolinium and first-pass imaging; ischaemia can be demonstrated with adenosine for coronary vasodilatation. Myocardial viability can be determined using gadolinium and ‘delayed enhancement’ images. With these techniques, CMR is increasingly used to assess both ischaemia in patients with suspected coronary disease, and myocardial viability prior to revascularization in patients with impaired cardiac function (Figs 23.29 and 23.30).

**FIGURE 23.29** Cardiac magnetic resonance (CMR) in a patient with type 2 diabetes mellitus and exertional breathlessness. A. Diagnostic coronary angiography demonstrates a severe stenosis (*) in the right coronary artery (RCA). B. There is a sub-totally occluded (+) circumflex coronary artery (LCX). C. A long diseased segment (X) is also seen in the left anterior descending coronary artery (LAD).
Cardiac magnetic resonance (CMR). A. Short-axis CMR FINEST cine-imaging (diastole top, systole bottom) demonstrates thinning and hypokinesia of the inferolateral wall (arrowed) but preserved function of the rest of the myocardium. B. First-pass perfusion CMR (mid top, apex bottom) demonstrates sub-endocardial perfusion defects in the inferolateral wall (+), infero-septum (*) and apical segments (X). C. Delayed-enhancement CMR confirms a transmural myocardial infarction of the mid-apical inferolateral wall (+) secondary to a previous infarction from the circumflex coronary artery, and confirms inducible ischaemia in the right and left coronary territories. LV, left ventricle; RV, right ventricle.

**Pulmonary vessels**

Magnetic resonance angiography (MRA) with gadolinium can provide high-quality images of the pulmonary veins, which can be fused with electrical data during pulmonary vein isolation for the treatment of atrial fibrillation.

**Positron emission tomography**

Positron emission tomography (PET) is based on detection of high-energy emissions caused by annihilation of positrons released from unstable isotopes. PET has several advantages over other techniques, such as improved spatial resolution, accurate quantification, and use of biological isotopes of carbon, nitrogen and oxygen. However, it is expensive and requires a cyclotron to produce the short-lived tracers. PET/CT has become a useful investigation in the detection of viable myocardium in patients who are suitable for revascularization.

Myocardial perfusion and ischaemia can be determined using PET with $^{13}$N-ammonia or $^{15}$oxygen with greater sensitivity than SPECT. Myocardial metabolism and viability can be detected with the use of $^{18}$F-fluorodeoxyglucose (FDG), which the cardiac myocyte utilizes for energy production in the presence of reduced oxygen supply and blood flow. There may be reduced perfusion to infarcted or fibrotic myocardium, but also reduced FDG uptake. In hibernating myocardium, with viable but dysfunctional myocardium, PET can demonstrate reduced myocardial perfusion but with preserved or increased FDG uptake.
Cardiac catheterization

Cardiac catheterization is the introduction of a thin radio-opaque tube (catheter) into the circulation. The right heart is catheterized by introducing the catheter into a peripheral vein (usually the right femoral or internal jugular vein) and advancing it through the right atrium and ventricle into the pulmonary artery. The pressures in the right heart chambers and in the pulmonary artery can be measured directly. An indirect measure of left atrial pressure can be obtained by ‘wedging’ a catheter into the distal pulmonary artery (see p. 1147). In this position, the pressure from the right ventricle is obstructed by the catheter, and only the pulmonary venous and left atrial pressures are recorded. Left heart catheterization is usually performed via the right femoral or radial artery. A pigtail catheter is advanced up the aorta and manipulated through the aortic valve into the left ventricle. Pressure tracings are taken from the left ventricular cavity. The end-diastolic pressure is invariably elevated in patients with left ventricular dysfunction. A power injection of radio-opaque contrast material is used to opacify the left ventricular cavity (left ventriculography) and thereby assesses left ventricular systolic function. The catheter is then withdrawn across the aortic valve into the aorta and the ‘pullback’ gradient across the valve is measured. Aortography (a power injection into the aortic root) can be performed to assess the aortic root and the presence and severity of aortic regurgitation. Specially designed catheters are then used to engage the left and right coronary arteries selectively, and contrast cine-angiograms are taken in order to define the coronary circulation and identify the presence and severity of any coronary artery disease. During the procedure, intracoronary nitrate or adenosine may be used to dilate the coronary arteries. During cardiac catheterization, blood samples may be withdrawn to measure the oxygen content. These estimations are used to quantify intracardiac shunts and measure cardiac output.

Therapeutic Procedures

Cardiac resuscitation

Each year in the UK, there are approximately 100,000 unexpected deaths occurring within 24 hours of the development of cardiac symptoms. About half of these deaths are almost instantaneous. Most deaths are due to ventricular fibrillation or rapid ventricular tachycardia; a small proportion are caused by severe bradyarrhythmias. Coronary artery disease accounts for approximately 80% of sudden cardiac deaths in Western society. Transient ischaemia is suspected of being the major trigger factor; however, only a small proportion of survivors have clinical evidence of acute myocardial infarction.

When cardiac arrest occurs, basic life support must be started immediately. The longer the period of respiratory and circulatory arrest, the lower is the chance of restoring healthy life. The chain of survival (Fig. 23.31) includes early recognition of cardiac arrest; early activation of emergency services; early cardiopulmonary resuscitation (CPR); early defibrillation and early advanced life support; and high-quality post-resuscitation care.

Basic life support

The first step in basic life support (BLS) is to ensure the safety of the victim and rescuer. The
next is to ascertain that the victim is unresponsive by shaking him/her and shouting into one ear. If no response is obtained, help should be sought immediately prior to commencement of BLS. If the victim has absent or abnormal breathing, then cardiac arrest is confirmed and BLS should be started *(Box 23.9)*.

---

**Box 23.9**

**Adult basic life support (out of hospital)**

(AED, automated external defibrillator; CPR, cardiopulmonary resuscitation. With permission from Resuscitation Council UK; [http://www.resus.org.uk](http://www.resus.org.uk).)

---

**Airway**

Debris (e.g. blood and mucus) in the mouth and pharynx should be removed. Loose or ill-fitting dentures should be removed. The airway should be opened gently by flexing the neck and extending the head (‘sniffing the morning air’ position). This manoeuvre is not recommended if a cervical spine injury is suspected. Any obstruction deep in the oral cavity or upper respiratory tract may need to be removed using abdominal and/or chest thrusts (Heimlich manoeuvre; see p. 1078).
Circulation

Most adult cardiac arrest is due to a primary cardiac disorder, such as acute coronary syndrome, and results in circulatory collapse. Pulse detection can be difficult, and if the victim is unresponsive, with absent or abnormal breathing, external chest compression should be started immediately. The heel of one hand is placed over the centre of the patient's chest and the heel of the second hand is placed over the first with the fingers interlocked. The arms are kept straight and the sternum is rhythmically depressed by 5–6 cm at a rate of approximately 100–120 per minute, allowing for complete recoil between compressions. Chest compressions do not massage the heart. The thorax acts as a pump and the heart provides a system of one-way valves to ensure forward circulation. Respiratory and circulatory support is continued by providing two effective breaths for every 30 cardiac compressions (30 : 2 for one or two persons, 15 : 2 in paediatric patients). It is easier for the lay public to give compressions without interruption (hands only). This maintains adequate cerebral and coronary perfusion pressures. The initiation of CPR by the lay public at the site of the arrest saves lives. There is evidence to suggest that if the person performing compressions tires, the quality of resuscitation deteriorates. Mechanical CPR devices are available but not yet widely used.

Breathing

After 30 compressions, the rescuer opens the victim's airway by tilting the head backwards (head tilt) and pulling the chin forwards (chin lift or jaw thrust). The rescuer then pinches the victim's nostrils firmly, takes a deep breath, and seals his/her lips around the mouth of the victim. Two effective breaths are given, each over 1 second. In paediatric patients, respiratory arrests are more common and patients should be given rescue breaths and a minute of CPR before a sole rescuer leaves the victim to seek help. CPR should not be interrupted to re-assess the victim unless he/she starts to show signs of life and starts to breathe normally.

Advanced cardiac life support

By the time effective life support has been established, more help should have arrived and advanced cardiac life support (ACLS) can begin. This consists of ECG monitoring, advanced airway management (endotracheal intubation or supraglottic airway tube) and establishment of an intravenous infusion in a large peripheral or central vein (an intra-osseous needle may be used if intravenous access is not possible). As soon as possible, the cardiac rhythm should be established, as this determines which pathway of the European Resuscitation Council and the Resuscitation Council UK ACLS algorithm is followed (Fig. 23.32). This can be determined with an automated external defibrillator (AED), or the paddles or limb leads of a standard defibrillator.
If the ECG shows a shockable rhythm – ventricular fibrillation or pulseless ventricular tachycardia, then an unsynchronized shock of 150–200 J biphasic (360 J monophasic) is delivered without delay via paddles or self-adhesive pads, followed immediately by 2 minutes of CPR. For a non-shockable rhythm – asystole or pulseless electrical activity, 2 minutes of CPR is delivered with 1 mg of intravenous adrenaline (epinephrine).

For both sides of the algorithm, it is vital to maintain CPR, ensure oxygenation and exclude or treat reversible causes: the ‘four Hs and four Ts’:

- **Hypoxia** should be minimized by ventilating the patient with oxygen and a bag-valve mask or
advanced airway (endotracheal intubation or supraglottic airway tube), ensuring that there is bilateral air entry and chest expansion. With an advanced airway, CPR should continue, with a ventilation rate of 10 per minute without interrupting cardiac massage.

- **Hypovolaemia** is a frequent cause of pulseless electrical activity due to haemorrhage. Intravenous volume should be replaced.

- **Hyper- or hypokalaemia** may cause ECG abnormalities and should be detected by biochemical testing. Intravenous calcium chloride may be helpful in hyperkalaemia or hypocalcaemia. Acidosis should be managed with effective ventilation.

- **Hypothermia** should be excluded with a low-reading thermometer and treated with external or internal warming.

- **Thromboembolism** and massive pulmonary embolism may cause pulseless electrical activity and patients should be considered for intravenous thrombolysis.

- **Tension pneumothorax** may occur during central venous cannulation or following chest trauma. Clinical diagnosis (deviated trachea, hyper-resonant chest, absent breath sounds, ultrasound) and needle thoracocentesis or thoracostomy may be required.

- **Tamponade** should be excluded with echocardiography; if present, it should be treated with pericardiocentesis.

- **Toxins** may have been ingested by accident or deliberate self-harm, and specific antidotes should be used in appropriate patients.

**Defibrillation**

This technique is used to convert ventricular fibrillation to sinus rhythm. When the defibrillator is discharged, a high-voltage field envelops the heart, depolarizing the myocardium and allowing an organized heart rhythm to emerge. Electrical energy is discharged through two paddles with gel pads or adhesive pads placed on the chest wall.

The paddles are placed in one of two positions:

- One paddle is placed to the right of the upper sternum and the other over the cardiac apex.
- One paddle is placed under the tip of the left scapula and the other is over the anterior wall of the left chest.

All personnel should stand clear of the patient. The person performing defibrillation has the responsibility for ensuring the safety of the patient and of the other people present. Conventional defibrillators employ a damped monophasic waveform. Biphasic defibrillators, which require less energy, are increasingly common. AEDs, which recognize ventricular fibrillation automatically, deliver a shock if indicated. These are available in some public places (in the UK, their location is signalled by a specific sign; **Fig. 23.33**). It is the responsibility of all healthcare practitioners to be familiar with the range of defibrillators they may be called on to use in their workplace.
Post resuscitation – therapeutic hypothermia

Initial studies suggested that therapeutic hypothermia (32–34°C for 12–24 h) might improve outcomes in unconscious adult patients with spontaneous circulation after an out-of-hospital cardiac arrest due to ventricular fibrillation. However, a recent multinational study demonstrated a similar improvement in outcome with therapeutic hypothermia at 33°C, compared to a targeted temperature of 36°C; thus, the value of hypothermia is unclear.

Neurological recovery appears to be more favourable in patients with purposeful movements and EEG activity within 3 days of a cardiac arrest.

Direct current cardioversion

Tachyarrhythmias that do not respond to medical treatment or that are associated with haemodynamic compromise (e.g. hypotension, worsening heart failure) may be converted to sinus rhythm by the use of a transthoracic electric shock. A short-acting general anaesthetic is used. Muscle relaxants are not usually given.

When the arrhythmia has definite QRS complexes, the delivery of the shock should be timed to coincide with the downstroke of the QRS complex (synchronization) (Fig. 23.34). The machine being used to perform the direct current cardioversion (DCC) will do this automatically if the appropriate button is pressed. There is a crucial difference between defibrillation and cardioversion: a non-synchronized shock is used to defibrillate. Accidental defibrillation of a patient who does not require it may itself precipitate ventricular fibrillation.
Typical indications for DCC include:

- atrial fibrillation
- atrial flutter
- sustained ventricular tachycardia
- junctional tachyarrhythmias.

If atrial fibrillation or flutter has been present for more than a few days, it is necessary to anticoagulate the patient adequately for 3 weeks before elective cardioversion to reduce the risk of embolization. The duration of anticoagulation after successful cardioversion for atrial fibrillation is a complex issue and depends on a number of factors: it should be given for at least 4 weeks after the procedure and may well be given for much longer.

Digoxin toxicity may lead to ventricular arrhythmias or asystole following cardioversion. Therapeutic digitalization does not increase the risks of cardioversion, but it is conventional to omit digoxin several days prior to elective cardioversion in order to be sure that toxicity is not present.

Cardiac enzyme levels may rise after a cardioversion.

**Temporary pacing**

Therapeutic cardiac pacing is employed in any patient with sustained symptomatic or haemodynamically compromising bradycardia. Bradycardias may be due to either a slow intrinsic heart rate (e.g. sinus node dysfunction) or AV block. Prophylactic cardiac pacing is employed in asymptomatic patients with either bradycardia or conduction abnormalities, in whom the risk of progression to symptomatic bradycardia justifies such a strategy.

**Transvenous pacing** is the preferred method in patients with symptomatic bradycardias. In summary, a thin (French gauge 5 or 6), bipolar pacing electrode wire is inserted via an internal jugular vein, a femoral vein or a subclavian vein and is positioned at the right ventricular apex using cardiac fluoroscopy. The energy needed for successful pacing (the pacing threshold) is assessed by reducing the energy until the pacemaker fails to stimulate the tissue (loss of capture). The output energy is then set at three times the threshold value to prevent inadvertent loss of capture. If the threshold increases above 5 V, the pacemaker wire should be resited.
temporary pacemaker unit (*Fig. 23.35A*) is almost always set to work ‘on demand’ – to fire only when a spontaneous beat has not occurred. The rate of temporary pacing is usually 60–80 per minute.
Transcutaneous pacing is the preferred method in selected patients with asymptomatic bradycardia or conduction abnormalities, and may be life-saving when a cardiac arrest is precipitated by bradycardia. In this method, the myocardium is depolarized by current flow
between two large adhesive electrodes positioned anteriorly and posteriorly on the chest wall. Transcutaneous pacing is uncomfortable for the conscious patient. However, it can usually be tolerated until a temporary transvenous pacemaker is inserted.

**Permanent pacing**

Permanent pacemakers are fully implanted in the body and connected to the heart by one or two electrode leads (*Fig. 23.35B*). The pacemaker is powered by solid-state lithium batteries, which usually last 5–10 years. Pacemakers are ‘programmable’, in that their operating characteristics (e.g. the pacing rate) can be changed by a programmer that transmits specific electromagnetic signals through the skin. The pacemaker leads are passed transvenously to the right heart chambers. Leadless pacemakers are in trials.

Pacemakers are designed both to pace and to sense either the ventricles, the atria or, more commonly, both chambers. A single-chamber ventricular pacemaker is described as a ‘VVI’ unit because it paces the ventricle (V), senses the ventricle (V) and is inhibited (I) by a spontaneous ventricular signal. Occasionally (e.g. in symptomatic sinus bradycardia), an atrial pacemaker (AAI) may be implanted. Pacemakers that are connected to both the right atrium and ventricle (‘dual-chamber’ pacemakers) are used to simulate the natural pacemaker and activation sequence of the heart. This form of pacemaker is called DDD because it paces the two (dual) chambers, senses both (D) and reacts in two (D) ways: pacing in the same chamber is inhibited by spontaneous atrial and ventricular signals, and ventricular pacing is triggered by spontaneous atrial events (*Fig. 23.35C*).

In addition, pacemakers may be ‘rate-responsive’ (R). A rate-responsive pacemaker detects motion (level of vibration or acceleration), respiration or changes in QT interval; by employing one or more biosensors, it changes its rate of pacing so that it is appropriate to the level of exertion.

The choice of pacemaker mostly depends on the underlying rhythm abnormality and the general condition of the patient. For example, complete heart block in patients with sinus rhythm should be treated with a dual-chamber device in order to maintain AV synchrony, whereas inactive or infirm patients may not benefit from the most sophisticated units. Specialized biventricular pacemakers are used for the treatment of severe heart failure.

Permanent pacemakers are inserted under local anaesthetic using fluoroscopy to guide the insertion of the electrode leads via the cephalic or subclavian veins. Perioperative prophylactic antibiotics are routinely prescribed. The pacemaker is usually positioned subcutaneously in front of the pectoral muscle. Following surgery, which usually takes 60–90 minutes, the patient rests in bed for 6–12 hours before being discharged. Patients may not drive for at least 1 week after implantation, and must inform the licensing authorities and their motor insurers.

Complications are few but can prove to be very difficult to manage, and patients should be referred to the pacemaker clinic. They include the following:

- infection
- erosion
• pocket haematoma
• lead displacement
• electromagnetic interference.

Pericardiocentesis

A pericardial effusion is an accumulation of fluid between the parietal and visceral layers of pericardium. Fluid is removed for relief of symptoms that are due to haemodynamic embarrassment or for diagnostic purposes. This can be a technically difficult procedure, particularly in the acute setting, and should be performed in a cardiac laboratory. In an emergency, it can be performed at the bedside.

Pericardial aspiration or pericardiocentesis (Fig. 23.36) is performed by inserting a needle into the pericardial space, usually via a sub-xiphisternal route under ultrasound guidance. Certain effusions, particularly posterior ones, require surgical drainage under a general anaesthetic. If a large volume of fluid is to be removed, a wide-bore needle and cannula are inserted. The needle may be removed and the cannula left in situ to drain the fluid. Fluid that is removed is sent for chemical analysis, microscopy, including cytology, Gram stain and culture. If a re-accumulation of pericardial fluid is anticipated, the cannula may be left in place for several days, or an operation can be performed to cut a window in the parietal pericardium (fenestration) or to remove a large section of the pericardium.
**Right-heart bedside catheterization**

Bedside catheterization (see Fig. 25.14) of the pulmonary artery with a pulmonary artery balloon flotation catheter (Swan–Ganz catheter) is performed in patients with:

- cardiac failure
- cardiogenic shock
- doubtful fluid status.

**Intra-aortic balloon pumping**

This technique is used to assist the failing left ventricle temporarily. A catheter with a long sausage-shaped balloon at its tip is introduced percutaneously into the femoral artery and manipulated under X-ray control so that the balloon lies in the descending aorta just below the aortic arch (Fig. 23.37). The balloon is rhythmically deflated and inflated with carbon dioxide gas. Using the ECG or intra-aortic pressure changes, the inflation is timed to occur during ventricular diastole to increase diastolic aortic pressure and, consequently, to improve coronary and cerebral blood flow. During systole, the balloon is deflated, resulting in a reduction in the resistance to left ventricular emptying. Intra-aortic balloon pumping is used for circulatory support in the following acute situations:
• **Acute heart failure.** Balloon pumping is employed to improve cardiac output when there is a transient or reversible depression of left ventricular function, such as in a patient with severe mitral valve regurgitation who is awaiting surgical replacement of the mitral valve, or in a patient with a ventricular septal defect that is due to septal infarction. It may also be used to support patients awaiting heart transplantation.

• **Unstable angina pectoris.** Balloon pumping is utilized to treat unstable angina pectoris by improving coronary flow and decreasing myocardial oxygen consumption by reducing the ‘afterload’. This technique may be successful, even when medical therapy has failed. It is followed by early angiography and appropriate definitive therapy, such as surgery or coronary angioplasty.

Balloon pumping should not be used when there is no remediable cause of cardiac dysfunction. It is also unsuitable in patients with severe aortic regurgitation, aortic dissection and severe peripheral vascular disease.
Complications of balloon pumping occur in about 20% of patients and include aortic dissection, leg ischaemia, emboli from the balloon, and balloon rupture. Embolic complications are reduced by anticoagulation with heparin.

**Further reading**

**Cardiac Arrhythmias**

An abnormality of the cardiac rhythm is called a cardiac arrhythmia. Arrhythmias may cause sudden death, syncope, heart failure, chest pain, dizziness, palpitations or no symptoms at all. There are two main types of arrhythmia:

- **Bradycardia**: the heart rate is slow (<60 b.p.m. during the day or <50 b.p.m. at night).
- **Tachycardia**: the heart rate is fast (>100 b.p.m.).

Tachycardias are more symptomatic when the arrhythmia is fast and sustained. Tachycardias are subdivided into supraventricular tachycardias, which arise from the atrium or the AV junction, and ventricular tachycardias, which arise from the ventricles.

Some arrhythmias occur in patients with apparently normal hearts; in others, arrhythmias originate from diseased tissue, such as scar, as a result of underlying structural heart disease. When myocardial function is poor, arrhythmias are more symptomatic and are potentially life-threatening.

**Sinus node function**

The normal cardiac pacemaker is the sinus node (see p. 933) and, like most cardiac tissue, it depolarizes spontaneously.

The rate of sinus node discharge is modulated by the autonomic nervous system. Normally, the parasympathetic system predominates, resulting in slowing of the spontaneous discharge rate from approximately 100 to 70 b.p.m. A reduction of parasympathetic tone or an increase in sympathetic stimulation leads to tachycardia; conversely, increased parasympathetic tone or decreased sympathetic stimulation produces bradycardia. The sinus rate in women is slightly faster than in men. Normal sinus rhythm is characterized by P waves that are upright in leads I and II of the ECG (see *Fig. 23.18*), but inverted in the cavity leads AVR and V₁ (*Fig. 23.38*).
Sinus arrhythmia

Fluctuations of autonomic tone result in phasic changes of the sinus discharge rate. During inspiration, parasympathetic tone falls and the heart rate quickens; on expiration, the heart rate falls. This variation is normal, particularly in children and young adults. Typically, sinus arrhythmia results in predictable irregularities of the pulse.

Sinus bradycardia

A sinus rate of <60 b.p.m. during the day or <50 b.p.m. at night is known as sinus bradycardia. It is usually asymptomatic unless the rate is very slow. Sinus bradycardia is normal in athletes owing to increased vagal tone. Other causes may be divided into systemic or cardiac, and are discussed below in the section entitled ‘Bradycardias and heart block’ (see pp. 964–968).

Sinus tachycardia

Sinus rate acceleration to >100 b.p.m. is known as sinus tachycardia. Again, causes may be divided into systemic or cardiac, and are discussed below in the section entitled ‘Supraventricular tachycardias’ (see pp. 968–973).

Mechanisms of arrhythmia production

Abnormalities of automaticity, which could arise from a single cell, and abnormalities of conduction, which require abnormal interaction between cells, account for both bradycardia
and tachycardia. Sinus bradycardia is a result of abnormally slow automaticity while bradycardia due to AV block is caused by abnormal conduction within the AV node or the intraventricular conduction system. The mechanisms generating tachycardia are shown in Figure 23.39.

**FIGURE 23.39**  Mechanisms of arrhythmogenesis. A–B. Action potentials (i.e. the potential difference between intracellular and extracellular fluid) of ventricular myocardium after stimulation. A. Increased (accelerated) automaticity due to reduced threshold potential or an increased slope of phase 4 depolarization (see pp. 944–945). B. Triggered activity due to early (E) or delayed (D) 'after-depolarizations' reaching threshold potential. C. Mechanism of circus movement or re-entry. In panel (1) the impulse passes down both limbs of the potential tachycardia circuit. In panel (2) the impulse is blocked in one pathway (α) but proceeds slowly down pathway β, returning along pathway α until it collides with refractory tissue. In panel (3) the impulse travels so slowly along pathway β that it can return along pathway α and complete the re-entry circuit, producing a circus movement tachycardia.

**Accelerated automaticity**

The normal mechanism of spontaneous cardiac rhythmicity is slow depolarization of the transmembrane voltage during diastole until the threshold potential is reached and the action potential of the pacemaker cells takes off. This mechanism may be accelerated by increasing the rate of diastolic depolarization or changing the threshold potential (**Fig. 23.39A**). For example, sympathetic stimulation releases adrenaline (epinephrine), which enhances automaticity. Such changes are thought to produce sinus tachycardia, escape rhythms and accelerated AV nodal (junctional) rhythms.
**Triggered activity**

Myocardial damage can result in oscillations of the transmembrane potential at the end of the action potential. These oscillations, which are called ‘after-depolarizations’, may reach threshold potential and produce an arrhythmia. If they occur before the transmembrane potential reaches its threshold (at the end of phase 3 of the action potential), they are called ‘early after-depolarizations’ (E in Fig. 23.39B). When they develop after the transmembrane potential is completed, they are called ‘delayed after-depolarizations’ (D in Fig. 23.39B).

The abnormal oscillations can be exaggerated by pacing, catecholamines, electrolyte disturbances, hypoxia, acidosis and some medications, which may then trigger an arrhythmia. The atrial tachycardias produced by digoxin toxicity are due to triggered activity. The initiation of ventricular arrhythmia in the long QT syndrome (see p. 975) may be caused by this mechanism.

**Re-entry (or circus movements)**

The mechanism of re-entry (Fig. 23.39C) occurs when a ‘ring’ of cardiac tissue surrounds an inexcitable core (e.g. in a region of scarred myocardium). Tachycardia is initiated if an ectopic beat finds one limb refractory (α), resulting in unidirectional block, and the other limb excitable. Provided conduction through the excitable limb (β) is slow enough, the other limb (α) will have recovered and will allow retrograde activation to complete the re-entry loop. If the time to conduct around the ring is longer than the recovery times (refractory periods) of the tissue within the ring, circus movement will be maintained, producing a run of tachycardia. The majority of regular paroxysmal tachycardias are produced by this mechanism.

**Bradycardias and Heart Block**

Bradycardias may be due to failure of impulse formation (sinus bradycardia) or failure of impulse conduction from the atria to the ventricles (atrioventricular block).

**Bradycardia**

**Sinus bradycardia**

Sinus bradycardia is due to extrinsic factors that influence a relatively normal sinus node, or due to intrinsic sinus node disease. The mechanism can be acute and reversible, or chronic and degenerative.

Common *extrinsic causes* of sinus bradycardia include:

- hypothermia, hypothyroidism, cholestatic jaundice and raised intracranial pressure
- drug therapy with beta-blockers, digitalis and other antiarrhythmic drugs
- neurally mediated syndromes (see below).

Common *intrinsic causes* include:
• acute ischaemia and infarction of the sinus node (as a complication of acute myocardial infarction)
• chronic degenerative changes, such as fibrosis of the atrium and sinus node (sick sinus syndrome).

_Sick sinus syndrome_ or _sinoatrial disease_ is usually caused by idiopathic fibrosis of the sinus node. Other causes of fibrosis, such as ischaemic heart disease, cardiomyopathy or myocarditis, can also cause the syndrome. Patients develop episodes of sinus bradycardia or sinus arrest (see _Fig. 23.38B_), and commonly experience paroxysmal atrial tachyarrhythmias (tachy–brady syndrome) owing to diffuse atrial disease.

**Neurally mediated syndromes**

Neurally mediated syndromes are due to a reflex (called Bezold–Jarisch) that may result in both bradycardia (sinus bradycardia, sinus arrest and AV block) and reflex peripheral vasodilatation. These syndromes usually present as syncope or pre-syncope (dizzy spells).
• **Carotid sinus syndrome** occurs in the elderly and mainly leads to bradycardia. Syncope occurs (see p. 940).

• **Neurocardiogenic (vasovagal) syncope (syndrome)** usually presents in young adults but may present for the first time in elderly patients (see pp. 939–940). It results from a variety of situations (physical and emotional) that affect the autonomic nervous system. The efferent output may be predominantly bradycardic, predominantly vasodilatory or mixed.

• **Postural orthostatic tachycardia syndrome (POTS)** is a sudden and significant increase in heart rate associated with normal or mildly reduced blood pressure and produced by standing. The underlying mechanism is a failure of the peripheral vasculature to constrict appropriately in response to orthostatic stress, which is compensated by an excessive increase in heart rate.

Many medications, such as antihypertensives, tricyclic antidepressants and neuroleptics, can be the cause of syncope, particularly in the elderly. Careful dose titration and avoidance of combining two agents with the potential to cause syncope help to prevent iatrogenic syncope.

### Management

The management of sinus bradycardia is first to identify and then, if possible, to remove any extrinsic causes. Temporary pacing may be employed in patients with reversible causes until a normal sinus rate is restored, and in patients with chronic degenerative conditions until a permanent pacemaker is implanted.

Chronic symptomatic sick sinus syndrome requires permanent pacing (DDD), with additional antiarrhythmic drugs (or ablation therapy) to manage any tachycardic element. Thromboembolism is common in tachy–brady syndrome and patients should be anticoagulated unless there is a contraindication.

Patients with carotid sinus hypersensitivity (asystole >3 s), especially if symptoms are reproduced by carotid sinus massage, and in whom life-threatening causes of syncope have been excluded, benefit from pacemaker implantation.

Treatment options in vasovagal attacks include avoidance, if possible, of situations known to cause syncope in a particular patient, and sitting/lying down and applying counter-pressure manoeuvres (pushing the palms together or crossing the legs) if an attack threatens. Increased salt intake, compression of the lower legs with hose, and drugs such as beta-blockers, alpha-agonists (e.g. midodrine) or myocardial negative inotropes (e.g. disopyramide) may be helpful.

In selected patients with ‘malignant’ neurocardiogenic syncope (syncope associated with injuries and demonstrated asystole), permanent pacemaker therapy is helpful. These patients benefit from dual-chamber pacemakers with a feature called ‘rate drop response’, which, once activated, paces the heart at a fast rate for a set period of time in order to prevent syncope.

### Heart block

Heart block or conduction block may occur at any level in the conducting system. Block in
either the AV node or the His bundle results in AV block, whereas block lower in the conduction system produces bundle branch block.

### Atrioventricular block

There are three forms.

#### First-degree AV block

This is simple prolongation of the PR interval to >0.22 s. Every atrial depolarization is followed by conduction to the ventricles but with delay (Fig. 23.40).

![FIGURE 23.40](image) An ECG showing first-degree atrioventricular block with a prolonged PR interval. In this trace, coincidental ST depression is also present.

#### Second-degree AV block

This occurs when some P waves conduct and others do not. There are several forms (Fig. 23.41):

- **Mobitz I block** (Wenckebach block phenomenon) is progressive PR interval prolongation until a P wave fails to conduct. The PR interval before the blocked P wave is much longer than the PR interval after the blocked P wave.
- **Mobitz II block** occurs when a dropped QRS complex is not preceded by progressive PR interval prolongation. Usually, the QRS complex is wide (>0.12 s).
- **2 : 1 or 3 : 1 (advanced) block** occurs when every second or third P wave conducts to the ventricles. This form of second-degree block is neither Mobitz I nor II.
FIGURE 23.41 Three varieties of second-degree atrioventricular (AV) block. A. *Wenckebach (Mobitz type I) AV block*. The PR interval gradually prolongs until the P wave does not conduct to the ventricles (arrowed). B. *Mobitz type II AV block*. The P waves that do not conduct to the ventricles (arrowed) are not preceded by gradual PR interval prolongation. C. *Two P waves to each QRS complex*. The PR interval prior to the dropped P wave is always the same. It is not possible to define this type of AV block as type I or type II Mobitz block and it is, therefore, a third variety of second-degree AV block (arrows show P waves).

_Wenckebach AV block_ in general is due to block in the AV node, whereas Mobitz II block signifies block at an infra-nodal level, such as the His bundle. The risk of progression to complete heart block is greater and the reliability of the resultant escape rhythm is less with Mobitz II block. Therefore, pacing is usually indicated in Mobitz II block, whereas patients with Wenckebach AV block are usually monitored.

_Acute myocardial infarction_ may produce _second-degree heart block_. In inferior myocardial infarction, close monitoring and transcutaneous temporary back-up pacing are all that is required. In anterior myocardial infarction, second-degree heart block is associated with a high risk of progression to complete heart block, and temporary pacing followed by permanent pacemaker implantation is usually indicated. Block either in the AV node or at an infra-nodal level may cause 2:1 heart block. Management depends on the clinical setting in which it occurs.
Third-degree (complete) AV block

Complete heart block occurs when all atrial activity fails to conduct to the ventricles (Fig. 23.42). In patients with complete heart block, the aetiology needs to be established (Box 23.10). In this situation, life is maintained by a spontaneous escape rhythm.

![ECG strip showing complete heart block](image)

**FIGURE 23.42** Two examples of complete heart block. A. *Congenital complete heart block*. The QRS complex is narrow (0.08 s) and the QRS rate is relatively rapid (52/min). B. *Acquired complete heart block*. The QRS complex is broad (0.13 s) and the QRS rate is relatively slow (38/min).

### Box 23.10

**Causes of complete heart block**

**Congenital**
- Autoimmune (e.g. maternal SLE)
- Structural heart disease (e.g. transposition of great vessels)

**Idiopathic fibrosis**
- Lev's disease (progressive fibrosis of distal His–Purkinje system in elderly patients)
- Lenegre's disease (proximal His–Purkinje fibrosis in younger patients)

**Ischaemic heart disease**
- Acute myocardial infarct
- Ischaemic cardiomyopathy
Non-ischaemic heart disease
• Calcific aortic stenosis
• Idiopathic dilated cardiomyopathy
• Infiltrations (e.g. amyloidosis, sarcoidosis, neoplasia)

Cardiac surgery
• e.g. Following aortic valve replacement, CABG, VSD repair

Iatrogenic
• Radiofrequency AV node ablation and pacemaker implantation

Drug-induced
• e.g. Digoxin, beta-blockers, non-dihydropyridine calcium-channel blockers, amiodarone

Infections
• Endocarditis
• Lyme disease
• Chagas' disease

Autoimmune rheumatic disease
• e.g. SLE, rheumatoid arthritis

Neuromuscular diseases
• e.g. Duchenne muscular dystrophy

AV, atrioventricular; CABG, coronary artery bypass graft surgery; SLE, systemic lupus erythematosus; VSD, ventricular septal defect.

Narrow-complex escape rhythm (<0.12 s QRS complex) implies that it originates in the His bundle and therefore that the region of block lies more proximally in the AV node. The escape rhythm occurs with an adequate rate (50–60 b.p.m.) and is relatively reliable. Treatment depends on the aetiology. Recent-onset, narrow-complex AV block that has transient causes may respond to intravenous atropine, but temporary pacing facilities should be available for the management of these patients. Chronic narrow-complex AV block requires permanent pacing (dual-chamber; see p. 960) if it is symptomatic or associated with heart disease. Pacing is also advocated for isolated, congenital AV block, even if asymptomatic.

Broad-complex escape rhythm (>0.12 s) implies that the escape rhythm originates below the His bundle and therefore that the region of block lies more distally in the His–Purkinje system. The resulting rhythm is slow (15–40 b.p.m.) and relatively unreliable. Dizziness and blackouts (Stokes–Adams attacks) often occur. In the elderly, it is usually caused by degenerative fibrosis and calcification of the distal conduction system (Lev's disease). In younger individuals, a proximal progressive cardiac conduction disease due to the
inflammatory process is known as Lenegre's disease. Sodium channel abnormalities have been identified in both syndromes. Broad-complex AV block may also be caused by ischaemic heart disease, myocarditis or cardiomyopathy. Permanent pacemaker implantation (see pp. 960–961) is indicated, as pacing considerably reduces the mortality. Because ventricular arrhythmias are not uncommon, an implantable cardioverter–defibrillator (ICD) may be indicated in those with severe left ventricular dysfunction (>0.30 s duration).

**Bundle branch block**

The His bundle gives rise to the right and left bundle branches. The left bundle subdivides into the anterior and posterior divisions of the left bundle. Various conduction disturbances can occur.

**Bundle branch conduction delay**

This produces slight widening of the QRS complex (up to 0.11 s). It is known as incomplete bundle branch block.

**Complete block of a bundle branch**

This is associated with a wider QRS complex (≥0.12 s). The shape of the QRS depends on whether the right or the left bundle is blocked.

**Right bundle branch block** *(Fig. 23.43A)* produces late activation of the right ventricle. This is seen as deep S waves in leads I and V₆, and as a tall late R wave in lead V₁ (late activation moving towards right-sided leads and away from left-sided leads).
**Left bundle branch block (Fig. 23.44)** produces the opposite: a deep S wave in lead V<sub>1</sub> and a tall late R wave in leads I and V<sub>6</sub>. Because left bundle branch conduction is normally responsible for the initial ventricular activation, left bundle branch block also produces abnormal Q waves.
**Hemiblock**

Delay or block in the divisions of the left bundle branch produces a swing in the direction of depolarization (electrical axis) of the heart. When the anterior division is blocked (left anterior hemiblock), the left ventricle is activated from inferior to superior. This produces a superior and leftward movement of the axis (left axis deviation). Delay or block in the postero-inferior division swings the QRS axis inferiorly to the right (right axis deviation).

**Bifascicular block**

Bifascicular block (see Fig. 23.43B) is a combination of a block of any two of the following: the right bundle branch, the left antero-superior division and the left postero-inferior division. Block of the remaining fascicle will result in complete AV block.

**Clinical features of heart blocks**

Bundle branch blocks are usually asymptomatic. Right bundle branch block causes wide but physiological splitting of the second heart sound. Left bundle branch block may cause reverse splitting of the second sound. Patients with intraventricular conduction disturbances may complain of syncope. This is due to intermittent complete heart block or to ventricular tachyarrhythmias. ECG monitoring and electrophysiological studies are needed to determine the cause of syncope in these patients.

**Aetiology**
Right bundle branch block occurs as an isolated congenital anomaly or is associated with cardiac or pulmonary conditions. Right bundle branch block can be a normal finding in about 5% of individuals. Conditions commonly associated with right bundle branch block include congenital cardiac disorders, such as atrial and ventricular septal defects, pulmonary stenosis and Fallot's tetralogy, pulmonary embolism, pulmonary hypertension, myocardial infarction, fibrosis of conduction tissue and Chagas' disease. Block in the right bundle alone does not tend to alter the electrical axis of the heart unless accompanied by right ventricular hypertrophy (RV overload) or coexistent fascicular block. The combination of right bundle branch block with left axis deviation is seen in patients with ostium primum atrial septal defects, but more often signifies diffuse conduction tissue disease affecting the right bundle and the left anterior fascicle. Complete left bundle branch block is often associated with extensive left ventricular disease. The most common causes include aortic stenosis, hypertension, myocardial infarction and severe coronary disease, and are similar to those of complete heart block.

Supraventricular Tachycardias

Supraventricular tachycardias (SVTs) arise from the atrium or the atrioventricular junction. Conduction is via the His–Purkinje system; therefore, the QRS shape during tachycardia is usually similar to that seen in the same patient during baseline rhythm. A classification of supraventricular tachycardia is given in Box 23.11. Some of these tachycardias are discussed in more detail below.

---

**Box 23.11**

**Causes of supraventricular tachycardia (SVT)**

**Inappropriate sinus tachycardia**

Inappropriate sinus tachycardia is a persistent increase in resting heart rate unrelated to, or out of proportion with, the level of physical or emotional stress. It is found predominantly in young women and is not uncommon in health professionals. Sinus tachycardia due to intrinsic sinus node abnormalities, such as enhanced automaticity, or abnormal autonomic regulation of the heart with excess sympathetic and reduced parasympathetic input, is extremely rare.

In general, sinus tachycardia is a secondary phenomenon and the underlying causes need to be actively investigated. Depending on the clinical setting, acute causes include exercise, emotion, pain, fever, infection, acute heart failure, acute pulmonary embolism and hypovolaemia. Chronic causes include pregnancy, anaemia, hyperthyroidism and catecholamine excess. The underlying cause should be found and treated, rather than treating the compensatory physiological response. If necessary, beta-blockers may be used to slow the sinus rate, in hyperthyroidism, for example (see p. 1206); ivabradine, an $I_F$ (pacemaker current) blocker, may be useful when beta-blockade cannot be tolerated.

**Atrioventricular junctional tachycardias**

AV nodal re-entrant and AV re-entrant tachycardias are usually referred to as paroxysmal SVTs and are often seen in young patients with no or little structural heart disease, although congenital heart abnormalities (e.g. Ebstein's anomaly, atrial septal defect, Fallot's tetralogy) can coexist in a small proportion of patients with these arrhythmias. The first presentation is commonly between ages 12 and 30, and the prevalence is approximately 2.5/1000.
In these tachycardias the AV node is an essential component of the re-entry circuit.

**Atrioventricular nodal re-entrant tachycardia**

Atrioventricular nodal re-entrant tachycardia (AVNRT) is twice as common in women. Clinically, the tachycardia often strikes suddenly without obvious provocation, but exertion, emotional stress, coffee, tea and alcohol may aggravate or induce the arrhythmia. An attack may stop spontaneously or may continue indefinitely until medical intervention.

**In AVNRT**, there are two functionally and anatomically different pathways predominantly within the AV node: one is characterized by a short effective refractory period and slow conduction, and the other has a longer effective refractory period and conducts faster. In sinus rhythm, the atrial impulse that depolarizes the ventricles usually conducts through the fast pathway. If the atrial impulse (e.g. an atrial premature beat) occurs early when the fast pathway is still refractory, the slow pathway takes over in propagating the atrial impulse to the ventricles. It then travels back through the fast pathway, which has already recovered its excitability, thus initiating the most common ‘slow–fast’, or typical, AVNRT.

The rhythm is recognized on ECG from normal regular QRS complexes, usually at a rate of 140–240/min (**Fig. 23.45A**). Sometimes, the QRS complexes will show typical bundle branch block. P waves either are not visible or are seen immediately before or after the QRS complex because of simultaneous atrial and ventricular activation. It is less common (5–10%) to observe a tachycardia when the atrial impulse conducts anterogradely through the fast pathway and returns through the slow pathway, producing a long RP’ interval (‘fast–slow’ or long RP’ tachycardia).
Atrioventricular re-entrant tachycardia

This large circuit comprises the AV node, the His bundle, the ventricle and an abnormal connection of myocardial fibres from the ventricle back to the atrium. It is called an accessory pathway or bypass tract and results from an incomplete separation of the atria and the ventricles during fetal development.

In contrast to AVNRT, atrioventricular re-entrant tachycardia (AVRT) is due to a macro re-entry circuit and each part of the circuit is activated sequentially. As a result, atrial activation occurs after ventricular activation and the P wave is usually seen clearly between the QRS and T waves (Fig. 23.45B).

Accessory pathways are most commonly situated on the left but may occur anywhere around the AV groove. The most common accessory pathways, known as Kent bundles, are in the free wall or septum. In about 10% of cases, multiple pathways occur. Mahaim fibres are atrio-fascicular or nodo-fascicular fibres that enter the ventricular myocardium in the region of the right bundle branch. Accessory pathways that conduct from the ventricles to the atria only are not visible on the surface ECG during sinus rhythm and are therefore ‘concealed’. Accessory pathways that conduct bidirectionally usually are manifest on the surface ECG. If the accessory pathway conducts from the atrium to the ventricle during sinus rhythm, the electrical impulse can conduct quickly over this abnormal connection to depolarize part of the ventricles abnormally (pre-excitation). A pre-excited ECG is characterized by a short PR interval and a wide QRS complex that begins as a slurred part known as the delta wave (Fig. 23.45C). Patients with a history of palpitations and a pre-excited ECG have a syndrome known as Wolff–Parkinson–White (WPW) syndrome.
During AVRT, the AV node and ventricles are activated normally (orthodromic AVRT), usually resulting in a narrow QRS complex. Less commonly, the tachycardia circuit can be reversed, with activation of the ventricles via the accessory pathway, and atrial activation via retrograde conduction through the AV node (antidromic AVRT). This results in a broad-complex tachycardia. These patients are also prone to atrial fibrillation.

During atrial fibrillation, the ventricles may be depolarized by impulses travelling over both the abnormal and the normal pathways. This results in pre-excited atrial fibrillation, a characteristic tachycardia that is characterized by irregularly irregular broad QRS complexes (Fig. 23.45D). If an accessory pathway has a short antegrade effective refractory period (<250 ms), it may conduct to the ventricles at an extremely high rate and may cause ventricular fibrillation. The incidence of sudden death is 0.15–0.39% per patient-year and it may be a first manifestation of the disease in younger individuals. Verapamil and digoxin may allow a higher rate of conduction over the abnormal pathway and precipitate ventricular fibrillation. Therefore, neither verapamil nor digoxin should be used to treat atrial fibrillation associated with the WPW syndrome.

Clinical features of AVNRT and AVRT

The leading symptom of most SVTs, in particular AVNRT and AVRT, is rapid regular palpitations, usually with abrupt onset and sudden termination, which can occur spontaneously or be precipitated by simple movements. A common feature is termination by Valsalva manoeuvres. In younger individuals with no structural heart disease, the rapid heart rate can be the main pathological finding.

Irregular palpitations may be due to atrial premature beats, atrial flutter with varying AV conduction block, atrial fibrillation or multifocal atrial tachycardia. In patients with depressed ventricular function, uncontrolled atrial fibrillation can reduce cardiac output and cause hypotension and congestive heart failure.

Other symptoms may include anxiety, dizziness, dyspnoea, neck pulsation, central chest pain and weakness. Polyuria may occur because of the release of atrial natriuretic peptide in response to increased atrial pressures during the tachycardia, especially during AVNRT and atrial fibrillation. Prominent jugular venous pulsations due to atrial contractions against closed AV valves may be observed during AVNRT.

Syncope has been reported in 10–15% of patients, usually just after initiation of the arrhythmia or in association with a prolonged pause following its termination. It is more common if the patient is standing. However, in older patients with concomitant heart disease, such as aortic stenosis, hypertrophic cardiomyopathy and cerebrovascular disease, significant hypotension and syncope may result from moderately fast ventricular rates.

Management of AVNRT and AVRT

Acute management
In an emergency, distinguishing between AVNRT and AVRT may be difficult, but it is usually not critical as both tachycardias respond to the same treatment. Patients presenting with SVTs and haemodynamic instability (e.g. hypotension, pulmonary oedema) require emergency cardioversion. If the patient is haemodynamically stable, vagal manoeuvres, including right carotid massage (see Box 23.7), the Valsalva manoeuvre and facial immersion in cold water, can be successfully employed.

The Valsalva manoeuvre is the best of these techniques and is often easier for the patient to perform successfully. It should be undertaken when the patient is resting in the supine position (thus avoiding elevated background sympathetic tone) and involves abrupt voluntary increase in intra-abdominal and intrathoracic pressure by straining. Patient should not take a deep inspiration before straining. Several seconds after the release of the strain, the resulting intense vagal effect may terminate AVNRT or AVRT, or may produce sufficient AV block to reveal an underlying atrial tachyarrhythmia.

If physical manoeuvres have not been successful, intravenous adenosine (initially 6 mg by i.v. push, followed by 12 mg if needed) should be tried. Adenosine is a very short-acting (half-life <10 s), naturally occurring purine nucleoside that causes complete heart block for a fraction of a second following intravenous administration. It is highly effective at terminating AVNRT and AVRT or unmasking underlying atrial activity, but rarely affects ventricular tachycardia. The side-effects of adenosine are very brief but include:

• bronchospasm
• flushing
• chest pain
• heaviness of the limbs
• sense of impending doom.

Adenosine is contraindicated in patients with a history of asthma. In some patients, it can induce atrial fibrillation.

An alternative treatment is verapamil 5–10 mg i.v. over 5–10 min, i.v. diltiazem, or beta-blockers (esmolol, propranolol, metoprolol). Verapamil (or diltiazem) must not be given after beta-blockers or if the tachycardia presents with broad (>0.12 s) QRS complexes.

**Long-term management**

Patients with suspected cardiac arrhythmias should always be referred to the cardiologist for electrophysiological evaluation and long-term management, as both pharmacological and non-pharmacological treatments, including ablation of an accessory pathway, are readily available. Verapamil, diltiazem and beta-blockers have proven efficacy in 60–80% of patients. Sodium-channel blockers (flecainide and propafenone), potassium repolarization current blockers (sotalol, dofetilide, azimilide) and the multichannel blocker amiodarone may also prevent the occurrence of tachycardia.

Refinement of catheter ablation techniques has rendered many AV junctional tachycardias entirely curable. Modification of the slow pathway is successful in 96% of patients with
AVNRT, although a 1% risk of AV block is present. In AVRT, the target for catheter ablation is the accessory pathway(s). The success rate of ablation of a single accessory pathway is approximately 95%, with a recurrence rate of 5%, requiring a repeat procedure.

**Atrial tachyarrhythmias**

Atrial tachyarrhythmias, including atrial fibrillation, atrial flutter, atrial tachycardia and atrial ectopic beats, all arise from the atrial myocardium *(Fig. 23.46)*. They share similar aetiologies, of which the most commonly encountered in clinical practice are increasing age, myocardial infarction, hypertension, obesity, diabetes mellitus, hypertrophic cardiomyopathy, heart failure, valvular heart disease, myocarditis, pericarditis, cardiothoracic surgery, electrolyte imbalance, alcohol use, obstructive airway disease, chest infections and hyperthyroidism.
Atrial fibrillation

This is a common arrhythmia, occurring in 1–2% of the general population and 5–15% of patients over 75 years of age. It also occurs, particularly in a paroxysmal form, in younger patients. Any condition resulting in raised atrial pressure, increased atrial muscle mass, atrial fibrosis, or inflammation and infiltration of the atrium may cause atrial fibrillation.

Although rheumatic heart disease, alcohol intoxication and thyrotoxicosis are the ‘classic’ causes of atrial fibrillation, hypertension and heart failure are the most common causes in the developed world. Hyperthyroidism may provoke atrial fibrillation, sometimes as virtually the
only feature of the disease, and thyroid function tests are mandatory in any patient with atrial fibrillation that is unaccounted for. Atrial fibrillation occurs in one-third of patients after cardiac surgery. It usually manifests during the first 4 days and is associated with increased morbidity and mortality, largely due to stroke and circulatory failure, a longer hospital stay and later recurrences.

In some patients, no cause can be found, and this group is labelled as having ‘lone’ atrial fibrillation. The pathogenesis of ‘lone’, or ‘idiopathic’, atrial fibrillation is unknown but genetic predisposition or even specific genetically predetermined forms of the arrhythmia have been proposed. About 30–40% of those with atrial fibrillation, especially those who present at a young age, have at least one parent with the arrhythmia, and genes associated with the sodium channel, the potassium channel, gap junction proteins and right–left isomerism have been implicated. Gene defects linked to chromosomes 10, 6, 5 and 4 have been associated with familial atrial fibrillation.

Atrial fibrillation is maintained by continuous, rapid (300–600/min) activation of the atria by multiple meandering re-entry wavelets, often driven by rapidly depolarizing automatic foci, located predominantly within the pulmonary veins. The atria respond electrically at this rate but there is no coordinated mechanical action and only a proportion of the impulses are conducted to the ventricles. The ventricular response depends on the rate and regularity of atrial activity, particularly at the entry to the AV node, the refractory properties of the AV node itself, and the balance between sympathetic and parasympathetic tone.

### Clinical features

Symptoms attributable to atrial fibrillation are highly variable. In some patients (about 30%), it is an incidental finding, while others attend hospital as an emergency with rapid palpitations, dyspnoea and/or chest pain following the onset of atrial fibrillation. Most patients with ongoing atrial fibrillation experience some deterioration of exercise capacity or wellbeing, but this may be appreciated only once sinus rhythm is restored. When caused by rheumatic mitral stenosis, the onset of atrial fibrillation results in considerable worsening of cardiac failure.

The patient has an ‘irregularly irregular’ pulse, as opposed to a basically regular pulse with an occasional irregularity (e.g. extrasystoles) or recurring irregular patterns (e.g. Wenckebach block). The irregular nature of the pulse in atrial fibrillation is maintained during exercise.

The ECG shows fine oscillations of the baseline (so-called fibrillation or f waves) and no clear P waves (Fig. 23.46A). The QRS rhythm is rapid and irregular. Untreated, the ventricular rate is usually 120–180/min but it slows with treatment.

The clinical classification of atrial fibrillation includes:

- first detected – irrespective of duration or severity of symptoms
- paroxysmal – stops spontaneously within 7 days
- persistent – continuous >7 days
- longstanding persistent – continuous >1 year
• permanent – continuous, with a joint decision between the patient and the physician to cease further attempts to regain sinus rhythm.

The classification is helpful in choosing between rhythm restoration and rate control. Atrial fibrillation may be asymptomatic and the ‘first detected episode’ should not be regarded as necessarily the true onset.

Management

Acute management

When atrial fibrillation is due to an acute precipitating event, such as alcohol toxicity, chest infection or hyperthyroidism, the provoking cause should be treated. Strategies for the acute management of atrial fibrillation are:

• **Ventricular rate control.** This is achieved by drugs that block the AV node (see below).

• **Cardioversion.** This is achieved electrically by DC shock (see p. 959), or medically by intravenous infusion of an antiarrhythmic drug such as flecainide, propafenone, vernakalant or amiodarone. Cardioversion can also be achieved by giving an oral agent (flecainide or propafenone) previously tested in hospital and found to be safe in a particular patient (‘pill-in-pocket’ approach).

  The choice depends on:

• how well the arrhythmia is tolerated (is cardioversion urgent?)

• whether anticoagulation is required before considering elective cardioversion

• whether spontaneous cardioversion is likely (previous history? reversible cause?).

  Conversion to sinus rhythm can be achieved by electrical DC cardioversion (see p. 959) in about 80% of patients. Biphasic waveform defibrillation is more effective than conventional (monophasic) defibrillation, and biphasic defibrillators are now standard. To minimize the risk of thromboembolism associated with cardioversion, patients are fully anticoagulated with warfarin (International Normalized Ratio (INR) 2.0–3.0) or with dabigatran 150 mg twice daily for 3 weeks before cardioversion (unless atrial fibrillation is of <48 h duration) and at least 4 weeks after the procedure. The patient is then assessed for the necessity for long-term anticoagulation based on their thromboembolic risk score (see below). If cardioversion is urgent and the patient is not on any anticoagulation, transoesophageal echocardiography is used to exclude the presence of atrial thrombus.

Long-term management

Two strategies are available:

• ‘rate control’ (AV nodal slowing agents **plus oral anticoagulation**)

• ‘rhythm control’ (antiarrhythmic drugs plus DC cardioversion **plus oral anticoagulation**).

  Major randomized studies in patients predominantly over the age of 65 years (AFFIRM) or
in patients with heart failure (AF-CHF) have shown that there is no net mortality or symptom benefit to be gained from one strategy compared with the other. Which strategy to adopt needs to be assessed for each individual patient. Factors to consider include the likelihood of maintaining sinus rhythm and the safety/tolerability of antiarrhythmic drugs in a particular patient.

**Rhythm control**

This is advocated for younger, symptomatic and physically active patients. **Recurrent paroxysms** may be prevented with oral medication. In general, patients with no significant heart disease can be treated with any class Ia, Ic or III antiarrhythmic drug, although it is recommended that amiodarone (because of its substantial extracardiac adverse effect profile) should be reserved until other drugs have failed. For patients with **heart failure** or **left ventricular hypertrophy** only amiodarone is recommended. Patients with **coronary artery disease** may be treated with sotalol or amiodarone. Patients with **paroxysmal atrial fibrillation** or with early **persistent atrial fibrillation** (little left atrial dilatation) may be treated with left atrial ablation. The ectopic triggers for atrial fibrillation are generally found in the pulmonary veins, which can be isolated from the atra using radiofrequency or cryothermal energy. Occasionally, more extensive ablation within the left atrium is needed. These techniques are more successful than antiarrhythmic drugs and may represent a ‘cure’ in some patients. However, the procedure is invasive and carries some hazard of serious complications such as stroke, and bleeding in about 2% of cases. In the long term, recurrence is not uncommon and an apparently successful ablation does not remove the obligation for appropriate anticoagulation. Ablation has not been shown to improve long-term cardiovascular outcome but it does successfully treat symptoms due to atrial fibrillation.

**Rate control**

As a primary strategy, this is appropriate in patients who:

- have the permanent form of the arrhythmia associated with symptoms that can be further improved by slowing heart rate, or are older than 65 years with recurrent atrial tachyarrhythmias (‘accepted’ atrial fibrillation)

- have persistent tachyarrhythmias and have failed cardioversion(s) and serial prophylactic antiarrhythmic drug therapy, and in whom the risk/benefit ratio from using specific antiarrhythmic agents is shifted towards increased risk.

Rate control is usually achieved with a combination of **digoxin**, **beta-blockers** or **non-dihydropyridine calcium-channel blockers** (verapamil or diltiazem). Digoxin monotherapy may be sufficient for elderly, non-ambulant patients. In younger patients, the effect of catecholamines easily overwhelms the vagotonic effect of digoxin and additional AV nodal slowing agents are needed. The ventricular rate response is generally considered to be controlled if the resting heart rate is <110 b.p.m. but stricter control, between 60 and 80 b.p.m. at rest and <110 b.p.m. during moderate exercise, may be needed if symptoms persist. To
assess the adequacy of rate control, an ECG rhythm strip may be sufficient in an elderly patient
but ambulatory 24-hour Holter monitoring and an exercise stress test (treadmill) are needed in
younger individuals. Older patients with poor rate control despite optimal medical therapy
should be considered for AV node ablation and pacemaker implantation (‘ablate and pace’
strategy). These patients usually experience a marked symptomatic improvement but require
life-long anticoagulation because of the on-going risk of thromboembolism.

**Anticoagulation**

This is indicated in patients with atrial fibrillation related to rheumatic mitral stenosis or in the
presence of a mechanical prosthetic heart valve. In patients with non-valvular atrial fibrillation
(in the absence of mitral stenosis, artificial heart valves or mitral valve repair), a scoring
system known as CHA$_2$DS$_2$VASC is used (Box 23.12) as the first step in determining the need
for anticoagulation.

### Box 23.12

- 1 point = 1.3% risk: Anticoagulant (oral) or aspirin
- 2+ points = 2.2% risk: Oral anticoagulant

TIA, transient ischaemic attack.

Long-term prophylaxis against ischaemic stroke with oral anticoagulation must be balanced
against the risk of haemorrhage. The HAS-BLED score is recommended by European,
Canadian and UK (NICE) guidelines. A high HAS-BLED score identifies patients with a high
risk of bleeding (Box 23.13 and Fig. 23.47).

INR, International Normalized Ratio.

(Adapted from European Society of Cardiology Clinical Practice Guidelines. *Eur Heart J* 2012; 33:2719–2747.)
Antiplatelet therapy with aspirin plus clopidogrel (or, less effectively, aspirin only) should be considered in patients who refuse any oral anticoagulant therapy or cannot tolerate anticoagulants for reasons unrelated to bleeding. (Adapted from European Society of Cardiology Clinical Practice Guidelines. Eur Heart J 2012; 33:2719–2747, with permission.)

When oral anticoagulation is required, either warfarin (dose adjusted to maintain an INR between 2.0 and 3.0) or one of the new oral anticoagulant agents (NOACs) can be used. These latter agents fall into two classes: direct thrombin inhibitors (e.g. dabigatran) and oral direct factor Xa inhibitors (e.g. rivaroxaban and apixaban). NOACs specifically block a single step in the coagulation cascade, in contrast to warfarin, which blocks several vitamin K-dependent factors (II, VII, IX and X). Unlike warfarin, the NOACs have a rapid onset of action, shorter half-life and fewer food and drug interactions, and do not require INR testing. Trial data have shown them to be equally effective as, and safer than, warfarin. However, these agents require dose reduction or avoidance in patients with renal impairment, the elderly or those with low body weight.
Atrial flutter

Atrial flutter is often associated with atrial fibrillation and frequently requires a similar initial therapeutic approach. Atrial flutter is usually an organized atrial rhythm with an atrial rate typically between 250 and 350 b.p.m. Typical, or isthmus-dependent, atrial flutter involves a macro re-entrant right atrial circuit around the tricuspid annulus. The wavefront circulates down the lateral wall of the right atrium, through the Eustachian ridge between the tricuspid annulus and the inferior vena cava, and up the interatrial septum, giving rise to the most frequent pattern, referred to as counter-clockwise flutter. Re-entry can also occur in the opposite direction (clockwise or reverse flutter).

The ECG shows regular sawtooth-like atrial flutter waves (F waves) between QRS complexes (Fig. 23.46B). In typical counter-clockwise atrial flutter, the F waves are negative in the inferior leads and positive in leads V₁ and V₂. In clockwise atrial flutter, the deflection of the F waves is the opposite. If F waves are not clearly visible, it is worth trying to reveal them by slowing AV conduction by carotid sinus massage or by the administration of AV nodal blocking drugs such as adenosine or verapamil.

Symptoms are largely related to the degree of AV block. Most often, every second flutter beat conducts, giving a ventricular rate of 150 b.p.m. Occasionally, every beat conducts, producing a heart rate of 300 b.p.m. More often, especially when patients are receiving treatment, AV conduction block reduces the heart rate to approximately 75 b.p.m.

Management

Management of a symptomatic acute paroxysm is by electrical cardioversion. Patients who have been in atrial flutter for more than 1–2 days should be treated in a similar manner to patients with atrial fibrillation and anticoagulated for 3 weeks prior to cardioversion. Acute pharmacological cardioversion can be achieved using class Ic (flecainide, propafenone) or certain class III antiarrhythmic agents (dofetilide, ibutilide; these have better efficacy than in atrial fibrillation but are not available in many countries).

Recurrent paroxysms may be prevented by class III antiarrhythmic agents (sotalol, amiodarone). AV nodal blocking agents may be used to control the ventricular rate if the arrhythmia persists. However, the treatment of choice for patients with recurrent atrial flutter is catheter ablation (see p. 979), which permanently interrupts re-entry by creating a line of conduction block within the isthmus between the inferior vena cava and the tricuspid valve ring. This technique offers patients whose only arrhythmia is typical atrial flutter an almost certain chance of a cure, although the later occurrence of atrial fibrillation is not uncommon.

Atrial tachycardia

This is an uncommon arrhythmia. Its prevalence is believed to be <1% in patients with arrhythmias. It is usually associated with structural heart disease but, in many cases, it is referred to as idiopathic. Macro re-entrant tachycardia often occurs after surgery for congenital
heart disease. Atrial tachycardia with block is often a result of digitalis poisoning.

The mechanisms of atrial tachycardia are attributed to enhanced automaticity, triggered activity or intra-atrial re-entry. Atrial re-entrant tachycardia is usually relatively slow (125–150 b.p.m.) and can be initiated and terminated by atrial premature beats. The P’P’ intervals are regular. The PR interval depends on the rate of tachycardia and is longer than in sinus rhythm at the same rate.

Automatic tachycardia usually presents with higher rates (125–250 b.p.m.) and is often characterized by a progressive increase in the atrial rate with onset of the tachycardia (‘warm-up’) and progressive decrease prior to termination (‘cool-down’). Atrial tachycardia is typically caused by a focus that is frequently located along the crista terminalis in the right atrium, adjacent to a pulmonary vein in the left atrium, or around one of the atrial appendages. Automatic atrial tachycardia may also present as an incessant variety leading to tachycardia-induced cardiomyopathy. Short runs of atrial tachycardia may provoke more sustained episodes of atrial fibrillation.

*Figure 23.46C* demonstrates an atrial tachycardia at an atrial rate of 150/min. The P waves are abnormally shaped and occur in front of the QRS complexes. Carotid sinus massage may increase AV block during tachycardia, thereby facilitating the diagnosis, but does not usually terminate the arrhythmia. Management options include *cardioversion, antiarrhythmic drug therapy* to maintain sinus rhythm, *AV nodal slowing agents* to control rate and, in selected cases, radiofrequency catheter *ablation*.

---

**Atrial ectopic beats**

These often cause no symptoms, although they may be sensed as an irregularity or heaviness of the heart beat. On the ECG, they appear as early and abnormal P waves and are usually, but not always, followed by normal QRS complexes (*Fig. 23.46D*). Treatment is not normally required unless the ectopic beats provoke more significant arrhythmias, when *beta-blockers* may be effective.

---

**Ventricular Tachyarrhythmias**

Ventricular tachyarrhythmias can be discussed under the following headings:

- life-threatening ventricular tachyarrhythmias (sustained ventricular tachycardia, ventricular fibrillation, torsades de pointes)
- normal heart ventricular tachycardia
- non-sustained ventricular tachycardia
- ventricular premature beats (ectopics).

Some of these conditions are cardiac channelopathies. These are congenital disorders that are caused by mutations that affect the function of cardiac ion channels and hence the electrical activity of the heart. They include Brugada syndrome, congenital long QT syndrome, short QT syndrome, catecholaminergic polymorphic ventricular tachycardia (CPVT) and idiopathic
Sustained ventricular tachycardia

Sustained ventricular tachycardia (>30 s) often results in pre-syncpe (dizziness), syncpe, hypotension and cardiac arrest, although it may be remarkably well tolerated in some patients. Examination reveals a pulse rate typically between 120 and 220 b.p.m. Usually, there are clinical signs of atrioventricular dissociation (i.e. intermittent cannon ‘a’ waves in the neck) and variable intensity of the first heart sound.

The ECG shows a rapid ventricular rhythm with broad (often ≥0.14 s), abnormal QRS complexes. AV dissociation may result in visible P waves, which appear to march through the tachycardia, capture beats (an intermittent narrow QRS complex owing to normal ventricular activation via the AV node and conducting system) and fusion beats (intermediate between ventricular tachycardia beat and capture beat).

Supraventricular tachycardia with bundle branch block may resemble ventricular tachycardia on the ECG. However, if a broad-complex tachycardia is due to SVT with either right or left bundle branch block, then the QRS morphology should resemble a typical right bundle branch block or left bundle branch block pattern (see Figs 23.43A and 23.44). Other ECG criteria to differentiate VT from SVT with aberrancy are indicated in Box 23.14. Some 80% of all broad-complex tachycardias are due to ventricular tachycardia, and the proportion is even higher in patients with structural heart disease. Therefore, in all cases of doubt, ventricular tachycardia should be diagnosed.

Box 23.14

ECG distinction between SVT with bundle branch block and VT

VT is more likely than SVT with bundle branch block where there is:
- a very broad QRS (>0.14 s)
- atrioventricular dissociation
- a bifid, upright QRS with a taller first peak in V<sub>1</sub>
- a deep S wave in V<sub>6</sub>
- a concordant (same polarity) QRS direction in all chest leads (V<sub>1</sub>–V<sub>6</sub>)

SVT, supraventricular tachycardia; VT, ventricular tachycardia.

Management

Treatment may be urgent, depending on the haemodynamic situation. If the patient is haemodynamically compromised (e.g. hypotensive or pulmonary oedema), emergency DC
cardioversion may be required. On the other hand, if the blood pressure and cardiac output are well maintained, intravenous therapy with beta-blockers (esmolol), class I drugs or amiodarone is usually used. DC cardioversion is necessary if medical therapy is unsuccessful.

**Ventricular fibrillation**

This involves very rapid and irregular ventricular activation with no mechanical effect. The patient is pulseless and becomes rapidly unconscious; respiration ceases (cardiac arrest). The ECG shows shapeless, rapid oscillations and there is no hint of organized complexes *(Fig. 23.48)*. It is usually provoked by a ventricular ectopic beat. Ventricular fibrillation rarely reverses spontaneously. The only effective treatment is electrical defibrillation. Basic and advanced cardiac life support is needed (see p. 957).

![Ventricular fibrillation](image)

**FIGURE 23.48** Ventricular fibrillation. Two beats of sinus rhythm are followed by a ventricular ectopic beat that initiates ventricular fibrillation. The ST segment during sinus rhythm is elevated owing to acute myocardial infarction in this case.

If the attack of ventricular fibrillation occurs during the first day or two of an acute myocardial infarction, it is probable that prophylactic therapy will be unnecessary. If the ventricular fibrillation was not related to an acute infarction, the long-term risk of recurrent cardiac arrest and sudden death is high.

Survivors of these ventricular tachyarrhythmias are, in the absence of an identifiable reversible cause (e.g. acute myocardial infarction, severe metabolic disturbance), at high risk of sudden death. Implantable cardioverter–defibrillators are first-line therapy in the management of these patients (see pp. 979–980).

**Brugada syndrome**

This inheritable condition accounts for part of a group of patients with idiopathic ventricular fibrillation who have no evidence of causative structural cardiac disease. It is more common in young male adults and in South-east Asia. The diagnosis is made by identifying the classic ECG changes that may be present spontaneously or may be provoked by the administration of a class I antiarrhythmic (flecainide or ajmaline): right bundle branch block with coved ST elevation in leads V₁–V₃ *(Fig. 23.49)*. Atrial fibrillation may occur.

In 20% of cases, this is a monogenic inheritable condition associated with loss of sodium-channel function due to a mutation in the SCN5A gene. Recently, other mutations in the SCN1B gene, glycerol-3-phosphate dehydrogenase-1-like gene (GPD1L-type) and genes related to calcium-channel sub-units CACNA1C and CACNB2 have also been implicated in the genesis of this syndrome. It can present with sudden death during sleep, resuscitated cardiac arrest and syncope, or the patient may be asymptomatic and diagnosed incidentally or during familial assessment. There is a high risk of sudden death, particularly in the symptomatic patient or those with spontaneous ECG changes. The only successful treatment is an ICD. Beta-blockade is not helpful and may be harmful in this syndrome.

### Long QT syndrome

This describes an ECG where the ventricular repolarization (QT interval) is greatly prolonged. The causes of long QT syndrome are listed in Box 23.15.

---

**Box 23.15**

**Causes of long QT syndrome**

**Congenital**
- Jervell–Lange-Nielsen syndrome (autosomal recessive)
- Romano–Ward syndrome (autosomal dominant)

**Acquired**

**Electrolyte abnormalities**
- Hypokalaemia
- Hypomagnesaemia
- Hypocalcaemia

**Drugs**
- Quinidine, disopyramide
- Sotalol, amiodarone
- Tricyclic antidepressants, e.g. amitriptyline
- Phenothiazine drugs, e.g. chlorpromazine
- Antipsychotics, e.g. haloperidol, olanzapine
- Macrolides, e.g. erythromycin
- Quinolones, e.g. ciprofloxacin
- Methadone

**Poisons**
- Organophosphate insecticides

**Miscellaneous**
- Bradycardia
- Mitral valve prolapse
- Acute myocardial infarction
- Diabetes
- Prolonged fasting and liquid protein diets (long-term)
- Central nervous system diseases, e.g. dystrophia myotonica

---

**Congenital long QT syndrome**

Two major syndromes have been described, which may (Jervell–Lange-Nielsen syndrome) or may not (Romano–Ward syndrome) be associated with congenital deafness.

The molecular biology of the congenital long QT syndromes has been shown to be heterogeneous. It is usually a monogenic disorder and has been associated with mutations in cardiac potassium and sodium-channel genes. The different genes involved appear to correlate with different phenotypes (Fig. 23.50A) that can exhibit such variable penetrance that carriers may have completely normal ECGs. To date, thirteen long QT (LQT) sub-types have been identified but three major sub-types account for the majority of cases. These are: LQT1
(KCNQ1 gene mutation affecting the $I_{ks}\alpha$ sub-unit), in which the arrhythmia is usually provoked by exercise, particularly swimming; LQT2 (KCNH2 gene mutation affecting the $I_{kr}\alpha$ sub-unit), in which arrhythmia provocation is associated with emotion and acoustic stimuli; and LQT3 (SCN5A gene mutation affecting the $I_{Na}\alpha$ sub-unit), in which the arrhythmias occur during rest or when asleep. It is likely that identification of the mutation involved will not only improve diagnostic accuracy, particularly with cascade screening in affected families, but also guide future therapy for the congenital long QT syndrome.

![FIGURE 23.50](image)

**Acquired long QT syndrome**

QT prolongation and torsades de pointes are usually provoked by bradycardia.

### Clinical features

Patients with a long QT develop syncope and palpitations as a result of polymorphic ventricular tachycardia (torsades de pointes). They usually terminate spontaneously but may degenerate to ventricular fibrillation, resulting in sudden death.

**Torsades de pointes** is characterized on the ECG by rapid, irregular, sharp complexes that continuously change from an upright to an inverted position (*Fig. 23.50B*).

Between spells of tachycardia, or immediately preceding the onset of tachycardia, the ECG
shows a prolonged QT interval; the corrected QT (see Box 23.6) is usually >0.50 s.

### Management

Acute (acquired) long QT syndrome is treated as follows:

- Any electrolyte disturbance is corrected.
- Causative drugs are stopped.
- The heart rate is maintained with atrial or ventricular pacing.
- Magnesium sulphate 8 mmol (Mg²⁺) is given over 10–15 min for acquired long QT.
- Intravenous isoprenaline may be effective when QT prolongation is acquired (isoprenaline is contraindicated for congenital long QT syndrome).

**Long-term**, congenital long QT syndrome is generally treated by beta-blockade, pacemaker therapy and, occasionally, left cardiac sympathetic denervation. LQT1 patients seem to respond well to beta-blockade while LQT3 patients are better treated with sodium-channel blockers. All long QT patients should avoid drugs known to prolong the QT interval. Patients who remain symptomatic despite conventional therapy, and those with marked QT prolongation or a strong family history of sudden death, usually need ICD therapy.

### Short QT syndrome

Five types have been described; they are caused by genetic abnormalities that lead to faster repolarization. Ventricular arrhythmias and sudden death may occur and an ICD is the best treatment.

### Normal heart ventricular tachycardia

Monomorphic ventricular tachycardia in patients with structurally normal hearts (idiopathic ventricular tachycardia) is usually a benign condition with an excellent long-term prognosis. Occasionally, it is incessant (so called Gallavardin's tachycardia) and, if untreated, may lead to cardiomyopathy.

Normal heart ventricular tachycardia arises from a focus either in the right ventricular outflow tract or in the left ventricular septum. Treatment of symptoms is usually with beta-blockers. There is a special form of verapamil-sensitive tachycardia that responds well to non-dihydropyridine calcium antagonists. In symptomatic patients, radiofrequency catheter ablation is highly effective, resulting in a cure in >90% of cases. It is sometimes difficult to distinguish arrhythmogenic right ventricular hypertrophy (see pp. 1038–1040) from this seemingly benign disorder.

### Non-sustained ventricular tachycardia

Non-sustained ventricular tachycardia (NSVT) is defined as ventricular tachycardia that is ≥5
consecutive beats but lasts <30 s (*Fig. 23.51A*). NSVT can be found in 6% of patients with normal hearts and usually does not require treatment. It is documented in up to 60–80% of patients with heart disease. There is insufficient evidence on prognosis, but an ICD has been shown to improve survival of patients with particularly poor left ventricular function (ejection fraction ≤30%) by preventing arrhythmic death. Antiarrhythmic suppression of NSVT is not usually advocated but beta-blockers may improve quality of life in symptomatic individuals.
FIGURE 23.51 Varieties of ventricular ectopic activity. A. A brief run of ventricular tachycardia (non-sustained ventricular tachycardia) that follows previous ectopic activity. B. Two ventricular ectopic beats of different morphology (multimorphological). C. Two ventricular premature beats (VPBs) occurring one after the other (a pair or couplet of VPBs). D. Frequently repetitive ventricular ectopic activity of a single morphology.

Ventricular premature beats (ectopics)
These may be uncomfortable, especially when frequent. The patient complains of extra beats, missed beats or heavy beats because it may be the premature beat, the post-ectopic pause or the next sinus beat that is noticed by the patient. The pulse is irregular owing to the premature beats. Some early beats may not be felt at the wrist. When a premature beat occurs regularly
after every normal beat, ‘pulsus bigeminus’ may occur. If premature ventricular beats are highly symptomatic, treatment with beta-blockade may be helpful. If the ectopics are very frequent, left ventricular dysfunction may develop; if the ectopics stem from a single focus, especially when in the right ventricle, catheter ablation can be very effective.

These premature beats (Fig. 23.51B–D) have a broad (>0.12 s) and bizarre QRS complex because they arise from an abnormal (ectopic) site in the ventricular myocardium. Following a premature beat, there is usually a complete compensatory pause because the AV node or ventricle is refractory to the next sinus impulse. Early ‘R-on-T’ ventricular premature beats (occurring simultaneously with the upstroke or peak of the T wave of the previous beat) may induce ventricular fibrillation in patients with heart disease, particularly following myocardial infarction.

Ventricular premature beats are usually treated only if symptomatic. Simple measures, such as reassurance and beta-blocker therapy, are normally all that is required.

### Long-term management of cardiac tachyarrhythmias

Options for the long-term management of cardiac tachyarrhythmias include:

- antiarrhythmic drug therapy
- ablation therapy
- device therapy.

To determine the optimal strategy for a given patient, the following questions must be addressed:

- Is the principal aim of treatment symptom relief or prevention of sudden death?
- Is maintaining sinus rhythm or controlling ventricular rates the treatment goal?

Commonly employed treatment strategies for the management of specific tachyarrhythmias are outlined in Box 23.16.

**Antiarrhythmic drugs**

Drugs that modify the rhythm and conduction of the heart are used to treat cardiac arrhythmias. Antiarrhythmic drugs may aggravate or produce arrhythmias (proarrhythmia) and they may also depress ventricular contractility and must therefore be used with caution. They are classified according to their effect on the action potential (Vaughan Williams' classification; *Box 23.17* and *Fig. 23.52*).

**FIGURE 23.52** Vaughan Williams’ classification of antiarrhythmic drugs based on their effect on cardiac action potentials (see also Fig. 23.39). (0 = 0 mV. The dotted curves indicate the effects of the drugs. AV, atrioventricular.)

### Class I drugs

These are membrane-depressant drugs that reduce the rate of entry of sodium into the cell (sodium-channel blockers). They may slow conduction, delay recovery or reduce the spontaneous discharge rate of myocardial cells. Class I agents have been found to increase mortality compared to placebo in post-myocardial infarction patients with ventricular ectopy.
Cardiac Arrhythmia Suppression Trial (CAST) trials – class Ic agents) and in patients treated for atrial fibrillation (class Ia agent, quinidine). In view of this, class Ic agents, such as flecainide, and all other class I drugs should be reserved for patients who do not have significant coronary artery disease, left ventricular dysfunction, or other forms of significant structural heart disease.

Class II drugs
These antisypathetic drugs prevent the effects of catecholamines on the action potential. Most are β-adrenoceptor antagonists. Cardioselective beta-blockers (β₁) include metoprolol, bisoprolol, atenolol and acebutolol. Beta-blockers suppress AV node conduction, which may be effective in preventing attacks of junctional tachycardia, and may help to control the ventricular rate during paroxysms of other forms of SVT (e.g. atrial fibrillation). In general, beta-blockers are anti-ischaemic and anti-adrenergic, and have proven beneficial effects in patients post myocardial infarction (by preventing ventricular fibrillation) and in patients with congestive heart failure. It is therefore advisable to use beta-blocker therapy either alone or in combination with other antiarrhythmic drugs in patients with symptomatic tachyarrhythmias, particularly in those with coronary artery disease.

Class III drugs
These prolong the action potential, usually by blocking the rapid component of the delayed rectifier potassium current (IKr), and do not affect sodium transport through the membrane. The drugs in this class are amiodarone and sotalol. Sotalol is also a beta-blocker. Sotalol may result in acquired long QT syndrome and torsades de pointes. The risk of torsades is increased in the setting of hypokalaemia, and particular care should be taken in patients taking diuretic therapy. Amiodarone therapy, in contrast to most other antiarrhythmic drugs, carries a low risk of proarrhythmia in patients with significant structural heart disease, but its use may be limited due to toxic and potentially serious side-effects. Dronedarone is a multichannel blocking drug that suppresses the recurrence of atrial fibrillation and reduces hospital admissions in patients with cardiovascular risk. However, it has proven harmful in patients with left ventricular dysfunction and is contraindicated in heart failure.

Vernakalant is a multichannel blocker that is approved for the rapid intravenous medical cardioversion of new-onset atrial fibrillation.

Class IV drugs
The non-dihydropyridine calcium-channel blockers are particularly effective at slowing conduction in nodal tissue. These drugs can prevent attacks of junctional tachycardia (AVNRT and AVRT) and may help to control ventricular rates during paroxysms of other forms of SVT (e.g. atrial fibrillation).

Antiarrhythmic drugs have not been shown to prolong life. Patient safety is the main factor in determining the choice of antiarrhythmic therapy, and proarrhythmic risks need to be carefully assessed prior to initiating therapy. As a generalization, class Ic agents are employed in
patients with structurally normal hearts, and class III agents are used in patients with structural heart disease, although exceptions exist.

Patients with structurally normal hearts and normal QT intervals, or those with implantable defibrillators, either are at very low risk of proarrhythmia or are protected from any life-threatening consequences; in these individuals, it is possible to persevere with drug therapy.

**Catheter ablation**

Catheter ablation (radiofrequency or cryoablation) is frequently employed in the management of symptomatic tachyarrhythmias. Ablations are performed percutaneously by placing electrode catheters into the heart chambers, usually via femoral vessels. Successful ablation depends on accurate identification of either the site of origin of a focal tachycardia or a critical component of a macro re-entry tachycardia. Catheter ablation has been found to be highly effective in the following tachyarrhythmias:

- AV node re-entrant tachycardia (AVNRT)
- AV re-entrant tachycardia (AVRT) with an accessory pathway, including Wolff–Parkinson–White (WPW) syndrome
- normal heart ventricular tachycardia
- atrial flutter
- atrial tachycardia
- paroxysmal atrial fibrillation (pulmonary vein isolation).

Symptomatic patients with a **pre-excited** ECG because of accessory pathway conduction (WPW syndrome) are advised to undergo catheter ablation as first-line therapy, owing to the risk of sudden death associated with this condition. This is especially the case in patients with pre-excited atrial fibrillation. Patients with accessory pathways that only conduct retrogradely from the ventricles to the atrium are not at increased risk of sudden death but experience symptoms due to AVRT. These patients are commonly offered an ablation procedure if simple measures, such as AV nodal slowing agents, fail to suppress tachycardia. Asymptomatic patients with the WPW ECG pattern are now frequently offered an ablation procedure for prophylactic reasons. The main risk associated with accessory pathway ablation is thromboembolism in patients with left-sided accessory pathways. The success rate for catheter ablation of AVNRT and accessory pathways is >95%.

Patients with **normal hearts and documented ventricular tachycardia** should be referred for specialist evaluation. Unlike VT in patients with structural heart disease, normal heart VT is not associated with increased risk of sudden death and is easily cured by catheter ablation.

Catheter ablation is recommended in patients with **atrial flutter** that is not easily managed medically. Ablation of typical flutter is effective in 90–95% of cases. In the direct comparison of catheter ablation and antiarrhythmic therapy, the rate of recurrence was significantly lower following ablation. **Atrial tachycardia**, especially in patients with structurally normal hearts, may also be cured by catheter ablation. In atrial fibrillation, adequate control of ventricular rates is sometimes not possible, despite optimal medical therapy. These patients experience a
marked symptomatic improvement following AV node ablation (which leads to complete heart block) and pacemaker implantation.

In younger patients with structurally normal hearts, atrial ectopic beats, which commonly arise from a focus situated in the pulmonary veins, may trigger atrial fibrillation. Catheter ablation of this ectopic focus includes the application of radiofrequency energy around the pulmonary veins in order to abolish the connection between the sleeves of arrhythmogenic atrial myocardium surrounding or extending into the veins from the atrium (pulmonary vein isolation). The trigger is therefore eliminated and the arrhythmia does not recur. These techniques appear to be highly effective, especially in young patients with paroxysmal atrial fibrillation, normal atrial size and no underlying heart disease (70–80% long-term success), but are presently time-consuming procedures (4 h or more) and carry a risk of serious complications such as stroke, pericardial haemorrhage, pulmonary vein stenosis and atrio-oesophageal fistula in a small minority of patients (in experienced centres <2% altogether).

**Implantable cardioverter–defibrillator**

Life-threatening ventricular arrhythmias (ventricular fibrillation or rapid ventricular tachycardia with hypotension) result in death in up to 40% within 1 year of diagnosis. Large multicentre prospective trials, such as the Antiarrhythmics (amiodarone) Versus Implantable Defibrillator (AVID) trial, have proven that implantable defibrillators improve overall survival in patients who have experienced an episode of life-threatening ventricular tachyarrhythmia.

The implantable cardioverter–defibrillator (ICD) recognizes ventricular tachycardia or fibrillation and automatically delivers pacing or a shock to the heart to cause cardioversion to sinus rhythm. Modern ICDs are only a little larger than a pacemaker and are implanted in a pectoral position *(Fig. 23.53)*. The device may have leads to sense and pace both the right atrium and ventricle, and the lithium batteries employed are able to provide energy for over 100 shocks, each of around 30 J. ICD discharges are painful if the patient is conscious. However, ventricular tachycardia may often be terminated by overdrive pacing the heart, which is painless. The ICD is superior to all other treatment options at preventing sudden cardiac death. The use of this device has cut the sudden death rate in patients with a history of serious ventricular arrhythmias to approximately 2% per year. However, the majority of these patients have significant structural heart disease and overall cardiac mortality due to progressive heart failure remains high. As a result, the ICD is now first-line therapy in the secondary prevention of sudden death.
ICDs are also employed in the primary prevention of sudden cardiac death. The chances of surviving an out-of-hospital cardiac arrest are as low as 10%. Therefore, selected patients who have never experienced a spontaneous episode of life-threatening ventricular tachyarrhythmia but who are assessed to be at high risk of sudden death are advised to undergo ICD implantation. In two large primary prevention ICD trials, Multicenter Automated Defibrillator Implantation Trial (MADIT II) and Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT), therapy with an ICD reduced mortality by 23–31% on top of conventional treatment, which included revascularization, beta-blockers and angiotensin-converting enzyme (ACE) inhibitors. ICD combined with cardiac resynchronization therapy may improve both symptoms and life expectancy of patients with any degree of heart failure (COMPANION, CARE-HF and MADIT-CRT).

The following groups of patients may merit prophylactic ICD placement for primary prevention:

• Patients with heart failure with a left ventricular ejection fraction of ≤35% and NYHA functional class <IV (see Box 23.21). In such patients who also have left bundle branch block (QRS >120 ms), there is additional benefit in combining ICD with cardiac resynchronization therapy (CRT-D; see p. 988).

• Those with a familial condition and high risk of sudden death, such as dilated and
hypertrophic cardiomyopathy, long QT syndrome, Brugada syndrome or other channelopathies, who have a strong family history of sudden cardiac death and arrhythmogenic right ventricular dysplasia.

**Further reading**

**Heart Failure**

Heart failure is a complex syndrome that can result from any structural or functional cardiac disorder that impairs the ability of the heart to function as a pump to support a physiological
circulation.

Worldwide, the incidence of heart failure is variable but increases with advancing age. For example, in Scotland, the prevalence of heart failure is high at 7.1 in 1000, increasing with age to 90.1 in 1000 among people over 85 years. In the UK, overall incidence is about 2 in 1000. Approximately 26 million people worldwide have heart failure.

The prognosis of heart failure has improved over the past 10 years with evidence-based therapy, but the mortality rate remains high and approximately 50% of patients are dead at 5 years. Heart failure accounts for 5% of admissions to hospital medical wards. The cost of managing heart failure in the UK exceeds £1 billion per year. Coronary artery disease is the most common cause of heart failure in Western countries.

The causes of heart failure are shown in Box 23.18.

---

**Box 23.18**

**Causes of heart failure**

**Main causes**

- Ischaemic heart disease (35–40%)
- Cardiomyopathy (dilated) (30–34%)
- Hypertension (15–20%)

**Other causes**

- Cardiomyopathy (undilated): hypertrophic, restrictive (amyloidosis, sarcoidosis)
- Valvular heart disease (mitral, aortic, tricuspid)
- Congenital heart disease (ASD, VSD)
- Alcohol and drugs (chemotherapy – trastuzumab, imatinib)
- Hyperdynamic circulation (anaemia, thyrotoxicosis, haemochromatosis, Paget's disease)
- Right heart failure (right ventricular infarct, pulmonary hypertension, pulmonary embolism, COPD)
- Tricuspid incompetence
- Arrhythmias (atrial fibrillation, bradycardia (complete heart block, sick sinus syndrome)
- Pericardial disease (constrictive pericarditis, pericardial effusion)
- Infections (Chagas' disease), e.g. myocarditis

ASD, atrial septal defect; COPD, chronic obstructive pulmonary disease; VSD, ventricular septal defect.

---

**Pathophysiology**

When the heart fails, considerable changes affect the heart and peripheral vascular system in
response to the haemodynamic changes associated with heart failure (Box 23.19). These physiological changes are compensatory and maintain cardiac output and peripheral perfusion. However, as heart failure progresses, these mechanisms are overwhelmed and become pathophysiological. The development of pathological peripheral vasoconstriction and sodium retention in heart failure by activation of the renin–angiotensin–aldosterone system entails a loss of beneficial compensatory mechanisms and represents cardiac decompensation. Factors involved are venous return, outflow resistance, contractility of the myocardium, and salt and water retention.

### Box 23.19

**Pathophysiological changes in heart failure**

- Ventricular dilatation
- Myocyte hypertrophy
- Increased collagen synthesis
- Altered myosin gene expression
- Altered sarcoplasmic Ca\(^{2+}\)-ATPase density
- Increased ANP secretion
- Salt and water retention
- Sympathetic stimulation
- Peripheral vasoconstriction

ANP, atrial natriuretic peptide; ATPase, adenosine triphosphatase.

### Venous return (preload)

In the intact heart, myocardial failure leads to a reduction of the volume of blood ejected with each heart beat, and an increase in the volume of blood remaining after systole. This increased diastolic volume stretches the myocardial fibres and, as Starling's law of the heart (see p. 935) would suggest, myocardial contraction is restored. However, the failing myocardium results in depression of the ventricular function curve (cardiac output plotted against the ventricular diastolic volume) (Fig. 25.7).

Mild myocardial depression is not associated with a reduction in cardiac output because it is maintained by an increase in venous pressure (and hence diastolic volume). However, the proportion of blood ejected with each heart beat (ejection fraction) is reduced early in heart failure. Sinus tachycardia also ensures that any reduction of stroke volume is compensated for by the increase in heart rate; cardiac output (stroke volume × heart rate) is therefore maintained.

When there is more severe myocardial dysfunction, cardiac output can be maintained only by a large increase in venous pressure and/or marked sinus tachycardia. The increased venous pressure contributes to the development of dyspnoea, owing to the accumulation of interstitial
and alveolar fluid, and to the occurrence of hepatic enlargement, ascites and dependent oedema due to increased systemic venous pressure. However, the cardiac output at rest may not be much depressed, but myocardial and haemodynamic reserve is so compromised that a normal increase in cardiac output cannot be produced by exercise.

In very severe heart failure, the cardiac output at rest is depressed, despite high venous pressures. The inadequate cardiac output is redistributed to maintain perfusion of vital organs, such as the heart, brain and kidneys, at the expense of the skin and muscle.

**Outflow resistance (afterload)**
Outflow resistance (afterload) (see Fig. 23.5) is the load or resistance against which the ventricle contracts. It is formed by:

- pulmonary and systemic resistance
- physical characteristics of the vessel walls
- the volume of blood that is ejected.

An increase in afterload decreases the cardiac output. This results in a further increase of end-diastolic volume and dilatation of the ventricle itself, which further exacerbates the problem of afterload. This is expressed by Laplace’s law: the tension of the myocardium (T) is proportional to the intraventricular pressure (P) multiplied by the radius of the ventricular chamber (R) – that is, \( T \propto PR \).

**Myocardial contractility (inotropic state)**
The state of the myocardium also influences performance. The sympathetic nervous system is activated in heart failure via baroreceptors as an early compensatory mechanism, which provides inotropic support and maintains cardiac output. Chronic sympathetic activation, however, has deleterious effects by further increasing neurohormonal activation and myocyte apoptosis. This is compensated by a downregulation of \( \beta \)-receptors. Increased contractility (positive inotropism) can result from increased sympathetic drive, and this is a normal part of the Frank–Starling relationship (see Fig. 23.5). Conversely, myocardial depressants (e.g. hypoxia) decrease myocardial contractility (negative inotropism).

**Neurohormonal and sympathetic system activation: salt and water retention**
The increase in venous pressure that occurs when the ventricles fail leads to retention of salt and water and their accumulation in the interstitium, producing many of the physical signs of heart failure. Reduced cardiac output also leads to diminished renal perfusion, activating the renin–angiotensin system and enhancing salt and water retention (see Fig. 20.6), which further increases venous pressure (Fig. 23.54). The retention of sodium is, in part, compensated by the action of circulating atrial natriuretic peptides and antidiuretic hormone (see pp. 150–153).
The compensatory physiological response to heart failure. Chronic activation of the renin–angiotensin and adrenergic systems results in a ‘vicious circle’ of cardiac deterioration that further exacerbates the physiological response. HR, heart rate.

The interaction of haemodynamic and neurohumoral factors in the progression of heart failure remains unclear. Increased ventricular wall stress promotes ventricular dilatation and further worsens contractile efficiency. In addition, prolonged activation of the sympathetic nervous and renin–angiotensin–aldosterone systems exerts direct toxic effects on myocardial cells.

**Myocardial remodelling in heart failure**

Left ventricular remodelling is a process of progressive alteration of ventricular size, shape and function owing to the influence of mechanical, neurohumoral and possibly genetic factors in several clinical conditions, including myocardial infarction, cardiomyopathy, hypertension and valvular heart disease. Its hallmarks include hypertrophy, loss of myocytes and increased interstitial fibrosis. Remodelling continues for months after the initial insult, and the eventual change in the shape of the ventricle becomes responsible for significant impairment of overall function of the heart as a pump (Fig. 23.55A). In cardiomyopathy, the process of progressive ventricular dilatation or hypertrophy takes place without ischaemic myocardial injury or infarction (Fig. 23.55B).
Changes in myocardial gene expression

Haemodynamic overload of the ventricle stimulates changes in cardiac contractile protein gene expression. The overall effect is to increase protein synthesis, but many proteins also switch to fetal and neonatal isoforms. Human myosin is composed of a pair of heavy chains and two pairs of light chains. Myosin heavy chains (MHCs) exist in two isoforms, α and β, that have different contractile properties and ATPase activity; αα-MHC predominates in the atria and ββ-MHC in the ventricles. In animal models, pressure overload results in a shift from αα- to ββ-MHC in the atria, in parallel with atrial size. This results in a reduction in atrial contractility but lower energy demands. This shift is less significant in the human ventricle, as the ββ-MHC isoform already predominates. Other genes affected in heart failure include those encoding Na⁺/K⁺-ATPase, Ca²⁺-ATPase and β₁-adrenoceptors.

Abnormal calcium homeostasis

Calcium ion flux within myocytes plays a pivotal role in the regulation of contractile function. Excitation of the myocyte cell membrane causes the rapid entry of calcium into myocytes from the extracellular space via calcium channels. This triggers the release of intracellular calcium from the sarcoplasmic reticulum and initiates contraction (see Fig. 23.3). Relaxation results from the uptake and storage of calcium by the sarcoplasmic reticulum (see Fig. 23.9), controlled by changes in nitric oxide. In heart failure, there is a prolongation of the calcium current in association with prolongation of contraction and relaxation.

Apoptosis

Apoptosis (or ‘programmed cell death’; see p. 105) of myocytes has been demonstrated in
animal models of ischaemic reperfusion, rapid ventricular pacing, mechanical stretch and pressure overload. Apoptosis is associated with irreversible congestive heart failure, and the spiral of ventricular dysfunction, characteristic of heart failure, results from the initiation of apoptosis by cytokines, free radicals and other triggers.

**Natriuretic peptides (ANP, BNP and C-type)**

- **Atrial natriuretic peptide (ANP)** is released from atrial myocytes in response to stretch. ANP induces diuresis, natriuresis, vasodilatation and suppression of the renin–angiotensin system. Levels of circulating ANP are increased in congestive cardiac failure and correlate with functional class, prognosis and haemodynamic state.

- **Brain natriuretic peptide (BNP)** (so called because it was first discovered in the brain) is predominantly secreted by the ventricles in response to increased myocardial wall stress. N-terminal (NT)-proBNP is an inactive protein that is cleaved from proBNP to release BNP. Both BNP and NT-proBNP are increased in patients with heart failure, and levels correlate with ventricular wall stress and the severity of heart failure. BNP and NT-proBNP are good predictors of cardiovascular events and mortality, and there is increasing interest in monitoring levels to help guide heart failure therapy.

- **C-type peptide**, which is limited to vascular endothelium and the central nervous system, has similar effects to those of ANP and BNP.

**Endothelial function in heart failure**

The endothelium has a central role in the regulation of vasomotor tone. In patients with heart failure, endothelium-dependent vasodilatation in peripheral blood vessels is impaired and may be one mechanism of exercise limitation. The cause of abnormal endothelial responsiveness relates to abnormal release of both nitric oxide and vasoconstrictor substances, such as endothelin (ET). The activity of nitric oxide, a potent vasodilator, is blunted in heart failure. ET secretion from a variety of tissues is stimulated by many factors, including hypoxia, catecholamines and angiotensin II. The plasma concentration of ET is elevated in patients with heart failure, and levels correlate with the severity of haemodynamic disturbance. The major source of circulating ET in heart failure is the pulmonary vascular bed.

ET has many actions that potentially contribute to the pathophysiology of heart failure: vasoconstriction, sympathetic stimulation, renin–angiotensin system activation and left ventricular hypertrophy. Acute intravenous administration of ET antagonists improves haemodynamic abnormalities in patients with congestive cardiac failure, and oral ET antagonists are being developed. Plasma concentrations of some cytokines, in particular tumour necrosis factor (TNF), are increased in patients with heart failure.

**Antidiuretic hormone (vasopressin)**

Antidiuretic hormone (ADH) is raised in severe chronic heart failure, particularly in patients on diuretic treatment. A high ADH concentration precipitates hyponatraemia, which is an ominous prognostic indicator.
Clinical syndromes of heart failure

There are many causes of heart failure (see Box 23.18) that can present suddenly, with acute heart failure (AHF), or more insidiously, with chronic heart failure (CHF).

- **Left ventricular systolic dysfunction (LVSD)** or **heart failure and a reduced (R) ejection fraction (HFREF)** is commonly caused by ischaemic heart disease but can also occur with valvular heart disease and hypertension.

- **Diastolic heart failure** is a syndrome consisting of symptoms and signs of **heart failure with preserved (P) left ventricular ejection fraction (HFPEF)** >45–50%. There is increased stiffness in the ventricular wall and decreased left ventricular compliance, leading to impairment of diastolic ventricular filling and hence decreased cardiac output. Echocardiography may demonstrate an increase in left ventricular wall thickness, increased left atrial size and abnormal left ventricular relaxation with normal or near-normal left ventricular volume. Diastolic heart failure is more common in elderly hypertensive patients but may occur with primary cardiomyopathies (hypertrophic, restrictive, infiltrative).

- **Right ventricular systolic dysfunction (RVSD)** may be secondary to chronic LVSD but can occur with primary and secondary pulmonary hypertension, right ventricular infarction, arrhythmogenic right ventricular cardiomyopathy and adult congenital heart disease.

Clinical features of heart failure

The symptoms and signs of heart failure are shown in **Box 23.20**.

### Box 23.20

Clinical features of heart failure

#### Symptoms
- Exertional dyspnoea
- Orthopnoea
- Paroxysmal nocturnal dyspnoea
- Fatigue

#### Signs
- Tachycardia
- Elevated jugular venous pressure
- Cardiomegaly
- Third and fourth heart sounds
- Bi-basal crackles
- Pleural effusion
• Peripheral ankle oedema
• Ascites
• Tender hepatomegaly

The New York Heart Association (NYHA) classification of heart failure (Box 23.21) can be used to describe the symptoms of heart failure and limitation of exercise capacity, and is useful for assessing response to therapy. It does not include left ventricular ejection fraction as a means of determining severity of heart failure.

<table>
<thead>
<tr>
<th>Class</th>
<th>Features</th>
</tr>
</thead>
<tbody>
<tr>
<td>Class I</td>
<td>No limitation. Normal physical exercise does not cause fatigue, dyspnoea or palpitations</td>
</tr>
<tr>
<td>Class II</td>
<td>Mild limitation. Comfortable at rest but normal physical activity produces fatigue, dyspnoea or palpitations</td>
</tr>
<tr>
<td>Class III</td>
<td>Marked limitation. Comfortable at rest but gentle physical activity produces marked symptoms of heart failure</td>
</tr>
<tr>
<td>Class IV</td>
<td>Symptoms of heart failure occur at rest and are exacerbated by any physical activity</td>
</tr>
</tbody>
</table>

**Diagnosis of heart failure**

The diagnosis of heart failure should not be based on history and clinical findings alone; it requires evidence of cardiac dysfunction using objective measures of left ventricular structure and function (usually echocardiography). Similarly, the underlying cause of heart failure should be established in all patients (Box 23.22 and Fig. 23.56).

**Box 23.22**

**Diagnosis of heart failure (European Society of Cardiology guidelines)**

**Diagnosis of HF-REF requires three conditions to be satisfied**

1. Symptoms typical of heart failure
2. Signs typical of heart failure
3. Reduced LV ejection fraction

**Diagnosis of HF-PEF requires four conditions to be satisfied**

1. Symptoms typical of heart failure
2. Signs typical of heart failure
3. Normal or only mildly reduced LV ejection fraction and LV not dilated
4. Relevant structural heart disease (LV hypertrophy/left atrial enlargement) and/or diastolic dysfunction

HF-REF = heart failure and a reduced ejection fraction; HF-PEF = heart failure with ‘preserved’ ejection fraction; LV = left ventricular.

**Investigations in heart failure**

- **Blood tests.** Full blood count, urea and electrolytes, liver biochemistry, cardiac enzymes in acute heart failure, BNP or NT-proBNP, and thyroid function should be tested.

- **Chest X-ray.** Look for cardiomegaly, pulmonary congestion with upper lobe diversion, fluid in fissures, Kerley B lines and pulmonary oedema.

- **Electrocardiogram.** Identify ischaemia, hypertension or arrhythmia.

- **Echocardiography.** Assess cardiac chamber dimension, systolic and diastolic function, regional wall motion abnormalities, valvular disease and cardiomyopathies.

- **Stress echocardiography.** Assess viability in dysfunctional myocardium – dobutamine identifies contractile reserve in stunned or hibernating myocardium.
• **Nuclear cardiology.** Radionucleotide angiography (RNA) can quantify ventricular ejection fraction; SPECT or PET can demonstrate myocardial ischaemia and viability in dysfunctional myocardium.

• **Cardiac MRI (CMR).** Assess cardiac structure and function and viability in dysfunctional myocardium with the use of dobutamine for contractile reserve or with gadolinium for delayed enhancement (‘infarct imaging’).

• **Cardiac catheterization.** This technique is employed for the diagnosis of ischaemic heart failure (and suitability for revascularization) and for measurement of pulmonary artery pressure, left atrial (wedge) pressure, left ventricular end-diastolic pressure.

• **Cardiac biopsy.** This is used for diagnosis of cardiomyopathies, such as amyloid, and for follow-up of transplanted patients to assess rejection.

• **Cardiopulmonary exercise testing.** Peak oxygen consumption (VO\textsubscript{2}) is predictive of hospital admission and death in heart failure. A 6-minute exercise walk is an alternative.

• **Ambulatory 24-hour ECG monitoring (Holter).** This is used in patients with suspected arrhythmia, and may be used in those with severe heart failure or inherited cardiomyopathy to determine whether a defibrillator is appropriate (non-sustained ventricular tachycardia).

### Management of heart failure

Management is aimed at relieving symptoms, prevention and control of disease leading to cardiac dysfunction and heart failure, retarding disease progression and improving quality and length of life.

Measures to prevent heart failure include cessation of smoking, alcohol and illicit drugs, effective treatment of hypertension, diabetes and hypercholesterolaemia, and pharmacological therapy following myocardial infarction.

The management of heart failure requires any factor aggravating the failure to be identified and treated. Similarly, the cause of heart failure must be elucidated and, where possible, corrected. Community nursing programmes to help with drug compliance and to detect early deterioration may prevent acute hospitalization.

### General lifestyle advice

**Education**

Effective counselling of patients and family, emphasizing weight monitoring and dose adjustment of diuretics, may prevent hospitalization.

**Dietary modification**

Large meals should be avoided and, if necessary, weight reduction instituted. Salt restriction is required and foods rich in salt or added salt in cooking and at the table should be avoided. In severe heart failure, fluid restriction is necessary and patients may need to weigh themselves
daily. Alcohol has a negative inotropic effect and heart failure patients should moderate consumption. Omega-3 polyunsaturated fatty acids (see p. 187) reduce mortality and hospital admission.

**Smoking**

Smoking should be stopped, with help from anti-smoking clinics if necessary (see p. 1075).

**Physical activity, exercise training and rehabilitation**

For patients with exacerbations of congestive cardiac failure, bed rest reduces the demands on the heart and is useful for a few days. Migration of fluid from the interstitium promotes diuresis, reducing heart failure. Prolonged bed rest may lead to the development of deep vein thrombosis (DVT); this can be avoided by daily leg exercises, low-dose subcutaneous heparin and elastic support stockings. Low-level endurance exercise (e.g. 20–30 min walking three or five times per week or 20 min cycling at 70–80% of peak heart rate five times per week) is actively encouraged in patients with compensated heart failure in order to reverse ‘deconditioning’ of peripheral muscle metabolism. Strenuous isometric activity should be avoided.

**Vaccination**

While prospective clinical trials are lacking, it is recommended that patients with heart failure be vaccinated against pneumococcal disease and influenza (see p. 1078).

**Air travel**

This is possible for most patients, subject to clinical circumstances. Check with the airline – most have guidelines on who should travel.

**Sexual activity**

Tell patients on nitrates not to take phosphodiesterase type 5 inhibitors (e.g. sildenafil), as they may induce profound hypotension.

**Driving**

Driving cars and motorcycles may continue, provided there are no symptoms that distract the driver's attention. The Driver and Vehicle Licensing Authority (DVLA) in the UK does not need to be notified. Symptomatic heart failure disqualifies patients from driving large lorries and buses. Re/licensing may be permitted, as long as the left ventricular ejection fraction is good (i.e. >40%), the exercise test requirements can be met and there are no other disqualifying conditions.

**Monitoring**

The clinical condition of a person with heart failure fluctuates; lengthy and repeated hospital admissions are common, with an average inpatient stay of between 5 and 10 days. Monitoring
of clinical status is necessary and this responsibility should be shared between primary and secondary healthcare professionals.

Essential monitoring includes assessment of:

- functional capacity (e.g. NYHA functional class, exercise tolerance test, echocardiography, maximum VO$_2$)
- fluid status (body weight, clinical assessment and urea and electrolytes)
- cardiac rhythm (ECG, 24-h tape).

**Multidisciplinary team approach**

Heart failure care should be delivered by a multidisciplinary team with an integrated approach across the healthcare community. The multidisciplinary team should involve specialist healthcare professionals: cardiologist or physician with a specialist interest in heart failure, heart failure nurse, dietician, pharmacist, occupational therapist, physiotherapist and palliative care adviser.

Understanding the information needs of patients and carers is vital. Good communication is essential for best clinical management, which should include advice on anxiety, depression and ‘end-of-life’ issues.

**Drug management**

*Box 23.23* lists the drugs used in heart failure. *Figure 23.57* shows the stages of heart failure and the treatment options.

---

</table>

ACE, angiotensin-converting enzyme; ARA, angiotensin II receptor antagonist; AV, atrioventricular.
Diuretics

These act by promoting the renal excretion of salt and water by blocking tubular reabsorption of sodium and chloride (see p. 156). Loop diuretics (e.g. furosemide and bumetanide) and thiazide diuretics (e.g. bendroflumethiazide, hydrochlorothiazide) should be given in patients with fluid overload. Although diuretics provide symptomatic relief of dyspnoea and improve exercise tolerance, there is limited evidence that they affect survival. In severe heart failure patients, the combination of a loop and thiazide diuretic may be required. Serum electrolytes and renal function must be monitored regularly (risk of hypokalaemia and hypomagnesaemia).

Angiotensin-converting enzyme inhibitors

The use of angiotensin-converting enzyme (ACE) inhibitors in patients with heart failure has been demonstrated in multiple large randomized controlled trials (CONSENSUS, SOLVD) to improve symptoms and significantly reduce mortality. ACE inhibitors also benefit patients with asymptomatic heart failure following myocardial infarction. Thus, ACE inhibitors improve survival in patients in all functional classes (NYHA I–IV) and are recommended in all patients at risk of developing heart failure. The main adverse effects of ACE inhibitors are cough, hypotension, hyperkalaemia and renal dysfunction. Contraindications to their use include renal artery stenosis, pregnancy and previous angio-oedema. In patients with heart failure, ACE inhibitors should be introduced at a low initial dose and gradually titrated, with regular monitoring of blood pressure and renal function.
**Angiotensin II receptor antagonists**

The angiotensin II receptor antagonists (ARAs; candesartan and valsartan) are indicated as second-line therapy in patients intolerant of ACE inhibitors. Unlike ACE inhibitors, they do not affect bradykinin metabolism and do not produce a cough. The CHARM Alternative Trial showed that candesartan reduced the risk of heart failure hospitalization compared to placebo in patients intolerant of ACE inhibitors. Other trials (Val HeFT and ELITE II) have assessed other ARAs. A recent study using the ARA valsartan and a neprilysin inhibitor sacubitril has shown promise in the treatment of heart failure.

**Beta-blockers**

Beta-blockers have been shown to improve functional status and reduce cardiovascular morbidity and mortality in patients with heart failure. Several trials (CIBIS, CIBIS II, MERIT-HF, COMET) have assessed the effects of beta-blockers in varying degrees of heart failure. Bisoprolol and carvedilol reduce mortality in any grade of heart failure. Nebivolol is used in the treatment of stable mild to moderate heart failure in patients over 70 years old (SENIORS). In patients with significant heart failure, beta-blockers are started at a low dose and gradually increased, with monitoring of heart rate and blood pressure.

**Aldosterone antagonists**

The aldosterone antagonists spironolactone and eplerenone have been shown to improve survival in patients with heart failure. In RALES, spironolactone reduced total mortality by 30% in patients with severe heart failure. However, gynaecomastia or breast pain occurred in 1 in 10 men taking spironolactone. In EPHESUS, eplerenone given to patients with an acute myocardial infarction and heart failure reduced total mortality by 15% and sudden cardiac death by 21%, with no gynaecomastia.

**Cardiac glycosides**

Digoxin is a cardiac glycoside that is indicated in patients in atrial fibrillation with heart failure. It is used as add-on therapy in symptomatic heart failure patients already receiving ACE inhibitors and beta-blockers. Although the DIG study demonstrated that digoxin reduced hospital admissions in patients with heart failure, a sub-analysis in the ROCKET AF trial suggested that mortality may, in fact, be increased.

**Vasodilators and nitrates**

The combination of hydralazine and nitrates reduces preload and afterload, and is used in patients intolerant of ACE inhibitors or ARAs. The Veterans Administration Cooperative Study demonstrated that the combination of hydralazine (with nitrates) improved survival in patients with chronic heart failure. The A-HeFT trial showed that the same combination reduced mortality and hospitalization for heart failure in black patients with heart failure.

**Inotropic and vasopressor agents**
Intravenous inotropes and vasopressor agents (see Box 23.27) are used in patients with acute heart failure and severe haemodynamic compromise. Although they produce haemodynamic improvements, they have not been shown to improve long-term mortality when compared with placebo.

**Other medications**

In hospital, all patients require prophylactic anticoagulation. Heart failure is associated with a fourfold increase in the risk of a stroke. Oral anticoagulants are recommended in patients with atrial fibrillation and in those with sinus rhythm and a history of thromboembolism, left ventricular aneurysm or thrombus. In patients with known ischaemic heart disease, antiplatelet therapy (aspirin, clopidogrel) and statin therapy should be continued. Arrhythmias are common in heart failure and are implicated in sudden death. Although treatment of complex ventricular arrhythmias might be expected to improve survival, there is no evidence to support this and it may increase mortality. In the Sudden Cardiac Death Heart Failure Trial (SCD-HeFT), amiodarone showed no benefit compared to placebo in patients with impaired left ventricular function and mild to moderate heart failure (whereas an ICD reduced mortality by 23% compared to placebo). Patients with heart failure and symptomatic ventricular arrhythmias should be assessed for suitability for an ICD.

Ivabradine selectively decreases heart rate without affecting blood pressure by inhibiting the $I_f$ channels in the sinoatrial node (see pp. 933–935). An elevated heart rate in patients with heart failure is associated with worse cardiovascular outcomes. The SHIFT study reported a reduction in cardiovascular death and heart failure hospitalization in patients in sinus rhythm with chronic heart failure and left ventricular dysfunction (LVEF ≤35%). Ivabradine can be used in patients in sinus rhythm with an elevated heart rate despite beta-blocker treatment or in those who are unable to tolerate beta-blockers.

**Non-pharmacological treatment**

**Revascularization**

While coronary artery disease is the most common cause of heart failure, the role of revascularization in patients with heart failure is unclear. Patients with angina and left ventricular dysfunction have a higher mortality from surgery (10–20%), but have the most to gain in terms of improved symptoms and prognosis. Factors that must be considered before recommending surgery include age, symptoms and evidence of reversible myocardial ischaemia.

**Hibernating myocardium and myocardial stunning**

‘Hibernating’ myocardium can be defined as reversible left ventricular dysfunction due to chronic coronary artery disease that responds positively to inotropic stress and indicates the presence of viable heart muscle that may recover after revascularization. It is due to reduced myocardial perfusion, which is just sufficient to maintain viability of the heart muscle.
Myocardial hibernation results from repetitive episodes of cardiac stunning that occur: for example, with repeated exercise in a patient with coronary artery disease.

*Myocardial stunning* is reversible ventricular dysfunction that persists following an episode of ischaemia when the blood flow has returned to normal: that is, there is a mismatch between flow and function.

The prevalence of hibernating myocardium in patients with coronary artery disease can be estimated from the frequency of improvement in regional abnormalities in wall motion after revascularization; it is thought to be 33% of such patients. Techniques to try to identify hibernating myocardium include stress echocardiography, nuclear imaging, CMR and PET.

The clinical relevance of the hibernating and stunned myocardium is that ventricular dysfunction due to these mechanisms may be wrongly ascribed to myocardial necrosis and scarring, which seems untreatable, whereas reversible hibernating and stunning myocardium responds to coronary revascularization.

**Cardiac resynchronization therapy or implantable cardioverter–defibrillator**

Cardiac resynchronization therapy (CRT) entails simultaneous pacing of both ventricles (biventricular pacing) using a lead placed in the right ventricle and another in the coronary sinus to pace the left ventricle (*Fig. 23.58*). It is an effective therapy in addition to optimal medical therapy in patients with significant left ventricular impairment and a prolonged QRS interval (left bundle branch block). Resynchronization may reverse the process of ventricular remodelling, reduce functional mitral regurgitation and improve left ventricular function. The CARE-HF and COMPANION trials reported symptomatic benefit and a reduction in heart failure events and mortality following CRT implantation in patients with heart failure in NYHA classes III and IV. Similar findings have been noted in more recent trials in patients with mild heart failure or no symptoms.

---

*FIGURE 23.58* Implantable biventricular pacemaker with implantable cardioverter–defibrillator device (CRT-D). LV, left ventricle; RA, right atrium; RV, right ventricle.
Most patients with heart failure who receive CRT also meet the criteria for use of an implantable cardioverter–defibrillator (ICD) and should receive a combined device (CRT-D). Patients with end-stage heart failure (NYHA IV) or other co-morbidities that may significantly reduce lifespan are generally not candidates for an ICD.

**Cardiac transplantation**

Cardiac transplantation has become the treatment of choice for younger patients with severe intractable heart failure, whose life expectancy is less than 6 months. With careful recipient selection, the expected 1-year survival for patients following transplantation is over 90%, and is 75% at 5 years. Irrespective of survival, quality of life is dramatically improved for the majority of patients. The availability of heart transplantation is limited.

Heart allografts do not function normally. Cardiac denervation results in a high resting heart rate, loss of diurnal blood pressure variation and impaired renin–angiotensin–aldosterone regulation. Some patients develop a ‘stiff heart’ syndrome, caused by rejection, denervation and ischaemic injury during organ harvest and implantation. Transplantation of an inadequately small donor heart can also result in elevated right and left heart pressure.

The complications of heart transplantation are summarized in *Box 23.24*. Many (infection, malignancy, hypertension and hyperlipidaemia) are related to immunosuppression. Allograft coronary atherosclerosis is the major cause of long-term graft failure and is present in 30–50% of patients at 5 years. It is due to a ‘vascular’ rejection process in conjunction with hypertension and hyperlipidaemia.

---

**Box 23.24**

**Complications of cardiac transplantation**

- **Allograft rejection:**
  - ‘Humoral’
  - ‘Vascular’
  - ‘Cell-mediated’
- **Infections:**
  - Early: hospital-acquired organisms – staphylococci; Gram-negative bacteria
  - Late (2–6 months): opportunistic (toxoplasmosis, cytomegalovirus, fungi, *Pneumocystis*)
- **Allograft vascular disease**
- **Hypertension**
- **Hypercholesterolaemia**
- **Malignancy**

There are specific contraindications to cardiac transplantation (*Box 23.25*); notably, high pulmonary vascular resistance and active malignancy are absolute contraindications. Several
options to transplantation are available: cardiomyoplasty (augmentation of left ventricular contraction by wrapping a latissimus dorsi muscle flap around the ventricle) and the Batista procedure (surgical ventricular size reduction and remodelling of the geometry of the left ventricle). Both procedures have a high mortality and there is limited evidence of substantial benefit in the medium term.

**Box 23.25**

**Contraindications to cardiac transplantation**

- Age >60 years (some variations between centres)
- Alcohol/drug misuse
- Uncontrolled psychiatric illness
- Uncontrolled infection
- Severe renal/liver failure
- High pulmonary vascular resistance
- Systemic disease with multiorgan involvement
- Treated cancer in remission but with <5 years' follow-up
- Recent thromboembolism
- Other disease with a poor prognosis

**Acute heart failure**

Acute heart failure (AHF) occurs with the rapid onset of symptoms and signs of heart failure secondary to abnormal cardiac function, causing elevated cardiac filling pressures. This leads to severe dyspnoea, and fluid accumulates in the interstitium and alveolar spaces of the lung (pulmonary oedema). AHF is the leading cause of hospital admission in people above the age of 65 years; it has a poor prognosis, with a 60-day mortality rate of nearly 10% and a rate of death or rehospitalization of 35% within 60 days. In patients with acute pulmonary oedema, the in-hospital mortality rate is 12% and by 12 months this rises to 30%. Poor prognostic indicators include a high (>16 mmHg) pulmonary capillary wedge pressure (PCWP), low serum sodium concentration, increased left ventricular end-diastolic dimension on echo and low oxygen consumption.

The aetiology of AHF is similar to that of chronic heart failure:

- **Ischaemic heart disease** patients present with an acute coronary syndrome or develop a complication of a myocardial infarction, such as papillary muscle rupture or ventricular septal defect requiring surgical intervention.

- **Valvular heart disease** patients also present with AHF due to valvular regurgitation in endocarditis or prosthetic valve thrombosis. A thoracic aortic dissection may produce severe
aortic regurgitation.

- **Hypertension** patients present with episodes of ‘flash’ pulmonary oedema despite preserved left ventricular systolic function.

- **Acute and chronic kidney disease** both involve fluid overload and reduced renal excretion, which will produce pulmonary oedema.

- **Atrial fibrillation** is frequently associated with AHF and may require emergency cardioversion.

Several clinical syndromes of AHF can be defined (Box 23.26). In a clinical environment, both the Killip score (see p. 1004, based on a cardiorespiratory clinical assessment) and Forrester classification (based on right catheterization findings) are used to provide therapeutic and prognostic information.

(Modified from the European Society of Cardiology.)

### Pathophysiology

The pathophysiology of AHF is similar to that of chronic heart failure with activation of the renin–angiotensin–aldosterone axis and sympathetic nervous system. In addition, prolonged ischaemia (e.g. in acute coronary syndromes) results in myocardial stunning (see p. 987), which exacerbates myocardial dysfunction but may respond to inotropic support. If myocardial ischaemia persists, the myocardium may exhibit hibernation (persistently impaired function due to reduced coronary blood flow), which may recover with successful revascularization.

### Diagnosis

In a person presenting with symptoms and signs of heart failure, a structured assessment should result in the clinical diagnosis of AHF and direct initial treatment to stabilize the patient. Initial
investigations performed in the emergency room should include the following:

- **A 12-lead ECG** will identify acute coronary syndromes, left ventricular hypertrophy, atrial fibrillation, valvular heart disease and left bundle branch block.

- **A chest X-ray** may demonstrate cardiomegaly, pulmonary oedema, pleural effusion or non-cardiac disease.

- **Blood investigations** should include serum creatinine and electrolytes, full blood count, blood glucose, cardiac enzymes and troponin, C-reactive protein (CRP) and D-dimer.

- **Plasma BNP or NT-proBNP** (BNP >100 pg/mL or NT-proBNP >300 pg/mL) is suggestive of heart failure.

- **Transthoracic echocardiography** should be performed without delay to confirm the diagnosis of heart failure (see pp. 949–951) and possibly identify the cause.

  If the baseline investigations confirm AHF, then treatment should be commenced.

### Management

The goals of treatment in a patient with AHF include:

- immediate relief of symptoms and stabilization of haemodynamics (short-term benefits)
- reduction in length of hospital stay and hospital re-admissions
- reduction in mortality from heart failure.

Patients with AHF should be managed in a high-dependency area with regular measurement of temperature, heart rate, blood pressure and cardiac monitoring. All require prophylactic anticoagulation with low-molecular-weight heparin.

Individuals with haemodynamic compromise may need arterial lines for invasive blood pressure monitoring and arterial gas sampling, central venous cannulation (intravenous medication, inotropic support, monitoring of central venous pressure) and pulmonary artery cannulation (calculation of cardiac output/index, peripheral vasoconstriction and pulmonary wedge pressure).

Initial therapy (**Fig. 23.59** and **Box 23.27**) includes oxygen and diuretics (e.g. i.v. furosemide 50 mg). If intravenous nitrates (e.g. glyceryl trinitrate infusion 10–200 µg/min) are required (e.g. concomitant myocardial ischaemia, severe hypertension), careful monitoring of the blood pressure is mandatory. Inotropic support (see pp. 1158–1160) with dobutamine, phosphodiesterase inhibitors or levosimendan can be added in patients who do not respond to the initial therapy (**Fig. 23.59**). A BNP (nesiritide) can also be used in AHF as a bolus injection followed by an infusion.
Algorithm for the management of acute heart failure with systolic dysfunction.

**Key:**
- ACEI = Angiotensin-converting enzyme inhibitor
- BNP = Brain natriuretic peptide, e.g. nesiritide
- CPAP = Continuous positive airway pressure
- NTG = Nitroglycerine (gliciril trinitrate)
- PDEI = Phosphodiesterase inhibitor
- SBP = Systolic blood pressure

| Non-invasive positive pressure ventilation (NIPPV), e.g. CPAP | Use if failing to maintain arterial saturation  
Increases pulmonary recruitment and functional residual capacity – reduces work of breathing |
| Intubation/mechanical ventilation | Use if patient is failing to maintain arterial saturation and is fatigued  
(reduced respiratory rate, increased arterial CO₂, confusion) |
| **Opiate** |  |
| Morphine | 2.5–5.0 mg i.v.  
(with antiemetic metoclopramide 10 mg i.v.) | Use in agitated patient  
Relieves dyspnoea, venous and arterial dilatation |
| **Antithrombin** |  |
| Low-molecular-weight heparin | e.g. Enoxaparin 1 mg/kg s.c. ×2 daily ACS or 40 mg s.c. daily prophylaxis | Use in patients with AHF, ACS or atrial fibrillation, or for DVT prophylaxis  
Caution if creatinine clearance <30 mL/min |
| **Vasodilators** |  |
| Glyceryl trinitrate | 10–200 µg/min i.v. infusion | Reduces pulmonary congestion; at low doses causes venodilatation, reducing preload; at high doses causes arterial vasodilatation, reducing afterload  
Ensure BP >85–90 mmHg |
| Sodium nitroprusside | 0.3–5 µg/kg per min i.v. infusion | Use in severe AHF where there is predominantly high afterload, e.g. hypertensive AHF  
Needs arterial BP monitoring for profound hypotension |
| **Diuretic** |  |
| Furosemide | Bolus 40–100 mg i.v. or infusion 5–40 mg/h | Low doses produce vasodilatation and reduce right atrial pressure and PCWP; promote diuresis  
Need to monitor sodium, potassium and creatinine |
| **Inotropes** |  |
| Dopamine | Low dose <2 µg/kg per min | Low dose acts on peripheral dopamine receptors to produce vasodilatation (renal, splanchnic, coronary, cerebrovascular) and may improve diuresis |
| | Medium dose ≥2 µg/kg per min | Medium dose acts on β-receptors to increase myocardial contractility and cardiac output |
| | High dose ≥5 µg/kg per min | High dose acts on α-receptors, causing vasoconstriction and increasing total peripheral resistance (increases afterload, PAP) |
| Dobutamine | 2–20 µg/kg per min (patients on beta-blockers may need high dose) | Stimulates β₁ and β₂-receptors, producing vasodilatation. Increases heart rate and cardiac output, and also diuresis as haemodynamics are improved |
| Milrinone | Bolus 25–75 µg/kg over 10–20 min then 0.375–0.75 µg/kg per min | Inhibits phosphodiesterase and maintains cAMP  
Increases cardiac output and stroke volume, reduces PAP/PCWP/total peripheral resistance/BP |
| Levosimendan | Bolus 12–24 µg/kg over 10 min then 0.05–2 µg/kg per min | Positive inotropic drug with vasodilator effects by increasing sensitivity of contractile proteins to calcium and opening potassium channels  
Increases cardiac output and reduces PCWP |
| **Vasopressors** |  |
| Noradrenaline (norepinephrine) | 0.2–1.0 µg/kg per min | Stimulates α-receptors  
Increases total peripheral resistance and BP |
| Adrenaline (epinephrine) | Bolus 1 mg at resuscitation then 0.05–0.5 µg/kg per min | Stimulates α, β₁- and β₂-receptors  
Increases cardiac output, heart rate, total peripheral resistance and BP |
| **Cardiac glycoside** |  |
| Digoxin | 0.5 mg i.v. repeated after 2–6 h | Inhibits myocardial sodium/potassium ATPase, leading to increased calcium and sodium exchange  
Increases cardiac output and slows AV conduction |
Patients with profound hypotension may require inotropes and vasopressors to improve the haemodynamic status and alleviate symptoms, but these have not been shown to improve mortality. Non-invasive continuous positive airway pressure/positive pressure ventilation (CPAP/NIPPV; see pp. 1165–1166) has been shown to provide earlier improvement in dyspnoea and respiratory distress than standard oxygen via mask; mortality is, however, unaffected.

**Mechanical assist devices**

Mechanical assist devices can be used in patients who fail to respond to standard medical therapy but in whom there is either transient myocardial dysfunction with likelihood of recovery (e.g. post anterior myocardial infarction treated with coronary angioplasty) or as a bridge to cardiac surgery, including transplantation.

**Ventricular assist devices**

Ventricular assist devices (VADs; Fig. 23.60) are mechanical devices that replace or help the failing ventricles in delivering blood around the body. A left ventricular assist device (LVAD) receives blood from the left ventricle and delivers it to the aorta; a right ventricular assist device (RVAD) receives blood from the right ventricle and delivers it to the pulmonary artery. The devices can be extracorporeal (suitable for short-term support) or intracorporeal (suitable for long-term support as a bridge to transplantation or as destination therapy in patients with end-stage heart failure not candidates for transplantation). The main problems with VADs include thromboembolism, bleeding, infection and device malfunction.

Developed in collaboration with the Heart Failure Association (HFA) of the ESC. *Eur J Heart Fail* 2012; 14:803–869.

Coronary Artery Disease

Myocardial ischaemia occurs when there is an imbalance between the supply of oxygen (and other essential myocardial nutrients) and the myocardial demand for these substances.

Coronary blood flow to a region of the myocardium may be reduced by a mechanical obstruction that is due to:

- atheroma
- thrombosis
- spasm
- embolus
- coronary ostial stenosis
- coronary arteritis (e.g. in systemic lupus erythematosus).

There can be a decrease in the flow of oxygenated blood to the myocardium that is due to:

- anaemia
- carboxyhaemoglobulinaemia
- hypotension, causing decreased coronary perfusion pressure.
An increased demand for oxygen may occur owing to an increase in cardiac output (e.g. thyrotoxicosis) or myocardial hypertrophy (e.g. from aortic stenosis or hypertension).

Myocardial ischaemia most commonly arises as a result of obstructive coronary artery disease (CAD) in the form of coronary atherosclerosis. In addition to this fixed obstruction, variations in the tone of smooth muscle in the wall of a coronary artery may add another element of dynamic or variable obstruction.

CAD is the largest single cause of death in the UK and many parts of the world. In 2010, cardiovascular diseases were the UK’s biggest killer, accounting for nearly 180,000 deaths. CAD was responsible for 1 in 5 male deaths and 1 in 10 female deaths (approximately 80,000 deaths). Sudden cardiac death is a prominent feature of CAD, 1 in every 6 coronary attacks presenting with sudden death as the first, last and only symptom.

Pathophysiology of coronary atherosclerosis

Coronary atherosclerosis is a complex inflammatory process characterized by the accumulation of lipid, macrophages and smooth muscle cells in intimal plaques in the large and medium-sized epicardial coronary arteries. The vascular endothelium plays a critical role in maintaining vascular integrity and homeostasis. Mechanical shear stresses (e.g. from morbid hypertension), biochemical abnormalities (e.g. elevated low-density lipoprotein (LDL), diabetes mellitus), immunological factors (e.g. free radicals from smoking), inflammation (e.g. infection such as *Chlamydia pneumoniae*) and genetic alteration may contribute to the initial endothelial ‘injury’ or dysfunction, which is believed to trigger atherogenesis.

The *development of atherosclerosis* follows the endothelial dysfunction, with increased permeability to and accumulation of oxidized lipoproteins, which are taken up by macrophages at focal sites within the endothelium to produce lipid-laden foam cells. Macroscopically, these lesions are seen as flat, yellow dots or lines on the endothelium of the artery and are known as ‘fatty streaks’. The ‘fatty streak’ progresses with the appearance of extracellular lipid within the endothelium (‘transitional plaque’). Release of cytokines, such as platelet-derived growth factor and transforming growth factor beta (TGF-β), by monocytes, macrophages or the damaged endothelium promotes further accumulation of macrophages, as well as smooth muscle cell migration and proliferation. The proliferation of smooth muscle with the formation of a layer of cells covering the extracellular lipid separates it from the adaptive smooth muscle thickening in the endothelium. Collagen is produced in larger and larger quantities by the smooth muscle and the whole sequence of events cumulates as an ‘advanced or raised fibrolipid plaque’. The ‘advanced plaque’ may grow slowly and encroach on the lumen, or become unstable, undergo thrombosis and produce an obstruction (‘complicated plaque’).

Two different mechanisms are responsible for thrombosis on the plaques *(Fig. 23.61)*:

- **The first process** is superficial endothelial injury, which involves denudation of the endothelial covering over the plaque. Sub-endocardial connective tissue matrix is then exposed and platelet adhesion occurs because of reaction with collagen. The thrombus is adherent to the surface of the plaque.
• The second process is deep endothelial fissuring, which involves an advanced plaque with a lipid core. The plaque cap tears (ulcerates, fissures or ruptures), allowing blood from the lumen to enter the inside of the plaque itself. The core with lamellar lipid surfaces, tissue factor (which triggers platelet adhesion and activation) produced by macrophages and exposed collagen, is highly thrombogenic. Thrombus forms within the plaque, expanding its volume and distorting its shape. Thrombosis may then extend into the lumen.

A 50% reduction in luminal diameter (producing a reduction in luminal cross-sectional area of approximately 70%) causes a haemodynamically significant stenosis. At this point, the smaller distal intramyocardial arteries and arterioles are maximally dilated (coronary flow reserve is near zero), and any increase in myocardial oxygen demand provokes ischaemia.

CAD gives rise to a wide variety of clinical presentations, ranging from relatively stable angina through to the acute coronary syndromes of unstable angina and myocardial infarction (Fig. 23.62). Figure 23.63 shows a plaque rupture.
Risk factors for coronary artery disease

CAD is an atherosclerotic disease that is multifactorial in origin, giving rise to the risk factor concept. Certain living habits promote atherogenic traits in genetically susceptible persons. A number of ‘risk’ factors are known to predispose to the condition (Box 23.28). Some of these, such as age, gender, race and family history, cannot be changed, whereas other major risk factors, such as serum cholesterol, smoking habits, diabetes and hypertension, can be modified.

### Box 23.28

**Risk factors for coronary disease**

**Fixed**
- Age
- Male sex
- Positive family history
- Deletion polymorphism in the angiotensin-converting enzyme (ACE) gene (DD)

**Potentially changeable**
- Hyperlipidaemia
- Cigarette smoking
- Hypertension
- Diabetes mellitus
- Lack of exercise
- Blood coagulation factors – high fibrinogen, factor VII
- Elevated C-reactive protein
- Homocysteinaemia
- Obesity
- Gout
- Soft water
- Drugs, e.g. contraceptive pill, nucleoside analogues, COX-2 inhibitors, rosiglitazone
- Heavy alcohol consumption

Atherosclerotic disease manifest in one vascular bed is often advanced in other territories. Patients with intermittent claudication have a two- to fourfold increased risk of CAD, stroke or heart failure. Following initial myocardial infarction (MI), there is a three- to six-fold increase in the risk of heart failure and stroke. After stroke, the risk of heart failure and MI is increased twofold.

The disease can be asymptomatic in its most severe form, with 1 in 3 myocardial infarctions going unrecognized. Some 30–40% of individuals who present with an acute coronary syndrome have had no prior warning symptom to suggest the presence of underlying disease.

**Diagnosis**

**Cardiovascular risk assessment for primary and secondary prevention of cardiovascular disease**

*Primary prevention* can be defined as the prevention of the atherosclerotic disease process and *secondary prevention* as the treatment of the atherosclerotic disease process (i.e. treatment of the disease or its complications). The objective of prevention is to reduce the incidence of first or recurrent clinical events due to CAD, ischaemic stroke and peripheral artery disease.

In the UK, NICE guidelines recommend that primary care should use the QRISK®2 risk
assessment tool (see ‘Further reading’) to identify people who are likely to be at high risk (10-year risk of cardiovascular disease ≥10%).

**Lipids**

A full lipid profile should be obtained, including total cholesterol, high-density lipoprotein (HDL) cholesterol, non-HDL cholesterol, and triglyceride concentrations. Patients with a total cholesterol concentration >7.5 mmol/L and a family history of premature coronary heart disease may have *familial hypercholesterolaemia.*

**Lifestyle modifications**

Patients should eat a diet with a reduced fat intake (≤30% of total energy intake, saturated fats ≤7% total energy intake) and a dietary cholesterol intake <300 mg/day. Saturated fats should be replaced by monounsaturated and polyunsaturated fats (rapeseed and olive oils). People should aim to reduce their intake of sugar and food products that contain refined sugars (e.g. fructose), and to eat at least five portions of fruit and vegetables per day, two portions of fish per week, and four to five portions of unsalted nuts, seeds and legumes per week. The weekly exercise recommendations are ≥150 minutes of moderate-intensity aerobic activity or 75 minutes of vigorous-intensity aerobic activity. Weight/body mass index should be <25 kg/m² (see p. 208). Daily alcohol intake should not exceed 3–4 units for men and 2–3 units for women, and smoking should be discontinued. Blood pressure and diabetes should be managed according to NICE guidelines in the UK.

**Statin treatment**

Atorvastatin 20 mg is recommended for the primary prevention of cardiovascular disease in people with a 10-year risk of cardiovascular disease of ≥10%. In patients with established cardiovascular disease, NICE recommends atorvastatin 80 mg, unless there are potential drug interactions, a high risk of adverse effects, or a different patient preference.

**Angina**

Myocardial ischaemia in patients with stable CAD occurs when there is a mismatch between blood supply and metabolic demand. This results in regional wall motion abnormalities, ST-T changes on the 12-lead ECG and cardiac ischaemic pain – angina. Ischaemic metabolites, including adenosine, stimulate nerve endings and produce pain.

**Epidemiology**

The prevalence of angina increases with age in both sexes; in women it is 5–7% at 45–64 years as opposed to 10–12% at 65–84 years, while in men it is 4–7% at 45–64 years as opposed to 12–14% at 65–84 years. The annual mortality rate ranges from 1.2% to 2.4% and there is an annual incidence of cardiac death of 0.6–1.4%. Risk factors include hypertension,
hyperlipidaemia, diabetes mellitus, sedentary lifestyle, obesity, smoking and family history.

Diagnosis

The diagnosis of angina is largely based on the clinical history.

- **Classical angina** is characterized by chest pain that is described as ‘heavy’, ‘tight’ or ‘gripping’. Typically, the pain is central/retrosternal and may radiate to the jaw and/or arms. The pain tends to occur with exercise or emotional stress, or when walking up slopes in cold weather, and eases rapidly with rest.

- **Stable angina** can be classified according to the Canadian Cardiovascular Society guidelines ([Box 23.29](#)).

<table>
<thead>
<tr>
<th>Class</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Class I</td>
<td>No angina with ordinary activity. Angina with strenuous activity</td>
</tr>
<tr>
<td>Class II</td>
<td>Angina during ordinary activity, e.g. walking up hills, walking rapidly upstairs, with mild limitation of activities</td>
</tr>
<tr>
<td>Class III</td>
<td>Angina with low levels of activity, e.g. walking 50–100 metres on the flat, walking up one flight of stairs, with marked restriction of activities</td>
</tr>
<tr>
<td>Class IV</td>
<td>Angina at rest or with any level of exercise</td>
</tr>
</tbody>
</table>

- **Unstable angina** refers to angina of recent onset (<24 h) or deterioration in previous stable angina, with symptoms frequently occurring at rest: that is, **acute coronary syndrome**.

- **Refractory angina** refers to patients with severe coronary disease in whom revascularization is not possible and angina is not controlled by medical therapy.

- **Vasospastic or variant (Prinzmetal’s) angina** refers to angina that occurs without provocation, usually at rest, as a result of coronary artery spasm. It occurs more frequently in women. Characteristically, there is ST segment elevation on the ECG during the pain.

- **Microvascular angina** patients have exercise-induced angina but normal or unobstructed coronary arteries (on coronary angiography, CTCA). Intracoronary acetylcholine may cause coronary spasm. Whilst they have a good prognosis, they are often highly symptomatic and can be difficult to treat. In women with this syndrome, the myocardium shows an abnormal metabolic response to stress, consistent with the suggestion that the myocardial ischaemia results from abnormal dilator responses of the coronary microvasculature to stress.
Examination

There are usually no abnormal findings in angina, although occasionally a fourth heart sound may be heard. Signs to suggest anaemia, thyrotoxicosis or hyperlipidaemia (e.g. lipid arcus, xanthelasma, tendon xanthoma) should be sought. It is essential to exclude aortic stenosis (i.e. slow-rising carotid impulse and ejection systolic murmur radiating to the neck) as a possible cause of the angina. The blood pressure should be taken to identify coexistent hypertension.

Investigations

Patients with suspected angina should have initial investigations (Box 23.30). The diagnosis of stable angina can be made on clinical assessment alone or by clinical assessment combined with anatomical (cardiac catheterization or CTCA) or functional imaging (SPECT, stress echocardiography, stress MRI).

Box 23.30
Investigations in stable angina

Laboratory tests

- Full blood count
- Thyroid function tests
- Fasting glucose
- HbA\textsubscript{1c} (see p. 1251)
- Fasting lipid profile
- Glomerular filtration rate
- Troponin if unstable

12-lead ECG
• Exclude: ACS, pathological Q waves, left ventricular hypertrophy, left bundle branch block

**Echocardiography**
- Regional wall motion abnormalities
- Left ventricular ejection fraction
- Diastolic function
- Alternative causes of chest pain

**Ambulatory ECG**
- Paroxysmal arrhythmia
- Vasospastic angina

**Chest X-ray**
- Atypical presentation
- Pulmonary disease
- Heart failure
  ACS, acute coronary syndrome.

UK NICE guidance recommends assessing the likelihood of CAD in patients without known CAD who present with typical angina, atypical angina or non-anginal chest pain (*Box 23.31*).

• Patients with **non-anginal chest pain** (more likely if the pain is continuous, unrelated to exertion, exacerbated by respiration, or associated with dizziness, palpitations or difficulty in swallowing) should be considered for alternative diagnoses and investigated appropriately.

• Patients with **typical angina and a risk of disease of >90%** do not need further diagnostic investigation and should be managed for stable angina.

• Patients with **typical or atypical angina and a risk of disease of 61–90%** should have cardiac catheterization *if appropriate*.

• Patients with **typical or atypical angina and a risk of disease of 30–60%** should be referred for functional testing (SPECT, stress echocardiography, stress MRI).

• Patients with **typical or atypical angina and a risk of disease of 10–29%** should be referred for CTCA:
  – If the CT calcium score is 0, then angina is unlikely and other causes of chest pain should be sought (although young patients may have non-calcified plaque and CT angiography may be appropriate if they are symptomatic).
  – If the CT calcium score is 1–400, proceed to CT angiography.
  – If the CT calcium score is >400, invasive coronary angiography or functional imaging would be appropriate.
• If stable angina cannot be diagnosed in patients with known coronary artery disease, then functional assessment would be appropriate.

aData are percentage of people at each mid-decade age with significant coronary artery disease. Hi, high risk – diabetes, smoking, hyperlipidaemia (total cholesterol >6.47 mmol/L); Lo, low risk – none of the above. Men >70 years with atypical or typical angina: assume risk >90%. Women >70 years: assume risk 61–90% unless high risk and typical angina (risk >90%). Resting ECG abnormalities (ST-T changes, Q waves, left bundle branch block) increase likelihood.

NICE does *not* recommend exercise ECG as a diagnostic test.

**Management of stable angina**

Patients should be informed as to the nature of their condition and reassured that the prognosis is good (annual mortality <2%). Lifestyle management should be instigated, as for prevention of CAD. The stable angina algorithm in *Figure 23.64* should be used to guide initial patient management, while *Box 23.32* outlines pharmacological therapy.
**Algorithm for management of patients with stable angina.**

CABG, coronary artery bypass grafting; PCI, percutaneous coronary intervention. (From NICE Guideline CG126. Management of Stable Angina. July 2011 (guidance under review), with permission.)

Revascularization
Percutaneous coronary intervention

Percutaneous coronary intervention (PCI) is the process of dilating a coronary artery stenosis by introducing an inflatable balloon and metallic stent (Fig. 23.65) into the arterial circulation via the femoral, radial or brachial artery (Fig. 23.66); the radial artery is the best (see below). Fractional flow reserve (FFR) measurement can be used to assess the severity of a stenosis prior to PCI. An FFR of >0.80 treated medically (i.e. no stent) is associated with improved patient outcomes. Complications of PCI include bleeding, haematoma, dissection and pseudoaneurysm from the arterial puncture site, although use of the radial artery reduces these risks and is the standard technique in the UK. Serious complications include acute myocardial infarction (2%), stroke (0.4%) and death (1%). *Bare metal stents* (BMS) are associated with a 20–30% risk of coronary artery re-stenosis within 6–9 months of implantation. First-generation *drug-eluting stents* (DES) with *sirolimus* and *paclitaxel* reduced re-stenosis but suffered from late and very late stent thrombosis. Second-generation DES (with thinner struts and biodegradable or biocompatible polymers) demonstrated better safety and efficacy, and are recommended for most patients (BMS may be preferred in patients requiring anticoagulation and early surgery). Dual antiplatelet therapy (aspirin and a P2Y12 inhibitor, e.g. prasugrel) should continue for 6–12 months.
PCI versus medical therapy

The Courage Trial, published in April 2007, randomized patients with stable but significant CAD and inducible ischaemia to PCI with stenting or optimal medical therapy. The primary composite outcome (all-cause death and non-fatal MI) occurred in 18.3% of the PCI patients and 17.8% of the medically treated patients. This supports an initial strategy of optimal medical therapy in patients with stable angina symptoms, although revascularization should be considered in those who remain symptomatic despite taking two anti-anginals.

Coronary artery bypass grafting

With coronary artery bypass grafting (CABG), autologous veins or arteries are anastomosed to the ascending aorta and to the native coronary arteries distal to the area of stenosis (see Fig. 23.67). Improved graft survival can be obtained with in situ internal mammary and gastroepiploic arteries grafted on to the stenosed coronary artery, compared to vein grafts. Off-pump surgery is very comparable to standard CABG surgery in all outcomes, except that there are possibly more repeat vascularizations in the first year with off-pump surgery.
CABG versus medical therapy

Three major randomized controlled trials compared CABG with medical therapy: the Coronary Artery Surgery Study (CASS), the Veterans Administration (VA) Cooperative Study and the European Coronary Surgery Study (ECSS). A meta-analysis has been performed and demonstrated that, compared to medical therapy, CABG significantly improved angina symptoms and exercise capacity, and reduced the need for anti-anginal therapy. Operative mortality is well below 1% in patients with normal left ventricular function. Perioperative strokes occur in up to 2% of cases and more subtle neurological deficits are common. CABG is recommended for patients with triple-vessel CAD and impaired left ventricular function (LVEF 35–49%). Left stem disease with a stenosis of ≥50% is a class I indication for revascularization.

PCI versus CABG

Comparative trials between CABG and PCI all demonstrate a higher need for repeat revascularization with PCI than with CABG. In the ERACI II study, PCI patients had fewer major adverse events initially and better 18-month survival than the CABG group. The Stent or Surgery (SoS) Trial reported a 2-year incidence of death or Q wave MI of 9% in PCI versus 10% in CABG patients, but fewer deaths with CABG (2% versus 5%). The SYNTAX study compared PCI with DES against CABG in patients with three-vessel disease and/or left main stem disease. The primary end-point (all-cause death, stroke, MI or repeat revascularization) occurred in more PCI patients. Although the draft NICE guidance for stable angina recommends PCI for young patients with single or multivessel disease (and no diabetes), the European Society of Cardiology (ESC) has recommended PCI only in cases of single- or
double-vessel disease that does not involve the proximal left anterior descending artery.

**Patients with intractable angina**

Some patients remain symptomatic despite medication and are not suitable for (further) revascularization. These patients need a pain management programme.

**Acute Coronary Syndromes**

Acute coronary syndromes (ACS) include:

- *ST-elevation myocardial infarction (STEMI)*
- *non-ST-elevation myocardial infarction (NSTEMI)*
- *unstable angina (UA)*.

The difference between UA and NSTEMI is that, in the latter, there is occluding thrombus, which leads to myocardial necrosis and a rise in serum troponins or creatine kinase-MB (CK-MB). Myocardial infarction (MI) occurs when cardiac myocytes die due to myocardial ischaemia, and can be diagnosed on the basis of appropriate clinical history, 12-lead ECG and elevated biochemical markers – troponin I and T, and CK-MB. The definition of MI is shown in Box 23.33.

---

**Box 23.33**

**Definition of myocardial infarction**

**Criteria for acute myocardial infarction**

The term acute myocardial infarction (MI) should be used when there is evidence of myocardial necrosis in a clinical setting consistent with acute myocardial ischaemia. Under these conditions, any one of the following criteria meets the diagnosis for MI:

- Detection of a rise and/or fall of cardiac biomarker values (preferably cardiac troponin, cTn), with at least one value above the 99th percentile upper reference limit (URL) and with at least one of the following:
  - symptoms of ischaemia
  - new, or presumed new, and significant ST-segment–T wave (ST–T) changes or new left bundle branch block (LBBB)
  - development of pathological Q waves on the ECG
  - imaging evidence of new loss of viable myocardium or new regional wall motion abnormality; identification of an intracoronary thrombus by angiography or autopsy.
- Cardiac death with symptoms suggestive of myocardial ischaemia and presumed new ischaemic ECG changes or new LBBB, but death occurred before cardiac biomarkers were obtained, or before cardiac biomarker values would be increased.
- Percutaneous coronary intervention (PCI)-related MI is arbitrarily defined by elevation of
cTn values (>5 × 99th percentile URL) in patients with normal baseline values (≤99th percentile URL), or a rise of cTn values of >20% if the baseline values are elevated and are stable or falling. In addition, one of the following is required:

- symptoms suggestive of myocardial ischaemia
- new ischaemic ECG changes
- angiographic findings consistent with a procedural complication or
- imaging demonstration of new loss of viable myocardium or new regional wall motion abnormality.

• Stent thrombosis associated with MI when detected by coronary angiography or autopsy in the setting of myocardial ischaemia and with a rise and/or fall of cardiac biomarker values with at least one value above the 99th percentile URL.

• Coronary artery bypass grafting (CABG)-related MI is arbitrarily defined by elevation of cardiac biomarker values (>10 × 99th percentile URL) in patients with normal baseline cTn values (≤99th percentile URL). In addition, either:
  - new pathological Q waves or new LBBB
  - angiographically documented new graft or new native coronary artery occlusion or
  - imaging evidence of new loss of viable myocardium or new regional wall motion abnormality.

Criteria for prior myocardial infarction

Any one of the following criteria meets the diagnosis for prior MI:

• pathological Q waves with or without symptoms in the absence of non-ischaemic causes
• imaging evidence of a region of loss of viable myocardium that is thinned and fails to contract, in the absence of a non-ischaemic cause
• pathological findings of a prior MI.

(From Thygesen K, Alpert JS, Jaffe AS et al. Third universal definition of myocardial infarction. Eur Heart J 2012; 33:2251–2267.)

There are five types of MI:

• **Type 1** – spontaneous MI with ischaemia due to a primary coronary event, e.g. plaque erosion/rupture, fissuring or dissection

• **Type 2** – MI secondary to ischaemia due to increased oxygen demand or decreased supply, such as in coronary spasm, coronary embolism, anaemia, arrhythmias, hypertension or hypotension

• **Type 3** – diagnosis of MI in sudden cardiac death

• **Type 4a** – MI related to PCI

• **Type 4b** – MI related to stent thrombosis

• **Type 5** – MI related to CABG.
Pathophysiology

The mechanism that is common to all ACS is rupture or erosion of the fibrous cap of a coronary artery plaque. This leads to platelet aggregation and adhesion, localized thrombosis, vasoconstriction and distal thrombus embolization. The presence of a rich lipid pool within the plaque and a thin, fibrous cap is associated with an increased risk of rupture. Thrombus formation and the vasoconstriction produced by platelet release of serotonin and thromboxane $\text{A}_2$ result in myocardial ischaemia due to reduction of coronary blood flow.

Diagnosis and investigations

Clinical features

Patients with an ACS may complain of a new onset of chest pain, chest pain at rest, or a deterioration of pre-existing angina. However, some present with atypical features, including indigestion, pleuritic chest pain or dyspnoea. Physical examination can detect alternative diagnoses, such as aortic dissection, pulmonary embolism or peptic ulceration. In addition, it can also identify adverse clinical signs, such as hypotension, basal crackles, fourth heart sounds and cardiac murmurs.

Electrocardiogram

Although the 12-lead ECG may be normal in patients, ST depression and T-wave inversion are highly suggestive of an ACS, particularly if associated with anginal chest pain. The ECG should be repeated when the patient is in pain, and continuous ST-segment monitoring is recommended. With a STEMI, complete occlusion of a coronary vessel will result in a persistent ST-elevation or left bundle branch block pattern, although transient ST elevation is seen with coronary vasospasm or Prinzmetal’s angina.

Biochemical markers

- The cardiac troponin complex is made up of three distinct proteins (I, T and C), which are situated with tropomyosin on the thin actin filament that forms the skeleton of the cardiac myofilament. Troponin T attaches the complex to tropomyosin, troponin C binds calcium during excitation–contraction coupling, and troponin I inhibits the myosin binding site on the actin. ‘Highly sensitive’ troponin assays can now detect troponins in normal people. There are many different assays and results should be interpreted in the context of the clinical picture and the ECG. A negative predictive value of 99.4% has been shown for a serum troponin of <5 ng/L; this has been shown to be consistent across a wide group of patients. If the initial troponin assay is negative, then it should be repeated 4–12 h later. The troponin assay has prognostic information: that is, a high serum troponin level has an increased mortality risk in ACS (Box 23.34), and defines which patients may benefit from aggressive medical therapy and early coronary revascularization.

- **CK-MB** level was the standard marker for myocyte death used in ACS. However, the presence of low levels of CK-MB in the serum of normal individuals and in patients with significant skeletal muscle damage has limited its accuracy. It can, however, be used to determine re-infarction, as levels drop back to normal after 36–72 h.

- **Myoglobin** becomes elevated very early in MI but the test has poor specificity for ACS, as myoglobin is present in skeletal muscle.

**NSTEMI and unstable angina**

**Risk stratification**

*Initial risk* in ACS is determined by complications of the acute thrombosis. This may produce recurrent myocardial ischaemia, marked ST depression, dynamic ST changes and a raised troponin level, and may be demonstrated with coronary angiography.

*Long-term risks* are defined by clinical risk factors: age, prior MI or bypass surgery, diabetes or heart failure. Biological markers, such as CRP, fibrinogen, BNP, modified albumin and serum creatinine, can be used to further stratify patient risk. Left ventricular dysfunction and the presence of left main or triple vessel disease significantly increase the future cardiovascular risk. Both the Thrombolysis in Myocardial Infarction (TIMI) score (*Box 23.35*) and the Global Registry of Acute Coronary Events (GRACE) prediction score can be used in patients with ACS to define risk. The GRACE score is based on age, heart rate, systolic blood pressure, serum creatinine and the Killip score (*Boxes 23.36* and 23.37; see also p. 1004).

Monitor renal function

**High-risk patients** for progression to MI or death require urgent coronary angiography (<24 h). This includes those individuals with persistent or recurrent angina with ST changes ≥2 mm or deep negative T-wave changes, clinical signs of heart failure or haemodynamic instability, or life-threatening arrhythmias (ventricular fibrillation, ventricular tachycardia).

Patients with **intermediate or high-risk** TIMI or GRACE scores should be referred for coronary angiography within <72 hours.

**Low-risk patients** can be managed with oral aspirin, ADP-receptor antagonists, beta-blockers and nitrates. These include patients with no recurrence of chest pain during observation, no signs of heart failure, normal ECG or minor T-wave changes on arrival and at

*[270x270] ABG, arterial blood gases; ACE, angiotensin-converting enzyme; APTT, activated partial thromboplastin time; BP, blood pressure; CABG, coronary artery bypass graft; COPD, chronic obstructive pulmonary disease; i.v., intravenous; PCI, percutaneous coronary intervention; s.c., subcutaneous.*
6–12 hours, and normal troponins on the initial assays and at 6–12 hours after admission. An exercise test should be performed; a negative result has a good prognosis but an early positive test should direct the patient to an invasive strategy. If the patient is unable to exercise satisfactorily, or if the baseline ECG is abnormal (e.g. left ventricular hypertrophy or left bundle branch block), then dobutamine stress echocardiography or myocardial perfusion scintigraphy is recommended. These tests are often used as the first-line investigation.

**Antiplatelet drugs**

The platelet is a key part of the thrombosis cascade involved in ACS. Rupture of the atheromatous plaque exposes the circulating platelets to adenosine diphosphate (ADP), thromboxane $A_2$ (TxA$_2$), adrenaline (epinephrine), thrombin and collagen tissue factor. This causes platelet activation, with thrombin as an especially potent stimulant of such activity. Platelet activation stimulates the expression of glycoprotein (GP) IIb/IIIa receptors on the platelet surface. These receptors bridge fibrinogen between adjacent platelets, causing platelet aggregates (see Fig. 16.39). ACS patients should be treated with dual antiplatelet agents: *aspirin 300 mg* loading dose then 75 mg daily and an ADP-receptor antagonist (*clopidogrel 300–600 mg* loading then 75 mg daily or *prasugrel 60 mg* loading then 10 mg daily or *ticagrelor 180 mg* loading then 90 mg twice daily).

**Antithrombin drugs**

An antithrombin should be added to dual antiplatelets in patients with ACS. *Unfractionated heparin (UFH)* requires frequent monitoring; the low-molecular-weight heparin *enoxaparin* appears to be superior and can be given subcutaneously twice daily. *Bivalirudin* is a direct thrombin inhibitor that reversibly binds to thrombin and inhibits clot-bound thrombin. In the ACUITY trial, bivalirudin appeared as effective as heparin plus GPIIb/IIIa inhibitors in reducing ischaemic events in patients pre-treated with a thienopyridine and undergoing diagnostic angiography or percutaneous intervention, but with less bleeding. *Fondaparinux* is a synthetic pentasaccharide that selectively binds to antithrombin; this inactivates factor Xa, resulting in a strong inhibition of thrombin generation and clot formation. It does not inactivate thrombin and has no effect on platelets.

**Activated glycoprotein (GP) IIb/IIIa receptors** on platelets bind to fibrinogen, initiating platelet aggregation. Receptor antagonists have been developed that are powerful inhibitors of platelet aggregation. *Abciximab* is a monoclonal antibody that binds tightly and has a long half-life. *Eptifibatide* is a cyclic peptide that selectively inhibits GPIIb/IIIa receptors, but has a short half-life and wears off in 2–4 hours. *Tirofiban* is a small non-peptide that rapidly blocks the GPIIb/IIIa receptors and is reversible in 4–6 hours. In the GUSTO-IV ACS study of 7800 patients, abciximab was administered but coronary intervention discouraged. At 30 days, 8.2% of abciximab patients and 8.0% of placebo patients had reached the composite end-point of death or MI. In the PRISM study of 3232 patients with angina, tirofiban reduced the 30-day death or MI rate from 7.1% with placebo to 5.8%. Troponin-positive patients with diabetes scheduled to have coronary intervention benefit most from GPIIb/IIIa receptor antagonists.
However, GPIIb/IIIa receptor antagonists may provide no extra benefit in patients who have already received clopidogrel and aspirin.

**Anti-ischaemia agents**

In patients with no contraindications (asthma, AV block, acute pulmonary oedema), beta-blockers are administered orally, to reduce myocardial ischaemia by blocking circulating catecholamines. This will lower the heart rate and blood pressure, reducing myocardial oxygen consumption. The dose can be titrated to produce a resting heart rate of 50–60 b.p.m. In patients with on-going angina, nitrates should be given either sublingually or intravenously. They effectively reduce preload and produce coronary vasodilatation. However, tolerance can become a problem and patients should be weaned off intravenous administration if symptoms resolve.

**Plaque stabilization/remodelling**

HMG-CoA reductase inhibitor drugs (statins) and ACE inhibitors are routinely administered to patients with ACS. These agents may produce plaque stabilization, improve vascular and myocardial remodelling, and reduce future cardiovascular events. Starting the drugs whilst the patient is still in hospital increases the likelihood of these individuals receiving secondary drug therapy.

**Coronary intervention**

Coronary revascularization is recommended in high-risk patients with ACS. Coronary stenting may stabilize the disrupted coronary plaque. The mortality rates with CABG are greater in the high-risk group patients, particularly those with a recent MI. Single-vessel lesions are usually treated with PCI, unless the anatomy is unfavourable. Conversely, patients with left main stem or triple-vessel disease with impaired left ventricular function are best managed with surgery.

**ST elevation myocardial infarction (STEMI)**

Myocardial infarction occurs when cardiac myocytes die due to prolonged myocardial ischaemia. The diagnosis can be made in patients with an appropriate clinical history together with findings from repeated 12-lead ECGs and elevated biochemical markers – troponin I and T, and CK-MB.

**Pathophysiology**

Rupture or erosion of a vulnerable coronary artery plaque can produce prolonged occlusion of a coronary artery, leading to myocardial necrosis within 15–30 minutes. The sub-endocardial myocardium is initially affected but, with continued ischaemia, the infarct zone extends through to the sub-epicardial myocardium, producing a transmural Q wave MI. Early reperfusion may salvage regions of the myocardium, reducing future mortality and morbidity. The in-hospital mortality rate is between 6% and 14%. Several risk factors can be identified.
that predict death rate at 30 days (TIMI STEMI score; \textit{Box 23.39}).

\caption{TIMI risk score in ST elevation myocardial infarction (STEMI)}
\end{table}

\textbf{Clinical features}

Any patient presenting with severe chest pain lasting more than 20 minutes may be suffering from an MI. The pain does not usually respond to sublingual glyceryl trinitrate, and opiate analgesia is required. The pain may radiate to the left arm, neck or jaw. However, in some patients, particularly elderly or diabetic ones, the symptoms may be atypical and include dyspnoea, fatigue, pre-syncope or syncope. Autonomic symptoms are common and on examination the patient is pale and clammy, with marked sweating. In addition, the pulse is thready with significant hypotension, bradycardia or tachycardia.
Electrocardiography

An ECG in patients with chest pain should be performed on admission to the accident and emergency department. The baseline ECG is rarely normal, but if it is, it should be repeated every 15 minutes, while the patient remains in pain. Continuous cardiac monitoring is required because of the high likelihood of significant cardiac arrhythmias. ECG changes (Box 23.40) are usually confined to the ECG leads that ‘face’ the infarction. The presence of new ST elevation (due to opening of the K⁺ channels) of ≥0.2 mV at the J-point in leads V₁–V₃, and ≥0.1 mV in other leads, suggests anterior MI (Fig. 23.68). An inferior wall MI is diagnosed when ST elevation is seen in leads II, III and AVF (Fig. 23.69). Lateral MI produces changes in leads I, AVL and V₅/V₆. In patients with a posterior MI, there may be ST depression in leads V₁–V₃ with a dominant R wave, and ST elevation in lead V₅/V₆. New, or presumed new, left bundle branch block is compatible with coronary artery occlusion requiring urgent reperfusion therapy. The evolution of the ECG during the course of STEMI is illustrated in Figure 23.70.

FIGURE 23.68 An acute anterolateral myocardial infarction, shown by a 12-lead ECG. Note the ST segment elevation in leads I, AVL and V₂–V₆. The T wave is inverted in leads I, AVL and V₃–V₆. Pathological Q waves are seen in leads V₂–V₆.

FIGURE 23.69 An acute inferior wall myocardial infarction, shown by a 12-lead ECG. Note the raised ST segment and Q waves in the inferior leads (II, III and AVF). The additional T-wave inversion in V₄ and V₅ probably represents anterior wall ischaemia.
Electrocardiographic evolution of myocardial infarction (STEMI). After the first few minutes, the T waves become tall, pointed and upright, and there is ST segment elevation. After the first few hours, the T waves invert, the R-wave voltage is decreased and Q waves develop. After a few days, the ST segment returns to normal. After weeks or months, the T wave may return to upright but the Q wave remains.

**Investigations**

Blood samples should be taken for cardiac troponin I or T levels, although treatment should not be deferred until the results are available. Full blood count, serum electrolytes, glucose and lipid profile should be obtained. Transthoracic echocardiography (TTE) may be helpful to confirm an MI, as wall-motion abnormalities are detectable early in STEMI. TTE may detect alternative diagnoses, such as aortic dissection, pericarditis or pulmonary embolism.

**Management**

**Early medical management**

Initial assessment involves rapid triage for chest pain (*Note: time is muscle*) and referral for reperfusion therapy (primary PCI or thrombolysis). Initial medical therapy includes oxygen,
intravenous opioids (morphine) and aspirin (300 mg) (see Box 23.38).

**Percutaneous coronary intervention**

PCI performed within 90 minutes is the preferred reperfusion therapy in interventional cardiology centres that have the expertise available. Current recommendations are to treat the target vessel only, unless the patient is in cardiogenic shock or there is ongoing ischaemia. Data from the RIVAL and RIFLE STEACS studies demonstrate that radial PCI reduces bleeding complications at the arterial puncture site. The TAPAS study showed some benefit from thrombus aspiration, although this did not reduce infarct size when combined with intracoronary abciximab (INFUSE-AMI study). Patients undergoing primary PCI should be given dual antiplatelet therapy with aspirin and an ADP-receptor blocker, such as prasugrel or ticagrelor. Anticoagulant options include unfractionated heparin, enoxaparin or bivalirudin. The routine use of GP IIb/IIIa inhibitors is no longer recommended.

**Fibrinolysis**

Fibrinolytic agents (see pp. 566–567) enhance the breakdown of occlusive thromboses by the activation of plasminogen to form plasmin. Fibrinolysis is still used if PCI is unavailable. A meta-analysis of fibrinolytics (FTT), fibrinolysis within 6 hours of STEMI or left bundle branch block MI, prevented 30 deaths in every 1000 patients treated. Between 7 and 12 hours, 20 in every 1000 deaths were prevented. After 12 hours, the benefits are limited, and there is evidence to suggest less benefit for older patients, possibly because of the increased risk of strokes. Prompt reperfusion therapy (door to needle time <30 min) will reduce the death rate following MI. Double-bolus reteplase (r-PA) and single-bolus tenecteplase (TNK-t-PA) facilitate rapid administration of fibrinolytic therapy and can be used for pre-hospital thrombolysis. For patients who fail to reperfuse by 60–90 minutes, as demonstrated by 50% resolution of the ST-segment elevation, re-thrombolysis or referral for rescue coronary angioplasty is recommended. The contraindications to thrombolysis are provided in Box 23.41. Aspirin and clopidogrel are recommended in patients undergoing fibrinolysis. Anticoagulant options include unfractionated heparin, enoxaparin or fondaparinux.

### Box 23.41

**Contraindications to thrombolysis**

**Absolute contraindications**

- Haemorrhagic stroke or stroke of unknown origin at any time
- Ischaemic stroke in preceding 3 months
- Central nervous system damage/neoplasm/vascular malformation
- Recent major trauma/surgery/head injury (within preceding 3 weeks)
- Gastrointestinal bleeding within the last month
• Known bleeding disorder
• Aortic dissection

**Relative contraindications**

• Ischaemic stroke in preceding 3 months
• Oral anticoagulant therapy
• Pregnancy or within 1 week postpartum
• Non-compressible vascular punctures
• Traumatic resuscitation
• Refractory hypertension (systolic blood pressure >180 mmHg)
• Advanced liver disease
• Internal bleeding, e.g. active peptic ulcer
• Dementia

**Coronary artery bypass surgery**

Cardiac surgery is usually reserved for the complications of MI, such as ventricular septal defect or mitral regurgitation.

**Complications of myocardial infarction**

**Heart failure**

Cardiac failure post STEMI is a poor prognostic feature that necessitates medical and invasive therapy to reduce the death rate. The Killip classification is used to assess patients with heart failure post-MI:

• **Killip I** – no crackles and no third heart sound
• **Killip II** – crackles in <50% of the lung fields or a third heart sound
• **Killip III** – crackles in >50% of the lung fields
• **Killip IV** – cardiogenic shock.

Mild heart failure may respond to intravenous furosemide 40–80 mg i.v., with glyceryl trinitrate administration if the blood pressure is satisfactory. Oxygen is required, with regular oxygen monitoring. ACE inhibitors can be given in <24–48 hours if the blood pressure is satisfactory. Patients with severe heart failure may require Swan–Ganz catheterization to determine the pulmonary wedge pressure. Intravenous inotropes, such as dopamine or dobutamine, are used in patients with severe heart failure. If the patient is in cardiogenic shock, then revascularization with or without intra-aortic balloon pump insertion may be required.

**Myocardial rupture and aneurysmal dilatation**
Rupture of the free wall of the left ventricle is usually an early, catastrophic and fatal event. The patient will have a haemodynamic collapse, then an electromechanical cardiac arrest. A sub-acute rupture may allow for pericardiocentesis followed by surgical repair of the rupture. Aneurysmal dilatation of the infarcted myocardium (Fig. 23.71) is a late complication that may require surgical repair.

**FIGURE 23.71** Two-dimensional echocardiogram (apical four-chamber view) showing a very large apical left ventricular aneurysm (arrowed). The relatively static blood in the aneurysm produces a swirling ‘smoke’ effect. This aneurysm was successfully resected surgically. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

**Ventricular septal defect**

A ventricular septal defect (VSD) may occur in 1–2.0% of patients with STEMI, and may be associated with delayed or failed fibrinolysis. However, mortality is very high and there is a 12-month inoperative mortality of 92%. An intra-aortic balloon pump (IABP) and coronary angiography may allow patient optimization prior to surgery. A post-infarct VSD is demonstrated in Figure 23.72.
Mitral regurgitation

Severe mitral regurgitation can occur early in the course of STEMI. Three mechanisms may be responsible for the mitral regurgitation, and a transoesophageal echocardiogram (TOE) may be necessary to confirm the aetiology:

- severe left ventricular dysfunction and dilatation, causing annular dilatation of the valve and subsequent regurgitation
- myocardial infarction of the inferior wall, producing dysfunction of the papillary muscle that may respond to coronary intervention
- myocardial infarction of the papillary muscles, producing sudden severe pulmonary oedema and cardiogenic shock (IABP, coronary angiography and early surgery may improve patient survival).

Cardiac arrhythmias

Ventricular tachycardia and ventricular fibrillation are common in STEMI, particularly with reperfusion. Cardiac arrest requires defibrillation. Ventricular tachycardia should be treated with intravenous beta-blockers (metoprolol 5 mg, esmolol 50–200 µg/kg per min), lidocaine 50–100 mg, or amiodarone 900–1200 mg/24 h. If the patient is hypotensive, synchronized cardioversion may be performed. Ensure that the serum potassium is >4.5 mmol/L. Refractory ventricular tachycardia or fibrillation may respond to magnesium 8 mmol/L over 15 min i.v.

Atrial fibrillation occurs frequently, and treatment with beta-blockers and digoxin may be required. Cardioversion is possible but relapse is common.

Bradyarrhythmias can be treated initially with i.v. atropine 0.5 mg repeated up to six times in 4 h. Temporary transcutaneous or transvenous pacemaker insertion may be necessary in patients with symptomatic heart block.

Conduction disturbances
These are common following MI. AV block may occur during acute MI, especially of the inferior wall (the right coronary artery usually supplies the sinoatrial and atrioventricular nodes). Heart block, when associated with haemodynamic compromise, may need treatment with atropine or a temporary pacemaker. Such blocks may last for only a few minutes, but frequently continue for several days. Permanent pacing may need to be considered if heart block persists for over 2 weeks.

**Post-MI pericarditis and Dressler syndrome**

See the section entitled ‘Pericardial disease’ (pp. 1042–1046).

**Post-ACS lifestyle modification**

After recovery from an ACS, patients should be encouraged to participate in a cardiac rehabilitation programme that provides education and information appropriate to their requirements. An exercise programme forms part of the rehabilitation.

- Dietary recommendations include calorie control of obesity, increased fruit and vegetables, reduced trans and saturated fats, and reduced salt intake in patients with hypertension.
- Alcohol consumption should be maintained within safe limits (≤21 units/week for men or <14 units for women) and avoid binge drinking.
- Patients should be physically active (30 min of moderate aerobic exercise 5 times per week).
- Patients should stop smoking (nicotine patches and buprenorphine are safe).
- A healthy weight (body mass index (BMI) <25 kg/m²) should be maintained.
- Blood pressure should be reduced to a systolic measurement <140 mmHg.
- Patients with diabetes should be treated to maintain HbA₁c <7% (53 mmol/mol).

**Post-ACS drug therapy and assessment**

Extensive clinical trial evidence has been gathered in post-MI patients, demonstrating that a range of pharmaceuticals are advantageous in reducing mortality over the following years. Therefore, after MI, most patients should be taking most of the following medications:

- aspirin 75 mg daily
- an ADP-receptor blocker
- an oral beta-blocker to maintain heart rate <60 b.p.m.
- ACE inhibitors or angiotensin receptor blockers, particularly if LVEF is <40%
- high-intensity statins with target LDL cholesterol <1.8 mmol/L
- aldosterone antagonist, if there is clinical evidence of heart failure and LVEF is <40%; the serum creatinine is <221 μmol/L (men) or <177 μmol/L (women); and the serum potassium is <5.0 mEq/L.

Valvular Heart Disease

Mitral Valve

The mitral valve consists of the fibrous annulus, anterior and posterior leaflets, chordae tendineae and the papillary muscles (Fig. 23.73).
Mitral stenosis

The most common cause of mitral stenosis is rheumatic heart disease secondary to previous rheumatic fever due to infection with group A β-haemolytic streptococcus; in the developing world, this affects nearly 20 million people. The condition is more common in women than men. Inflammation leads to commissural fusion and a reduction in mitral valve orifice area, causing the characteristic doming pattern seen on echocardiography. Over many years, the condition progresses to valve thickening, cusp fusion, calcium deposition, a severely narrowed (stenotic) valve orifice and progressive immobility of the valve cusps.

Other causes of mitral stenosis include:

- congenital mitral stenosis
- Lutembacher syndrome (the combination of acquired mitral stenosis and an atrial septal defect)
- mitral annular calcification, rarely; this may lead to mitral stenosis if extensive, particularly in elderly patients and those with end-stage renal disease
- carcinoid tumours metastasizing to the lung, or primary bronchial carcinoid.

Pathophysiology

When the normal valve orifice area of 4–6 cm² is reduced to <1 cm², severe mitral stenosis is present. In order for sufficient cardiac output to be maintained, the left atrial pressure increases and left atrial hypertrophy and dilatation occur. Consequently, pulmonary venous, pulmonary arterial and right heart pressures also increase. The increase in pulmonary capillary pressure is followed by the development of pulmonary oedema, particularly when the rhythm deteriorates to atrial fibrillation with tachycardia and loss of coordinated atrial contraction. This is partially prevented by alveolar and capillary thickening and pulmonary arterial
vasoconstriction (reactive pulmonary hypertension). Pulmonary hypertension leads to right ventricular hypertrophy, dilatation and failure with subsequent tricuspid regurgitation.

### Clinical features

#### Symptoms

Usually, there are no symptoms until the valve orifice is moderately stenosed (area <2 cm²). In Europe, this does not usually occur until several decades after the first attack of rheumatic fever, but in developing countries, children of 10–20 years of age may have severe mitral stenosis.

Progressively severe dyspnoea develops from the elevation in left atrial pressure, vascular congestion and interstitial pulmonary oedema. A cough productive of blood-tinged, frothy sputum or frank haemoptysis may occur. The development of pulmonary hypertension eventually leads to right heart failure and its symptoms of weakness, fatigue, and abdominal or lower limb swelling.

The large left atrium predisposes to atrial fibrillation, giving rise to symptoms such as palpitations. Atrial fibrillation may result in systemic emboli, most commonly to the cerebral vessels, producing neurological sequelae, but mesenteric, renal and peripheral emboli are also seen.

#### Signs

See the ‘Clinical memo’ in Figure 23.74.

![Figure 23.74](image)

**FIGURE 23.74** Features associated with mitral regurgitation and mitral stenosis. A2, aortic component of the second heart sound; MDM, mid-diastolic murmur; OS, opening snap; P2, pulmonary component of the second heart sound (loud with pulmonary hypertension); PSA, pre-systolic accentuation; PSM, pansystolic murmur; RV, right ventricle; S1, first heart sound; S2, second heart sound; S3, third heart sound.
Face
Severe mitral stenosis with pulmonary hypertension is associated with the so-called mitral facies or malar flush. This is a bilateral, cyanotic or dusky pink discoloration over the upper cheeks, which is due to arteriovenous anastomoses and vascular stasis.

Pulse
Mitral stenosis may be associated with a small-volume pulse, which is usually regular early on in the disease process, when most patients are in sinus rhythm. However, as the severity of the disease progresses, many patients develop atrial fibrillation, resulting in an ‘irregularly irregular’ pulse. The development of atrial fibrillation in these patients often causes a dramatic clinical deterioration.

Jugular veins
If right heart failure develops, there is obvious distension of the jugular veins. If pulmonary hypertension or tricuspid stenosis is present, the ‘a’-wave will be prominent, provided that atrial fibrillation has not supervened.

Palpation
There is a tapping impulse felt parasternally on the left side. This is the result of a palpable first heart sound combined with left ventricular backward displacement produced by an enlarging right ventricle. A sustained parasternal impulse due to right ventricular hypertrophy may also be felt.

Auscultation
Auscultation (Fig. 23.74) reveals a loud first heart sound if the mitral valve is pliable, but this will not occur in calcific mitral stenosis. As the valve suddenly opens with the force of the increased left atrial pressure, an ‘opening snap’ will be heard. This is followed by a low-pitched, ‘rumbling’, mid-diastolic murmur, best heard with the bell of the stethoscope held lightly at the apex and the patient lying on the left side in expiration. If the patient is in sinus rhythm, the murmur becomes louder at the end of diastole as a result of atrial contraction (pre-systolic accentuation).

The severity of mitral stenosis is judged clinically on the basis of several criteria:
• The presence of pulmonary hypertension implies that mitral stenosis is severe. Pulmonary hypertension is recognized by a right ventricular heave, a loud pulmonary component to the second heart sound and, eventually, signs of right-sided heart failure, such as oedema and hepatomegaly. Pulmonary hypertension results in pulmonary valvular regurgitation, which causes an early diastolic murmur in the pulmonary area, known as a Graham Steell murmur.
• The time between the opening snap and second heart sound (S2–OS interval) shortens with more severe degrees of mitral stenosis.
• The length of the mid-diastolic murmur is proportional to the severity.
• As the valve cusps become immobile, the loud first heart sound softens and the opening snap disappears. (For recordings of heart sounds, see online at Student Consult.) When pulmonary hypertension occurs, the pulmonary component of the second sound is increased in intensity and the mitral diastolic murmur may become quieter because of the reduction of cardiac output.

Investigations

Chest X-ray
The chest X-ray may show left atrial enlargement with straightening of the left heart border and a ‘double shadow’ on the border of the right and left atria (see Fig. 23.14). Late in the course of the disease, a calcified mitral valve may be seen on a penetrated or lateral view. Pulmonary vascular congestion and enlargement of the main pulmonary arteries may also be apparent in severe disease.

Electrocardiogram
In sinus rhythm, the ECG shows a bifid P wave owing to delayed left atrial activation (Fig. 23.75). However, atrial fibrillation is frequently present. As the disease progresses, the ECG features of right ventricular hypertrophy (right axis deviation and, perhaps, tall R waves in lead V₁) may develop (Fig. 23.76).

![FIGURE 23.75](image-url) A bifid P wave, as seen on the ECG in mitral stenosis (P mitrale). Other P wave abnormalities are also shown for comparison.
Echocardiogram

*Transthoracic echocardiography* is able to determine left atrial size and the degree of thickening, calcification and mobility of the mitral leaflets, as well as the degree of commissural fusion (*Fig. 23.77*). The severity of the mitral stenosis (*Box 23.42*) can be defined by mitral valve area on two-dimensional echocardiography, with continuous wave (CW) Doppler to measure the pressure half-time (the time taken for the pressure to halve from the peak value) and mean pressure drop across the valve. CW Doppler may also be used to estimate pulmonary artery pressure through measurement of the degree of tricuspid regurgitation.
FIGURE 23.77  Echocardiograms in rheumatic mitral valve disease. A. A two-dimensional long-axis view, showing an enlarged left atrium and the 'hooked' appearance of the mitral valve leaflets, resulting from commissural fusion. B. A magnified short-axis view, showing the mitral valve orifice as seen from the left atrium. The orifice area can be planimetered to assess the severity; in this case, it is 1.5 cm², indicating moderately severe disease. C. A continuous-wave (CW) Doppler recording, showing the slow rate of decay of flow velocity from the left atrium to the left ventricle during diastole. It is also possible to derive the valve orifice area from the velocity decay rate. AMVL, anterior mitral valve leaflet; LA, left atrium; LV, left ventricle; PMVL, posterior mitral valve leaflet.

(Source: British Society of Echocardiography.)

Transoesophageal echocardiography (TOE) is performed to detect the presence of left atrial thrombus (see p. 951) or to carry out a detailed assessment prior to consideration of surgical or percutaneous intervention. The Wilkins score can be used to determine whether the valve is suitable for percutaneous valvotomy. The Wilkins score is an echocardiographic assessment of the mitral valve (leaflet mobility, valve thickening, valve calcification and sub-valvular apparatus) and is used to determine suitability for percutaneous mitral valvuloplasty.

Cardiac magnetic resonance

CMR (see pp. 953–955) can show mitral valve anatomy accurately, although it is rarely used in mitral stenosis.

Cardiac catheterization

This is seldom required and is only used if coexisting cardiac problems (e.g. mitral regurgitation or CAD) are suspected. Right heart catheterization may be needed to determine pulmonary artery pressure in patients referred for valve intervention.

Management

Mild mitral stenosis may need no treatment other than prompt therapy for attacks of bronchitis. Infective endocarditis in pure mitral stenosis is uncommon. Early symptoms of mitral stenosis, such as mild dyspnoea, can usually be treated with low doses of diuretics. The onset of atrial fibrillation requires treatment with beta-blockers or DC cardioversion and anticoagulation to prevent atrial thrombus and systemic embolization. If pulmonary hypertension develops or the symptoms of pulmonary congestion persist despite therapy, surgical relief of the mitral stenosis is advised. There are four operative measures.

Trans-septal balloon valvotomy

A catheter is introduced into the right atrium via the femoral vein under local anaesthesia in the
cardiac catheter laboratory. The interatrial septum is then punctured and the catheter advanced into the left atrium and across the mitral valve. A balloon is passed over the catheter to lie across the valve, and then inflated briefly to split the valve commissures. As with other valvotomy techniques, significant regurgitation may result, necessitating valve replacement (see below). This procedure is ideal for patients with pliable valves in whom there is little involvement of the sub-valvular apparatus and minimal mitral regurgitation. Contraindications include heavy calcification or more than mild mitral regurgitation and thrombus in the left atrium. TOE must be performed prior to this technique in order to exclude left atrial thrombus.

**Closed valvotomy**

This operation is advised for patients with mobile, non-calcified and non-regurgitant mitral valves. The fused cusps are forced apart by a dilator introduced through the apex of the left ventricle and guided into position by the surgeon's finger inserted via the left atrial appendage. Cardiopulmonary bypass is not needed for this operation. Closed valvotomy may produce a good result for 10 years or more. The valve cusps often re-fuse and, eventually, another operation may be necessary.

**Open valvotomy**

This operation is often preferred to closed valvotomy. The cusps are carefully dissected apart under direct vision. Cardiopulmonary bypass is required. Open dissection reduces the likelihood of causing traumatic mitral regurgitation.

**Mitral valve replacement**

Replacement of the mitral valve is necessary if:

- mitral regurgitation is also present
- there is a badly diseased or calcified stenotic valve that cannot be re-opened without producing significant regurgitation
- there is moderate or severe mitral stenosis and thrombus in the left atrium despite anticoagulation.

Artificial valves (see pp. 1016–1017) may work successfully for >20 years. Anticoagulants are generally necessary to prevent the formation of thrombus, which might obstruct the valve or embolize.

**Mitral regurgitation**

Mitral regurgitation can occur due to abnormalities of the valve leaflets, the annulus, the chordae tendineae or papillary muscles, or the left ventricle. The most frequent causes of mitral regurgitation are degenerative (myxomatous) disease, ischaemic heart disease, rheumatic heart disease and infectious endocarditis. Mitral regurgitation is also seen in diseases of the myocardium (dilated and hypertrophic cardiomyopathy), rheumatic autoimmune
diseases (e.g. systemic lupus erythematosus), collagen diseases (e.g. Marfan and Ehlers–Danlos syndromes) and disorders caused by drugs, including centrally acting appetite suppressants (fenfluramine) and dopamine agonists (cabergoline).

**Pathophysiology**

Regurgitation into the left atrium produces left atrial dilatation but little increase in left atrial pressure if the regurgitation is longstanding, as the regurgitant flow is accommodated by the large left atrium. With acute mitral regurgitation, the normal compliance of the left atrium does not allow much dilatation and the left atrial pressure rises. Thus, in acute mitral regurgitation, the left atrial v-wave is greatly increased and pulmonary venous pressure rises, leading to pulmonary oedema. Since a proportion of the stroke volume is regurgitated, the stroke volume increases to maintain the forward cardiac output and the left ventricle therefore enlarges.

The Carpentier classification (Fig. 23.78) uses mitral leaflet motion to divide patients into different classes according to the mechanism of regurgitation, which can be useful when considering surgical intervention.

---

**Clinical features**

**Symptoms**

Mitral regurgitation can be present for many years and the cardiac dimensions greatly increased before any symptoms occur. The increased stroke volume is sensed as a ‘palpitation’. *Dyspnoea* and *orthopnoea* develop because of pulmonary venous hypertension that arises as a direct result of the mitral regurgitation and secondarily as a consequence of left ventricular failure. *Fatigue* and *lethargy* develop because of the reduced cardiac output. In the late stages of the disease, the symptoms of *right heart failure* also occur and eventually lead to congestive cardiac failure. *Cardiac cachexia* may develop. Thromboembolism is less common than in mitral stenosis but *subacute infective endocarditis* is much more common.
Signs

See the ‘Clinical memo’ in Figure 23.74.

The physical signs of uncomplicated mitral regurgitation are:

- **Laterally displaced (forceful) diffuse apex beat** and a **systolic thrill** (if severe).
- **Soft first heart sound**, owing to the incomplete apposition of the valve cusps and their partial closure by the time ventricular systole begins.
- **Pansystolic murmur**, due to the occurrence of regurgitation throughout the whole of systole, being loudest at the apex but radiating widely over the precordium and into the axilla.
- **Mid-systolic click**, which may be present with a floppy mitral valve (see below); it is produced by the sudden prolapse of the valve and the tensing of the chordae tendineae that occurs during systole. This may be followed by a late systolic murmur owing to some regurgitation.
- **Prominent third heart sound** (S3), owing to the sudden rush of blood back into the dilated left ventricle in early diastole (sometimes a short mid-diastolic flow murmur may follow the third heart sound).

The signs related to atrial fibrillation, pulmonary hypertension, and left and right heart failure develop later in the disease. The onset of atrial fibrillation has a much less dramatic effect on symptoms than in mitral stenosis.

Investigations

Chest X-ray

The chest X-ray may show left atrial and left ventricular enlargement. There is an increase in the cardiothoracic ratio and valve calcification may be present.

Electrocardiogram

The ECG shows the features of left atrial delay (bifid P waves) and left ventricular hypertrophy (**Fig. 23.79**), as manifested by tall R waves in the left lateral leads (e.g. leads I and V₆) and deep S waves in the right-sided precordial leads (e.g. leads V₁ and V₂). (Note that S in V₁ plus R in V₅ or R in V₆ >35 mm indicates left ventricular hypertrophy.) Left ventricular hypertrophy occurs in about 50% of patients with mitral regurgitation. Atrial fibrillation may be present.
**Echocardiogram**

The echocardiogram *(Fig. 23.80)* shows a dilated left atrium and left ventricle. There may be specific features of chordal or papillary muscle rupture. The severity of regurgitation can be assessed with the use of colour Doppler, looking at the narrowest jet width (vena contracta) and area, and calculating the regurgitant fraction, volume or orifice area. Useful information regarding the severity of the condition can be obtained indirectly by observing the dynamics of ventricular function. *Transoesophageal echocardiography* can be helpful to identify structural valve abnormalities before surgery *(Fig. 23.80)* and intraoperative TOE can aid assessment of the efficacy of valve repair.
FIGURE 23.80 Mitral regurgitation. A. Transoesophageal echocardiography with marked prolapse of part of the posterior mitral valve leaflet (PMVL). B. Transoesophageal echocardiography with colour Doppler demonstrates severe mitral regurgitation (MR) into the left atrium (LA). AMVL, aortic mitral valve leaflet; LV, left ventricle; PISA, proximal isovelocity surface area.

Cardiac catheterization
This demonstrates a prominent left atrial systolic pressure wave; when contrast is injected into the left ventricle, it is seen regurgitating into an enlarged left atrium during systole.

Management
Mild mitral regurgitation in the absence of symptoms can be managed conservatively by following the patient with serial echocardiograms. Prophylaxis against endocarditis is discussed on pages 236–237. Any evidence of progressive cardiac enlargement generally warrants early surgical intervention by either mitral valve repair or replacement. The current ESC guidelines recommend surgical intervention in patients with symptomatic severe mitral regurgitation, left ventricular ejection fraction >30% and end-diastolic dimension of <55 mm, and in asymptomatic patients with left ventricular dysfunction (end-systolic dimension >45 mm
and/or ejection fraction of <60%). Surgery should also be considered in patients with asymptomatic severe mitral regurgitation with preserved left ventricular function and atrial fibrillation and/or pulmonary hypertension. The advantages of surgical intervention are diminished in more advanced disease. *(Sudden torrential mitral regurgitation, as seen with chordal or papillary muscle rupture or infective endocarditis, necessitates emergency mitral valve replacement.)* When patients are not suited to surgical intervention, or when surgery will be performed at a later date, management involves treatment with diuretics, ACE inhibitors and possibly anticoagulants. A percutaneous mitral valve repair (MitraClip) has been compared to cardiac surgery in the EVEREST II trial and appears effective in the short term at reducing the severity of mitral regurgitation and providing symptomatic relief. It is appropriate in selected patients unsuitable for cardiac surgery.

### Prolapsing (billowing) mitral valve

This is also known as Barlow syndrome or floppy mitral valve. It is due to excessively large mitral valve leaflets, an enlarged mitral annulus, abnormally long chordae or disordered papillary muscle contraction. Histology may demonstrate myxomatous degeneration of the mitral valve leaflets. Prolapsing mitral valve is more commonly seen in young women than in men or older women, and has a familial incidence. Its cause is unknown but it is associated with connective tissue disorders (Marfan syndrome, Ehlers–Danlos syndrome and pseudoxanthoma elasticum). It also occurs in association with an atrial septal defect and Ebstein's anomaly (see p. 1016).

### Aortic Valve

#### Aortic stenosis

Aortic stenosis is a chronic progressive disease that produces obstruction to the left ventricular stroke volume, leading to symptoms of chest pain, breathlessness, syncope and pre-syncope, and fatigue.

**Aortic valve stenosis** includes calcific stenosis of a trileaflet aortic valve, stenosis of a congenitally bicuspid valve, and rheumatic aortic stenosis.

**Calcific aortic valvular disease (CAVD)** is the most common cause of aortic stenosis and mainly occurs in the elderly. This is an inflammatory process involving macrophages and T lymphocytes, initially with thickening of the sub-endothelium and adjacent fibrosis. The lesions contain lipoproteins, which calcify, increasing leaflet stiffness and reducing systolic opening. This can occur in a tri- or bileaflet aortic valve. Risk factors for CAVD include old age, male gender, elevated lipoprotein(a) and LDL, hypertension, diabetes and smoking.

**Bicuspid aortic valve (BAV) (Fig. 23.81)** is the most common form of congenital heart disease, occurring in 1–2% of live births; in about 9% of cases, it is familial. Patients with CAVD of a bicuspid valve tend to present at an earlier age. BAV is associated with aortic
coarctation, root dilatation and, potentially, aortic dissection, and patients should have regular follow-up echocardiography.

**Rheumatic fever** can produce progressive fusion, thickening and calcification of the aortic valve. In rheumatic heart disease, the aortic valve is affected in about 30–40% of cases and there is usually associated mitral valve disease.

**Other causes of valvular stenosis** include chronic kidney disease, Paget's disease of bone, previous radiation exposure and systemic lupus erythematosus. **Valvular aortic stenosis** should be distinguished from other causes of obstruction to left ventricular emptying (Fig. 23.82), which include:

- supravalvular obstruction – a congenital fibrous diaphragm above the aortic valve, often associated with mental retardation and hypercalcaemia (Williams syndrome)
- subvalvular aortic stenosis – a congenital condition in which a fibrous ridge or diaphragm is situated immediately below the aortic valve.
- hypertrophic cardiomyopathy – septal muscle hypertrophy obstructing left ventricular outflow.
Pathophysiology

Obstructed left ventricular emptying leads to increased left ventricular pressure and compensatory left ventricular hypertrophy. In turn, this results in relative ischaemia of the left ventricular myocardium, and consequent angina, arrhythmias and left ventricular failure. The obstruction to left ventricular emptying is relatively more severe on exercise. Normally, exercise causes a many-fold increase in cardiac output, but when there is severe narrowing of the aortic valve orifice, the cardiac output can hardly increase. Thus, the blood pressure falls, coronary ischaemia worsens, the myocardium fails and cardiac arrhythmias develop. Left ventricular systolic function is typically preserved in patients with aortic stenosis (compare this with aortic regurgitation).

Clinical features

Symptoms

There are usually no symptoms until aortic stenosis is moderately severe (when the aortic orifice is reduced to one-third of its normal size). At this stage, *exercise-induced syncope*, *angina* and *dyspnoea* develop. When symptoms occur, the prognosis is poor – on average, death occurs within 2–3 years, if there has been no surgical intervention.

Signs

See the ‘Clinical memo’ in Figure 23.83.
Pulse
The carotid pulse is of small volume and is slow-rising or plateau in nature (see pp. 940–941).

Precordial palpation
The apex beat is not usually displaced because hypertrophy (as opposed to dilatation) does not produce noticeable cardiomegaly. However, the pulsation is sustained and obvious. A double impulse is sometimes felt because the fourth heart sound or atrial contraction (‘kick’) may be palpable. A systolic thrill may be felt in the aortic area.

Auscultation
The most obvious auscultatory finding in aortic stenosis is an ejection systolic murmur that is usually ‘diamond-shaped’ (crescendo–decrescendo). The murmur is usually longer when the disease is more severe, as a longer ejection time is needed. The murmur is usually rough in quality and best heard in the aortic area. It radiates into the carotid arteries and also the precordium. The intensity of the murmur is not a good guide to the severity of the condition because it is lessened by a reduced cardiac output. In severe cases, the murmur may be inaudible.

Other findings include:
- **systolic ejection click**, unless the valve has become immobile and calcified
- **soft or inaudible aortic second heart sound** when the aortic valve becomes immobile
- **reversed splitting of the second heart sound** (splitting on expiration) (see p. 942)
- **prominent fourth heart sound**, caused by atrial contraction, and heard unless coexisting mitral stenosis prevents this.

FIGURE 23.83  Features of aortic stenosis and aortic regurgitation. EC, ejection click; EDM, early diastolic murmur; LSE, left sternal edge; MSM, mid-systolic murmur; A2, aortic component of the second heart sound; S1, first heart sound; S4, fourth heart sound.
Investigations

Chest X-ray
The chest X-ray usually reveals a relatively small heart with a prominent, dilated, ascending aorta. This occurs because turbulent blood flow above the stenosed aortic valve produces so-called ‘post-stenotic dilatation’. The aortic valve may be calcified. The cardiothoracic ratio increases when heart failure occurs.

Electrocardiogram
The ECG shows left ventricular hypertrophy and left atrial delay. A left ventricular ‘strain’ pattern due to ‘pressure overload’ (depressed ST segments and T-wave inversion in leads orientated towards the left ventricle, i.e. leads I, AVL, V₅ and V₆) is common when disease is severe. Usually, sinus rhythm is present, but ventricular arrhythmias may be recorded.

Echocardiogram
Echocardiography readily demonstrates the thickened, calcified and immobile aortic valve cusps, and the presence of left ventricular hypertrophy; it can be used to determine the severity of aortic stenosis (Box 23.43 and Fig. 23.84). Transoesophageal echocardiography is rarely indicated.

(Source: British Society of Echocardiography.)
Cardiac echograms. A. Two-dimensional echocardiogram (long-axis view) in a patient with calcific aortic stenosis. The calcium in the valve generates abnormally intense echoes. There is some evidence of associated left ventricular hypertrophy. B. Continuous-wave (CW) Doppler signals obtained from the right upper parasternal edge, where the high-velocity jet from the stenotic valve is coming towards the transducer. AV, aortic valve; IVS, interventricular septum; LA, left atrium; LV, left ventricle; MV, mitral valve; PVW, posterior ventricular wall.

**Cardiac catheterization**

Cardiac catheterization is rarely necessary since all of this information can be gained non-invasively with echocardiography and CMR. Coronary angiography is required before surgery is recommended.

**Cardiac magnetic resonance and cardiac computed tomography**

These techniques are indicated for assessing the thoracic aorta for the presence of aneurysm, dissection or coarctation but are rarely needed.

**Management**

In patients with aortic stenosis, symptoms are a good index of severity and all symptomatic
patients should have aortic valve replacement. Patients with a BAV and ascending aorta \( \geq 50 \text{ mm} \) or expanding at \( >5 \text{ mm/year} \) should be considered for surgical intervention. Asymptomatic patients should be under regular review for assessment of symptoms and echocardiography. Surgical intervention for asymptomatic people with severe aortic stenosis is recommended in those with:

- symptoms during an exercise test or with a drop in blood pressure
- an LVEF of <50%
- moderate to severe stenosis undergoing CABG, surgery of the ascending aorta or other cardiac valve.

Antibiotic prophylaxis against infective endocarditis is discussed on pages 236–237.

Provided that the valve is not severely deformed or heavily calcified, critical aortic stenosis in childhood or adolescence can be treated by valvotomy (performed under direct vision by the surgeon or by balloon dilatation using X-ray visualization). This produces temporary relief from the obstruction. Aortic valve replacement will usually be needed a few years later. Balloon dilatation (valvuloplasty) has been tried in adults, especially in the elderly, as an alternative to surgery. Generally results are poor and such treatment is reserved for patients unfit for surgery or as a ‘bridge’ to surgery (as systolic function will often improve).

**Percutaneous valve replacement**

A novel treatment for patients unsuitable for surgical aortic valve replacement is transcatheter implantation with a balloon expandable stent valve. Valve implantation has been shown to be successful (86%) with a procedural mortality of 2% and 30-day mortality of 12%. Good results have been reported in 5-year follow-up studies but further larger and randomized studies with long-term follow-up are required.

**Aortic regurgitation**

Aortic regurgitation can occur in diseases affecting the aortic valve, such as endocarditis, and diseases affecting the aortic root, such as Marfan syndrome (Box 23.44).

### Box 23.44

**Causes and associations of aortic regurgitation**

**Acute aortic regurgitation**

- Acute rheumatic fever
- Infective endocarditis
- Dissection of the aorta
- Ruptured sinus of Valsalva aneurysm
- Failure of prosthetic valve
Chronic aortic regurgitation

• Rheumatic heart disease
• Syphilis
• Arthritides:
  – Reactive arthritis
  – Ankylosing spondylitis
  – Rheumatoid arthritis
• Hypertension (severe)
• Bicuspid aortic valve
• Aortic endocarditis
• Marfan syndrome
• Osteogenesis imperfecta

Pathophysiology
Aortic regurgitation is reflux of blood from the aorta through the aortic valve into the left ventricle during diastole. If net cardiac output is to be maintained, the total volume of blood pumped into the aorta must increase and, consequently, the left ventricular size must enlarge. Because of the aortic runoff during diastole, diastolic blood pressure falls and coronary perfusion is decreased. In addition, the larger left ventricular size is mechanically less efficient, so that the demand for oxygen is greater and cardiac ischaemia develops.

Clinical features

Symptoms
In aortic regurgitation, significant symptoms occur late and do not develop until left ventricular failure occurs. As with mitral regurgitation, a common symptom is pounding of the heart because of the increased left ventricular size and its vigorous pulsation. Angina pectoris is a frequent complaint. Varying grades of dyspnoea occur, depending on the extent of left ventricular dilatation and dysfunction. Arrhythmias are relatively uncommon.

Signs
See the ‘Clinical memo’ in Figure 23.83. The signs of aortic regurgitation are many and are due to the hyperdynamic circulation, reflux of blood into the left ventricle and the increased left ventricular size.

The pulse is bounding or collapsing (see p. 940). The following signs, which are rare, also indicate a hyperdynamic circulation:

• Quincke’s sign – capillary pulsation in the nail beds
• **de Musset’s sign** – head nodding with each heart beat

• **Duroziez's sign** – a to-and-fro murmur heard when the femoral artery is auscultated with pressure applied distally (if found, it is a sign of severe aortic regurgitation)

• **pistol shot femorals** – a sharp bang heard on auscultation over the femoral arteries in time with each heart beat.

   The apex beat is displaced laterally and downwards, and is forceful in quality. On auscultation, there is a high-pitched early diastolic murmur best heard at the left sternal edge in the fourth intercostal space with the patient leaning forwards and the breath held in expiration. Because of the volume overload there is commonly an ejection systolic flow murmur. The regurgitant jet can impinge on the anterior mitral valve cusp, causing a mid-diastolic murmur (Austin Flint rumble).

### Investigations

#### Chest X-ray

The chest X-ray features are those of left ventricular enlargement and, possibly, of dilatation of the ascending aorta. The ascending aortic wall may be calcified in syphilis, and the aortic valve calcified if valvular disease is responsible for the regurgitation.

#### Electrocardiogram

The ECG appearances are those of left ventricular hypertrophy due to ‘volume overload’ – tall R waves and deeply inverted T waves in the left-sided chest leads, and deep S waves in the right-sided leads. Normally, sinus rhythm is present.

#### Echocardiogram

The echocardiogram ([Fig. 23.85](#)) demonstrates vigorous cardiac contraction and a dilated left ventricle. The aortic root may also be enlarged. Diastolic fluttering of the mitral leaflets or septum occurs in severe aortic regurgitation (producing the Austin Flint rumble). The severity of aortic regurgitation is assessed with a combination of colour Doppler (extent of the regurgitant jet, width of the vena contracta; [Fig. 23.85](#)) and CW Doppler (diastolic flow reversal in the descending thoracic aorta, pressure half-time). Transoesophageal echocardiography may provide additional information about the valves and aortic root.
**Cardiac catheterization**

Cardiac catheterization is required to assess CAD in patients requiring surgery. During cardiac catheterization, injection of contrast medium into the aorta (aortography) will outline aortic valvular abnormalities and allow assessment of the degree of regurgitation.

**Cardiac magnetic resonance and cardiac computed tomography**

These techniques may be indicated for assessing the thoracic aorta in cases of aortic dilatation or dissection. CMR can be used to quantify regurgitant volume.

**Management**

The underlying cause of aortic regurgitation (e.g. syphilitic aortitis or infective endocarditis) may require specific treatment. Patients with acute aortic regurgitation may need treatment with vasodilators and inotropes. ACE inhibitors are useful in patients with left ventricular dysfunction and beta-blockers may slow aortic dilatation in Marfan patients. Because symptoms do not develop until the myocardium fails and because the myocardium does not recover fully after surgery, operative valve replacement may be performed before significant symptoms occur.

Aortic surgery is indicated in:

- acute severe aortic regurgitation, e.g. endocarditis
- symptomatic patients (dyspnoea, NYHA class II–IV, angina) with chronic severe aortic regurgitation
- in asymptomatic patients with an LVEF of ≤50%
- in asymptomatic patients with an LVEF of >50% but with a dilated left ventricle (end-diastolic dimension >70 mm or systolic dimension >50 mm)
- in those undergoing CABG or surgery of the ascending aorta or other cardiac valve.
Both mechanical prostheses and tissue valves are used. Tissue valves are preferred in the elderly and when anticoagulants must be avoided, but are contraindicated in children and young adults because of the rapid calcification and degeneration of the valves. Antibiotic prophylaxis against infective endocarditis (see pp. 236–237) is not recommended.

**Tricuspid Valve**

**Tricuspid stenosis**

This uncommon valve lesion, which is seen much more often in women than in men, is usually due to rheumatic heart disease and is frequently associated with mitral and/or aortic valve disease. Tricuspid stenosis is also seen in the carcinoid syndrome.

**Pathophysiology**

Tricuspid valve stenosis results in a reduced cardiac output, which is restored towards normal when the right atrial pressure increases. The resulting systemic venous congestion produces hepatomegaly, ascites and dependent oedema.

**Clinical features**

**Symptoms**

Usually, patients with tricuspid stenosis complain of symptoms due to associated left-sided rheumatic valve lesions. The *abdominal pain* (due to hepatomegaly) and swelling (due to ascites), and *peripheral oedema* that occur are relatively severe when compared with the degree of *dyspnoea*.

**Signs**

If the patient remains in sinus rhythm, which is unusual, there is a prominent jugular venous *a*-wave. This pre-systolic pulsation may also be felt over the liver. There is usually a rumbling mid-diastolic murmur, which is heard best at the lower left sternal edge and is louder on inspiration. It may be missed because of the murmur of coexisting mitral stenosis. A tricuspid opening snap may occasionally be heard.

Hepatomegaly, abdominal ascites and dependent oedema may be present.

**Investigations**

On the chest X-ray, there may be a prominent right atrial bulge. On the ECG, the enlarged right atrium is shown by peaked, tall P waves (>3 mm) in lead II. The echocardiogram may show a thickened and immobile tricuspid valve, but this is not so clearly seen as an abnormal mitral
valve.

Management

Medical management consists of diuretic therapy and salt restriction. Tricuspid valvotomy is occasionally possible but tricuspid valve replacement is often necessary. Usually, other valves also need replacement because tricuspid valve stenosis is rarely an isolated lesion.

Tricuspid regurgitation

**Functional** tricuspid regurgitation (see *Fig. 23.25*) may occur whenever the right ventricle dilates: for example, in cor pulmonale, MI or pulmonary hypertension.

**Organic** tricuspid regurgitation may occur with rheumatic heart disease, infective endocarditis, carcinoid syndrome, Ebstein's anomaly (a congenitally malpositioned tricuspid valve) and other congenital abnormalities of the AV valves.

Clinical features

The valvular regurgitation gives rise to high right atrial and systemic venous pressures. Patients may complain of the symptoms of **right heart failure** (see pp. 1006–1007).

Physical signs include a large jugular venous ‘cv’-wave and a palpable liver that pulsates in systole. Usually, a right ventricular impulse may be felt at the left sternal edge, and there is a blowing pansystolic murmur, best heard on inspiration at the lower left sternal edge. Atrial fibrillation is common.

Investigations

An **echocardiogram** shows dilatation of the right ventricle with thickening of the valve.

Management

Functional tricuspid regurgitation usually disappears with medical management. Severe organic tricuspid regurgitation may require operative repair of the tricuspid valve (annuloplasty or annuloplication). Very occasionally, tricuspid valve replacement may be necessary. In drug addicts with infective endocarditis of the tricuspid valve, surgical removal of the valve is recommended to eradicate the infection. This is usually well tolerated in the short term. The insertion of a prosthetic valve for this condition is sometimes necessary.

Pulmonary Valve

Pulmonary stenosis
This is usually a congenital lesion but may rarely result from rheumatic fever or from the carcinoid syndrome. Congenital pulmonary stenosis may be associated with Fallot's tetralogy, Noonan syndrome or congenital rubella syndrome.

Pulmonary stenosis may be valvular, sub-valvular or supra-valvular.

Clinical features

The obstruction to right ventricular emptying results in right ventricular hypertrophy, which, in turn, leads to right atrial hypertrophy. Severe pulmonary obstruction may be incompatible with life, but lesser degrees of obstruction give rise to fatigue, syncope and the symptoms of right heart failure. Mild pulmonary stenosis may be asymptomatic.

The physical signs are characterized by a harsh mid-systolic ejection murmur, best heard on inspiration, to the left of the sternum in the second intercostal space. This murmur is often associated with a thrill. The pulmonary closure sound is usually delayed and soft. There may be a pulmonary ejection sound if the obstruction is valvular. A right ventricular fourth sound and a prominent jugular venous a-wave are present when the stenosis is moderately severe. A right ventricular heave (sustained impulse) may be felt.

Investigations

The chest X-ray usually shows a prominent pulmonary artery owing to post-stenotic dilatation. The ECG demonstrates both right atrial and right ventricular hypertrophy, although it may sometimes be normal, even in severe pulmonary stenosis. A Doppler echocardiogram is the investigation of choice.

Management

Management of severe pulmonary stenosis requires pulmonary valvotomy (balloon valvotomy or direct surgery).

Pulmonary regurgitation

This is the most common acquired lesion of the pulmonary valve. It results from dilatation of the pulmonary valve ring, which occurs with pulmonary hypertension (Graham Steell murmur). It may also occur following tetralogy of Fallot repair. It is characterized by a decrescendo diastolic murmur, beginning with the pulmonary component of the second heart sound that is difficult to distinguish from the murmur of aortic regurgitation. Pulmonary regurgitation usually causes no symptoms and treatment is rarely necessary.

Prosthetic Valves

There is no ideal replacement for our own normally functioning, native heart valves. There are
two options for valve prostheses: mechanical or tissue (bioprosthetic) (Fig. 23.86).

The valves consist of two basic components: an opening to allow blood to flow through and an occluding mechanism to regulate the flow. Mechanical prostheses rely on artificial concluders: a ball and cage (Starr–Edwards), tilting disc (Bjork–Shiley) or double tilting disc (St Jude). Tissue prostheses are derived from human (homograft) or from porcine or bovine (xenograft) sources. A valve replacement from within the same patient (i.e. pulmonary to aortic valve position) is termed an autograft.

Mechanical versus tissue valves

Mechanical valves, being artificial structures, are more durable than their tissue counterparts, which tend to degenerate after 10 years. However, artificial structures are more thrombogenic. Mechanical valves require formal anticoagulation for the lifetime of the prosthesis. The target INR is determined by what type of valve is inserted, where it is positioned, and whether the patient has additional risk factors for thromboembolism (mitral, tricuspid, pulmonary valve disease; previous thromboembolism; atrial fibrillation; left atrial diameter >50 mm; mitral stenosis; LVEF <35%; hypercoagulable state) (see p. 575):

- low thrombogenicity valve (Carbomedics (aortic position), Medtronic Hall, St Jude Medical (without silzone)): INR 2.5 without and 3.0 with additional risk factors
- medium thrombogenicity valve (Bjork–Shiley, other bileaflet valves): INR 3.0 without and 3.5 with additional risk factors
- high thrombogenicity valve (Lillehei–Kaster, Omniscience, Starr–Edwards): INR 3.5 without and 4.0 with additional risk factors.

Tissue valves require anticoagulation for a limited postoperative period only, while the
suture lines endothelialize (the ESC recommends 3 months with a target INR of 2.5, although some centres use low-dose aspirin 75–100 mg daily); it can then be discontinued unless another risk factor for thromboembolism (e.g. atrial fibrillation) persists. There is currently no role for the non-vitamin K antagonist oral anticoagulants (NOACs).

On auscultation, tissue valve heart sounds are comparable to those of a native valve. Mechanical valve heart sounds are generally louder and both opening and closing sounds can be heard.

### Complications

All prostheses carry a risk of infection. Prosthetic valve endocarditis is associated with significant morbidity and mortality; prevention is the cornerstone of management. Patient education about antibiotic prophylaxis is vital and this should be reinforced at clinic visits. Any procedure that results in a breach of the body’s innate defences (i.e. dental treatment, catheter insertion) increases the risk of exposing the prosthesis to a bacteraemia. This must be borne in mind when managing a patient with a prosthetic heart valve and steps should be taken to minimize the risk involved. The prosthetic valve occluding mechanism can be interrupted by vegetations, but also by thrombosis and calcification, resulting in either stenosis or regurgitation. The prosthesis can become detached from the valve ring, resulting in a para-prosthetic leak. Evidence of structural failure can be detected by simple auscultation, with echocardiography as the initial investigation of choice. Transthoracic echocardiography is non-invasive, but scattering of echoes by mechanical valves makes assessment difficult. Transoesophageal echocardiography provides alternative views and higher image resolution, making it the investigation of choice when prosthetic valve endocarditis is suspected.

### Interruption of anticoagulant therapy

For minor surgical procedures, including dental extraction and diagnostic endoscopy, anticoagulation should not be interrupted, although the INR should be reduced to a target of 2.0. Percutaneous arterial puncture is safe with an INR <2.0, although radial catheterization may be possible at higher INR levels. For major surgical procedures, anticoagulation should be discontinued 5 days before the procedure and intravenous unfractionated heparin or subcutaneous low-molecular-weight heparin commenced when the INR is <2.0.

### Pregnancy and prosthetic heart valves

The types of valve prosthesis in women of childbearing age are as follows:

- **Bioprosthetic valves** are preferable during pregnancy, as they are less thrombogenic and do not require anticoagulation. However, valve degradation in women of childbearing age has been shown to be as high as 50% at 10 years and 90% at 15 years; women with a bioprosthetic valve may require redo valve surgery.

- **Mechanical heart valves** have excellent durability but are thrombogenic and require lifelong anticoagulation with warfarin. Pregnancy is a hypercoagulable state due to increased levels of fibrinogen and factors VII, VIII and X, decreased levels of protein S activity, venous
hypertension and stasis.

Pregnancy in women with a mechanical heart valve is associated with increased maternal mortality (1–4%) due to valve thrombosis because safe anticoagulation in these patients is complex. Warfarin crosses the placenta and is associated with a 5–12% risk of embryopathy during the first trimester. Warfarin also has an anticoagulant effect in the fetus, which may lead to spontaneous fetal intracranial haemorrhage. Many women will choose unfractionated heparin or low-molecular-weight heparin, as they do not cross the placenta and do not cause fetal embryopathy. However, unfractionated heparin may not provide consistent therapeutic anticoagulation during pregnancy and there is a high incidence (25%) of valve thrombosis. Low-molecular-weight heparin provides a more consistent anticoagulant effect when given twice daily, with dose adjustment to maintain anti-Xa levels of 0.8–1.2 U/mL 4 h after administration.

**Further reading**

**Infective Endocarditis**

Infective endocarditis is an endovascular infection of cardiovascular structures, including cardiac valves, atrial and ventricular endocardium, large intrathoracic vessels and intracardiac foreign bodies, such as prosthetic valves, pacemaker leads and surgical conduits. The annual incidence in the UK is 6–7/100 000, but it is more common in developing countries. Without treatment, the mortality approaches 100%; even with treatment, there is a significant morbidity and mortality.

**Aetiology**

Endocarditis is usually the consequence of two factors: the presence of organisms in the bloodstream, and abnormal cardiac endothelium that facilitates their adherence and growth.
Bacteraemia may arise for patient-specific reasons (poor dental hygiene, intravenous drug use, soft tissue infections) or may be associated with diagnostic or therapeutic procedures (dental treatment, intravascular cannulae, cardiac surgery or permanent pacemakers). Although bacteraemia may occur, there is no good evidence that it leads to infective endocarditis (see pp. 236–237).

Damaged endocardium promotes platelet and fibrin deposition, which allows organisms to adhere and grow, leading to an infected vegetation. Valvular lesions may create non-laminar flow, and jet lesions from septal defects or a patent ductus arteriosus result in abnormal vascular endothelium. Aortic and mitral valves are most commonly involved in infective endocarditis; intravenous drug users are the exception, as right-sided lesions are more common in them.

**Organisms**

Common organisms and the sources of infection are shown in *Figure 23.87*.

**Rare causes**

These include the HACEK group of organisms, which tend to run a more insidious course (*Box 23.45*).
**Modified Duke criteria for endocarditis**

**Major criteria**

- A positive blood culture for infective endocarditis, as defined by the recovery of a typical microorganism from two separate blood cultures in the absence of a primary focus (viridans streptococci, *Abiotrophia* species and *Granulicatella* species; *Streptococcus bovis*, HACEK group\(^b\), or community-acquired *Staphylococcus aureus* or enterococcus species) or
- A persistently positive blood culture, defined as the recovery of a microorganism consistent with endocarditis from either blood samples obtained more than 12 h apart or all three or a majority of four or more separate blood samples, with the first and last obtained at least 1 h apart or
- A positive serological test for Q fever, with an immunofluorescence assay showing phase 1 IgG antibodies at a titre >1 : 800 or
- Echocardiographic evidence of endocardial involvement:
  - an oscillating intracardiac mass on the valve or supporting structures, in the path or regurgitant jets, or on implanted material in the absence of an alternative anatomical explanation; or
  - an abscess; or
- New partial dehiscence of a prosthetic valve; or
- New valvular regurgitation.

**Minor criteria**

- Predisposition: predisposing heart condition or intravenous drug use
- Fever: temperature ≥38°C (100.4°F)
- Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial haemorrhage, conjunctival haemorrhages, Janeway lesion
- Immunological phenomena: glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor
- Microbiological evidence: a positive blood culture but not meeting a major criterion as noted above, or serological evidence of an active infection with an organism that can cause infective endocarditis\(^c\)
- Echocardiogram: findings consistent with infective endocarditis but not meeting a major criterion as noted above.

\(^{a}\)The diagnosis of infective endocarditis is definite when: (1) a microorganism is demonstrated by culture of a specimen from a vegetation, an embolism or an intracardiac abscess; (2) active endocarditis is confirmed by histological examination of the vegetation or intracardiac abscess; (3) two major clinical criteria, one major and three minor criteria,
or five minor criteria are met.

HACEK denotes Haemophilus species, Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens and Kingella kingae.

Excluded from this criterion is a single positive blood culture for coagulase-negative staphylococci or other organisms that do not cause endocarditis. Serological tests for organisms that cause endocarditis include tests for Brucella, Coxiella burnetii, Chlamydia, Legionella and Bartonella species.

Culture-negative endocarditis

This accounts for 5–10% of endocarditis cases. The usual cause is prior antibiotic therapy (good history-taking is vital) but some cases are due to a variety of fastidious organisms that fail to grow in normal blood cultures. These include Coxiella burnetii (the cause of Q fever), Chlamydia species, Bartonella species (organisms that cause trench fever and cat scratch disease) and Legionella.

Clinical features

The clinical presentation of infective endocarditis (Box 23.46) is dependent on the organism and the presence of predisposing cardiac conditions. Infective endocarditis may occur as an acute, fulminating infection but also as a chronic or subacute illness with low-grade fever and non-specific symptoms. A high index of clinical suspicion is required to identify patients with infective endocarditis and certain criteria should alert the physician.

**High clinical suspicion**

- New valve lesion/(regurgitant) murmur.
- Embolic event(s) of unknown origin.
- Sepsis of unknown origin.
- Haematuria, glomerulonephritis and suspected renal infarction.
- ‘Fever’ plus:
  - Prosthetic material inside the heart
  - Other high predisposition for infective endocarditis, e.g. intravenous drug use
  - Newly developed ventricular arrhythmias or conduction disturbances
  - First manifestation of congestive cardiac failure
  - Positive blood cultures (with typical organism)
  - Cutaneous (Osler, Janeway) or ophthalmic (Roth) lesions *(Fig. 23.88)*

- Peripheral abscesses (renal, splenic, spine) of unknown origin
- Predisposition and recent diagnostic/therapeutic interventions known to result in significant bacteraemia.

**Low clinical suspicion**

- Fever plus none of the above.

**Diagnosis**

The criteria for the clinical diagnosis of endocarditis have been established – the modified Duke criteria (see Box 23.45).

**Investigations**

Investigations are required to confirm the diagnosis of infective endocarditis, to identify the organism in order to ensure appropriate therapy, and to monitor the patient's response to therapy (Box 23.47). Echocardiography is an extremely useful tool if used appropriately. A negative echocardiogram does not exclude a diagnosis of endocarditis. It is not an appropriate screening test for patients with just a fever or an isolated positive blood culture, where there is
a low pre-test probability of endocarditis.

#### Management

The location of the infection means that prolonged courses of antibiotics are usually required in the treatment of infective endocarditis. The combination of antibiotics may be synergistic in eradicating microbial infection and minimizing resistance. Blood cultures should be taken prior to empirical antibiotic therapy (but this should not delay therapy in unstable patients). Antibiotic treatment should continue for 4–6 weeks. Typical therapeutic regimens are shown in **Box 23.48** but advice on specific therapy should be sought from the local microbiology department, according to the organism identified and current sensitivities. Serum levels of gentamicin and vancomycin need to be monitored to ensure adequate therapy and prevent toxicity. In patients with penicillin allergy, one of the glycopeptide antibiotics, vancomycin or teicoplanin, can be used. Penicillins, however, are fundamental to the therapy of bacterial endocarditis; allergies therefore seriously compromise the choice of antibiotics. It is essential to confirm the nature of a patient's allergy to ensure that the appropriate treatment is not withheld needlessly. Anaphylaxis would be much more influential on antibiotic choice than a simple gastrointestinal disturbance.

Notes: (1) Monitor vancomycin and gentamicin levels, and adjust if necessary. (2) Choice of antibiotic for staphylococci depends on sensitivities. (3) Optimum choice of therapy needs close liaison with microbiology/infectious diseases departments. All antibiotics given i.v. IVDU, intravenous drug user. *MRSA can affect valves.

Persistent fever

Most patients with infective endocarditis should respond within 48 hours of initiation of appropriate antibiotic therapy. This is evidenced by a resolution of fever, reduction in serum markers of infection, and relief of systemic symptoms of infection. Failure of these factors to occur needs to be taken very seriously. The following should be considered:

- perivalvular extension of infection and possible abscess formation
- drug reaction (the fever should resolve promptly after drug withdrawal)
- hospital-acquired infection (i.e. venous access site, urinary tract infection)
- pulmonary embolism (secondary right-sided endocarditis or prolonged hospitalization).

In such cases, samples for culture should be taken from all possible sites and evidence sought of the above causes. A change of antibiotic dosage or regimen should be avoided unless there are positive cultures or a drug reaction is suspected. Emergence of bacterial resistance is uncommon. Close liaison with the microbiology department is recommended and a cardiothoracic surgical opinion should be sought.

Surgery

Decisions about surgical intervention in patients with infective endocarditis should be made after joint consultation between the cardiologist and cardiothoracic surgeon, taking into account patient-specific features (age, non-cardiac morbidities, presence of prosthetic material or cardiac failure) and infective endocarditis features (infective organism, vegetation size,
presence of perivalvular infection, systemic embolization).

**Prevention**

Evidence suggested that antibiotic prophylactic therapy is not required (see pp. 236–237) but a recent study has disputed this. Another study shows no increase in the number of new cases following implementation of the NICE guidelines.

**Further reading**

**Congenital Heart Disease**

A congenital cardiac malformation occurs in about 1% of live births. There is an overall male predominance, although some individual lesions (e.g. atrial septal defect and persistent ductus arteriosus) occur more commonly in females. As a result of improved medical and surgical management, more children with congenital cardiac disease are surviving into adolescence and adulthood. Thus, there is a need for an increased awareness, among general physicians and cardiologists, of the problems posed by these individuals.

**Fetal circulation**

In the developing fetus, oxygenated blood and nutrients are supplied to the fetus via the placenta and the umbilical vein (*Fig. 23.89*). Half of that blood is directed to the fetal ductus venosus and carried to the inferior vena cava (IVC); the other half enters the liver.
Blood moves from the IVC to the right atrium of the heart. In the fetus, there is an opening between the right and left atrium (the foramen ovale), and most of the blood (which is a mixture of oxygenated and deoxygenated blood) flows from the right into the left atrium, bypassing the pulmonary circulation. This blood goes into the left ventricle and is pumped through the aorta into the fetal body. Some of the blood flows from the aorta through the internal iliac arteries to the umbilical arteries and re-enters the placenta, where carbon dioxide and other waste products from the fetus are taken up and enter the woman's circulation.

Some of the blood from the right atrium does not enter the left atrium, but enters the right ventricle and is pumped into the pulmonary artery. In the fetus, there is a connection between the pulmonary artery and the aorta, the ductus arteriosus, which directs most of this blood away from the lungs. With the first breath after delivery, the vascular resistance in the pulmonary arteries falls and more blood moves from the right atrium to right ventricle and pulmonary arteries, and oxygenated blood travels back to the left atrium through the pulmonary veins. The decrease in right atrial pressure and relative increase in left atrial pressure results in closure of the foramen ovale.

The ductus arteriosus usually closes off within 1 or 2 days of birth, completely separating the left and right systems. The umbilical vein and the ductus venosus closes off within 2–5 days of birth, leaving behind the ligamentum teres and the ligamentum venosus of the liver, respectively.

Aetiology

The aetiology of congenital cardiac disease is often unknown but recognized associations
include:
• maternal prenatal rubella infection (persistent ductus arteriosus, and pulmonary valvular and arterial stenosis)
• maternal alcohol misuse (septal defects)
• maternal drug treatment and radiation
• genetic abnormalities (e.g. the familial form of atrial septal defect and congenital heart block)
• chromosomal abnormalities (e.g. septal defects and mitral and tricuspid valve defects, which are associated with Down syndrome (trisomy 21), or coarctation of the aorta in Turner syndrome (45, XO)).

### Classification

See Box 23.49.

**Clinical features**

**Symptoms and signs**

Congenital heart disease should be recognized as early as possible, as the response is usually better the earlier the treatment is initiated. Some symptoms, signs and clinical problems are common in congenital heart disease:

• **Central cyanosis** occurs because of right-to-left shunting of blood or because of complete mixing of systemic and pulmonary blood flow. In the latter case, such as in Fallot's tetralogy, the abnormality is described as cyanotic congenital heart disease.

• **Pulmonary hypertension** results from large left-to-right shunts. The persistently raised
pulmonary flow leads to the development of increased pulmonary artery vascular resistance and consequent pulmonary hypertension. This is known as Eisenmenger's reaction (or Eisenmenger's complex when due specifically to a ventricular septal defect). The development of pulmonary hypertension significantly worsens the prognosis.

- **Clubbing of the fingers** occurs in congenital cardiac conditions associated with prolonged cyanosis.

- **Paradoxical embolism** of thrombus from the systemic veins to the systemic arterial system may occur when a communication exists between the right and left heart. There is therefore an increased risk of cerebrovascular emboli and also abscesses (as with endocarditis).

- **Polycythaemia** can develop secondary to chronic hypoxaemia, leading to a hyperviscosity syndrome and an increased thrombotic risk, such as in strokes.

- **Growth retardation** is common in children with cyanotic heart disease.

- **Syncope** is common when severe right or left ventricular outflow tract obstruction is present. Exertional syncope, associated with deepening central cyanosis, may occur in Fallot's tetralogy. Exercise increases resistance to pulmonary blood flow but reduces systemic vascular resistance. Thus, the right-to-left shunt increases and cerebral oxygenation falls.

- **Squatting** is the posture adopted by children with Fallot's tetralogy. It results in obstruction of venous return of desaturated blood and an increase in the peripheral systemic vascular resistance. This leads to a reduced right-to-left shunt and improved cerebral oxygenation.

**Presentation**

Adolescents and adults with congenital heart disease present with specific common problems related to the longstanding structural nature of these conditions and any surgical treatment:

- endocarditis (particularly in association with otherwise innocuous lesions, such as a small ventricular septal defect or a bicuspid aortic valve that can give up to 10% lifetime risk)

- progression of valvular lesions (calcification and stenosis of congenitally deformed valves, e.g. bicuspid aortic valve)

- atrial and ventricular arrhythmias (often quite resistant to treatment)

- sudden cardiac death

- right heart failure (especially when surgical palliation results in the right ventricle providing the systemic supply)

- end-stage heart failure (rarely managed by heart or heart–lung transplantation).

**Genetic counselling**

These conditions necessitate active follow-up of adult patients. Pregnancy is normally safe, except when pulmonary hypertension or vascular disease is present, in which case the prognosis for both mother and fetus is poor.

**Box 23.50** lists the most common congenital lesions and their occurrence in first-degree
Genetic factors should be considered in all patients presenting with congenital heart disease. For example, parents with a child suffering from Fallot's tetralogy stand a 4% chance of conceiving another child with the disease, and so fetal ultrasound screening of the mother during pregnancy is essential. Parents with congenital heart disease are also more likely to have affected offspring. Fathers have a 2% risk, while mothers have a higher risk (around 5%). Individual families can exhibit even higher risks of recurrence.

**Ventricular septal defect**

Ventricular septal defect (VSD; **Fig. 23.90**) is the most common congenital cardiac malformation (1:500 live births). The haemodynamic consequences are dependent on the shunt size. Left ventricular pressure is higher than right; blood therefore moves from left to right and pulmonary blood flow increases. In large defects, the large volumes of blood flow through the pulmonary vasculature leads to pulmonary hypertension and eventual Eisenmenger's complex, when right ventricular pressure becomes higher than left; as a result, blood starts to shunt from right to left, causing cyanosis.

- **Small restrictive VSDs** (‘maladie de Roger’) are often found incidentally, as patients are asymptomatic. They are associated with a loud pansystolic murmur. The majority close spontaneously by the age of 10 years.
- **Large (non-restrictive) VSDs** result in significant left atrial and left ventricular dilatation (due to left ventricular volume overload). Large defects usually present with heart failure symptoms in childhood and eventually lead to pulmonary hypertension and Eisenmenger's complex. As pressures equalize, the murmur becomes softer.
Investigations and treatment

A small VSD produces no abnormal X-ray or ECG findings. In larger defects, the chest X-ray may demonstrate prominent pulmonary arteries owing to increased pulmonary blood flow, but with pulmonary hypertension there may be ‘pruned’ pulmonary arteries. Cardiomegaly occurs when a moderate or large VSD is present and the ECG may show both left and right ventricular hypertrophy. Echocardiography can assess the size and location of the VSD and its haemodynamic consequences. Interventional options are either surgical patch repair or device closure, if it is an isolated muscular VSD. Indications for intervention include left atrial and ventricular enlargement, with or without early left ventricular dysfunction; reversible pulmonary hypertension (mild) where there is a residual left-to-right shunt and no significant desaturation with exercise; and infective endocarditis. Patients with a restrictive VSD and those who have had a successful closure have an excellent long-term outcome. Prophylaxis of endocarditis is discussed on pages 236–237.
Atrial septal defect

Atrial septal defect (ASD) is often first diagnosed in adulthood and represents one-third of congenital heart disease. It is 2–3 times more common in women than in men. There are three main types of ASD *(Fig. 23.91)*:

- **Sinus venosus defects** – located in the superior part of the septum near the superior vena cava (superior sinus venosus defect), or the inferior part of the septum near the IVC (inferior sinus venosus defect) entry point.

- **Ostium secundum defects** (75%) – located in the mid-septum (fossa ovalis). This should not be confused with a patent foramen ovale (PFO), which is a normal variant and not a true septal defect. PFO is usually asymptomatic but is associated with paradoxical emboli and an increased incidence of embolic stroke.

- **Ostium primum (atrioventricular septal) defects** (15%) – located in the lower part of atrial septum.

Adult patients with an unrepaired ASD with a significant left-to-right shunt develop right
heart overload and dilatation. These patients develop symptoms of dyspnoea and exercise intolerance, and may develop atrial arrhythmias from right atrial dilatation. There is also increased pulmonary vascular flow, but significant pulmonary hypertension develops in <5% of patients and it is thought that these individuals have additional factors, including genetic predisposition to pulmonary hypertension. The physical signs of ASD reflect the volume overloading of the right ventricle (Fig. 23.91). A right ventricular heave can usually be felt.

Investigations and treatment

The chest X-ray may demonstrate prominent pulmonary arteries with pulmonary plethora. Right bundle branch block and right axis deviation may be present on the ECG (because of dilatation of the right ventricle). Ostium primum defects may have left axis deviation on the ECG. Echocardiography may demonstrate hypertrophy and dilatation of the right heart and pulmonary arteries. Subcostal views with two-dimensional and colour Doppler demonstrate the ASD (Fig. 23.92) and allow calculation of the left-to-right shunt (QP : QS ratio). CMR and CT are helpful for assessing anomalous pulmonary venous drainage, which may accompany an ASD. Indications for intervention include: an ASD with significant left-to-right shunting, resulting in right atrial/ventricular enlargement, which should be closed irrespective of symptoms; and thromboembolic events, including a patent foramen ovale in certain patients. The options for intervention include device closure using a transcatheter clamshell device (Fig. 23.93) for most secundum ASDs (if they are of a suitable size), and surgical closure for all other ASD types.
FIGURE 23.92  Ostium secundum atrial septal defect (arrowed) in a young girl. A. The defect is shown by a two-dimensional echocardiogram subcostal four-chamber view. B. Colour Doppler can demonstrate the left-to-right shunt. LA, left atrium; RA, right atrium.
Patent ductus arteriosus

A patent ductus arteriosus (PDA) is a persistent communication between the proximal left pulmonary artery and the descending aorta, resulting in a continuous left-to-right shunt (*Fig. 23.94*). Normally, the ductus arteriosus closes within a few hours of birth in response to decreased pulmonary resistance; however, in some cases (particularly in premature babies and in cases with maternal rubella), the ductus persists. Indometacin (a prostaglandin inhibitor) is given to stimulate duct closure. If the shunt is moderate to large, it will result in left heart volume overload and, in some cases, pulmonary hypertension and Eisenmenger syndrome. The characteristic clinical signs are a bounding pulse and continuous ‘machinery murmur’; however, as pulmonary hypertension develops in a large PDA, the murmur becomes softer.
In investigations and treatment

With a large shunt, the aorta and pulmonary arterial system may be prominent on chest X-ray. The ECG may demonstrate left atrial abnormality and left ventricular hypertrophy. The development of an Eisenmenger reaction will produce right ventricular hypertrophy. Echocardiography may show a dilated left atrium and left ventricle, with right heart changes occurring late. Colour Doppler imaging of the proximal pulmonary arteries may demonstrate the shunt. Indications for intervention (usually with percutaneous devices) include left ventricular dilatation, and mild to moderate pulmonary arterial hypertension (not Eisenmenger's). Small defects may predispose to endarteritis and should be considered for device closure unless clinically silent.

Coarctation of the aorta

A coarctation of the aorta is a narrowing of the aorta at, or just distal to, the insertion of the ductus arteriosus (distal to the origin of the left subclavian artery; Fig. 23.95). Rarely, it can occur proximal to the left subclavian. It occurs twice as commonly in men as in women. It is also associated with Turner syndrome (see p. 1220). In 80% of cases, the aortic valve is bicuspid (and potentially stenotic or endocarditic). Other associations include patent ductus arteriosus, ventricular septal defect, mitral stenosis or regurgitation, and circle of Willis aneurysms. Severe narrowing of the aorta encourages the formation of a collateral arterial circulation involving the periscapular and intercostal arteries. Decreased renal perfusion can lead to the development of systemic hypertension that persists even after surgical correction.
Coarctation of the aorta is often asymptomatic for many years. **Headaches** and **nose bleeds** (due to hypertension), and **claudication** and cold legs (due to poor blood flow in the lower limbs) may be present. Physical examination reveals hypertension in the upper limbs, and weak, delayed (radiofemoral delay) pulses in the legs. If coarctation is present in the aorta, proximal to the left subclavian artery, there will be asynchronous radial pulses in right and left arms. Poor peripheral pulses are seen in severe cases. For heart sounds and murmurs in coarctation of aorta, see **Figure 23.95**.

### Investigations and treatment

Chest X-ray may reveal a dilated aorta indented at the site of the coarctation. This is manifested by an aorta (seen in the upper right mediastinum) shaped like a ‘number 3’. In adults, tortuous and dilated collateral intercostal arteries may erode the under-surfaces of the ribs (‘rib notching’). The ECG demonstrates left ventricular hypertrophy. Echocardiography sometimes shows the coarctation and other associated anomalies. CT and CMR (Fig. 23.96) scanning can accurately demonstrate the coarctation and quantify flow.
Intervention is required if there is a peak–peak gradient across the coarctation of $>20$ mmHg and/or proximal hypertension. In neonates, coarctation is treated with surgical repair. In older children and adults, balloon dilatation and stenting is an option, although many centres still prefer surgery. Balloon dilatation is preferred for re-coarctation.

**Fallot’s tetralogy**

Tetralogy of Fallot (Fig. 23.97) consists of:

- a large, malaligned VSD
- an overriding aorta
- right ventricular outflow tract obstruction
- right ventricular hypertrophy.
Symptoms depend on the degree of pulmonary stenosis. Often, this is progressive in the first year of life and cyanosis develops due to increased right-sided pressures, resulting in a right-to-left shunt. Fallot's spells are episodes of severe cyanosis noted in children due to spasm of the subpulmonary muscle; these can be relieved by increasing systemic resistance using postural manoeuvres, such as squatting. In babies with severe pulmonary stenosis, systemic-to-pulmonary artery shunts (i.e. a Blalock–Taussig, or subclavian-to-pulmonary artery shunt) may be used initially to increase pulmonary blood flow in severe cases of pulmonary stenosis. The majority of adults with tetralogy of Fallot will have undergone complete repair, which involves relief of the right ventricular outflow tract obstruction and closure of the VSD. The overall survival of those who have had operative repair is excellent. DiGeorge syndrome is found in 15% of those who have tetralogy of Fallot.

**Transposition of the great arteries**

**Complete transposition of the great arteries**

In complete transposition of the great arteries (TGA), the right atrium connects to the morphological right ventricle, which gives rise to the aorta, and the left atrium connects to the morphological left ventricle, which gives rise to the pulmonary artery (Fig. 23.98). This is incompatible with life, as blood circulates in two parallel circuits: that is, deoxygenated blood from the systemic veins passes into the right heart and then via the aorta back to the systemic circulation. Oxygenated blood from the pulmonary veins passes through the left heart and back to the lungs. Babies with transposition are usually born cyanosed; if there is a significant ASD, VSD or PDA allowing a shunt (i.e. mixing of oxygenated and deoxygenated blood), the diagnosis might be delayed. In those without a shunt, an atrial septostomy is performed. A Rashkind’s balloon is deployed to dilate the foramen ovale and is used to maintain saturations at 50–80% until a definitive procedure can be performed. The arterial switch procedure is now performed in the first 2 weeks of life; the aorta is reconnected to the left ventricle and the
pulmonary artery is connected to the right ventricle. The coronary arteries are re-implanted.

Currently, the majority of adult patients with transposition of the great arteries will have had an ‘atrial switch’ operation. The right ventricle remains the systemic ventricle in this situation. Although most of these patients do well for many years, life expectancy is clearly limited by eventual failure of the systemic right ventricle.

**Congenitally corrected transposition of the great arteries**

In congenitally corrected transposition of the great arteries (ccTGA), systemic venous return to the right atrium enters a morphological left ventricle, which pumps into the pulmonary artery. Pulmonary venous blood returns to the left atrium and then, via the morphological right ventricle, to the aorta. The circulation is physiologically corrected but the systemic circulation is supported by a morphological right ventricle. ccTGA is often associated with cardiac lesions; systemic (tricuspid) AV valve abnormalities with valve insufficiency; VSD; subpulmonary stenosis; complete heart block; Wolff–Parkinson–White syndrome; and dextrocardia. Many patients with ccTGA live a normal life, although others require pacemaker insertion (the AV node is abnormal, leading to heart block), or surgery for a regurgitant tricuspid valve, or they develop heart failure from the systemic (right) ventricle.

Marfan Syndrome

Clinical features
Marfan syndrome (MFS) is one of the most common autosomal dominant inherited disorders of connective tissue, affecting the heart and blood vessels (aortic aneurysm and dissection, mitral valve prolapse), eye (dislocated lenses, retinal detachment) and skeleton (tall, thin body build with long arms, legs and fingers; scoliosis and pectus deformity) (*Figs 23.99* and *23.100*).

![Marfan syndrome. A. High arched palate. B. Eye lens dislocation.](https://example.com/figure23.99)
Clinically, two of three major systems must be affected, to avoid over-diagnosing the condition. Diagnosis may be confirmed by studying family linkage to the causative gene, or by demonstrating a mutation in the Marfan syndrome gene (MFS1) for fibrillin (FBN1) on chromosome 15q21.

MFS affects approximately 1 in 5000 of the population worldwide, and 25% of patients are affected as a result of a new mutation. This group includes many of the more severely affected patients, with high cardiovascular risk. Other known associations with early death due to aortic aneurysm and dissection are: family history of early cardiac involvement; family history of dissection with an aortic root diameter of >5 cm; male sex; and extreme physical characteristics, including markedly excessive stature and widespread striae. Histological examination of aortas often shows widespread medial degeneration, described as ‘cystic medial necrosis’.

### Investigations

Cardiac investigations are as follows:

- **Chest X-ray** is often normal but may show signs of aortic aneurysm and unfolding, or of widened mediastinum. Pneumothorax affects 11% and scoliosis is present in 70% of patients.

- **ECG** may be misleadingly normal with an acute dissection. In conjunction with mitral valve prolapse, 40% of patients usually have an arrhythmia, with premature ventricular and atrial arrhythmias.

- **Echocardiography** shows mitral valve prolapse, and mitral regurgitation in the majority of patients. High-quality serial echocardiogram measurements of aortic root diameter in the sinuses of Valsalva, at 90° to the direction of flow, are the basis for medical and surgical management (Fig. 23.100B).

- **CT or CMR** can detect aortic dilatation and both are useful in monitoring.

### Management
• **Beta-blocker therapy** slows the rate of dilatation of the aortic root and atenolol is now standard therapy.

• **Angiotensin receptor blockers** specifically inhibit TNF-β, which is upregulated in Marfan. A trial of losartan compared with atenolol has shown no difference in aortic root dilatation at 3 years.

• **Lifestyle alterations** are required because of ocular, cardiac or skeletal involvement. Sports that necessitate prolonged exertion at maximum cardiac output, such as cross-country running, are to be avoided. Sedentary occupations are usually best, as patients tend to suffer from easy fatigability and hypermobile, painful joints.

• **Monitoring** should be carried out, with yearly echocardiograms up to aortic root diameter of 4.5 cm, and 6-monthly with diameters of 4.5–5 cm; the patient is then referred directly for elective surgery to a surgeon who is experienced in aortic root replacement in Marfan syndrome.

  **Pregnancy** is generally well tolerated if no serious cardiac problems are present, but is preferably avoided if the aortic root diameter is >4 cm, with aortic regurgitation. Echocardiography should be performed every 6–8 weeks throughout pregnancy and during the initial 6 months postpartum. Blood pressure should be regularly monitored and hypertension treated actively. Delivery should be by the least stressful method, ideally vaginal. Caesarean section should not be routinely performed. However, if the aortic root is >4.5 cm, delivery at 39 weeks by induction or caesarean section is recommended. Beta-blocker therapy may be safely instituted or continued throughout pregnancy, to help prevent aortic dissection.

  Medical and surgical management have increased the overall survival rate. On average, 13 years of life are added when surgical survival is compared to that reported in the natural history of MFS.

**Genetic counselling**

The condition is inherited in an autosomal dominant mode, with each child of one affected parent having a 50 : 50 chance of inheriting the condition. Males and females are affected equally often. In 25% of all cases, the condition arises as the result of a **spontaneous mutation in gene 5** of one of the parents. FBN1 gene mutations can be identified in 80% of those affected, confirming diagnosis and aiding prognosis. The mutation can also be used to screen at-risk family members, including postnatal or prenatal offspring.

**Further reading**

**Pulmonary Heart Disease**

The normal mean pulmonary artery pressure (mPAP) at rest is 14 ± 3 mmHg with an upper limit
of normal of 20 mmHg. The normal values for mPAP, mean capillary wedge pressure (mPCWP) and cardiac output (CO) are 12 ± 2 mmHg, 6 ± 2 mmHg and 5 L/min, respectively. The fall in pressure across the lung circulation is known as the transpulmonary gradient and reflects the difference between mPAP and mPCWP. The normal transpulmonary gradient is 6 ± 2 mmHg.

The *pulmonary vascular resistance* (PVR) is calculated by the formula:

\[
\text{PVR} = \frac{\text{mPAP} - \text{mPCWP}}{\text{CO}}
\]

It is normally about 1.5 mmHg/L per min (1.5 Wood units). Approximately 60% of the body's endothelial surface is in the lungs and the lungs normally offer a low resistance to blood flow. This is because the media of the pre-capillary pulmonary arterioles is thin, as compared with their more muscular systemic counterparts that have to respond constantly to postural changes under the influence of gravity. The fact that the lung circulation normally offers a low resistance to flow explains the preferential passage of blood through the lungs in specific forms of congenital heart disease, which may eventually lead to remodelling of the lung circulation and pulmonary hypertension.

**Pulmonary hypertension**

Pulmonary hypertension (PH) is defined as an mPAP of >25 mmHg at rest, as measured on right heart catheterization. The clinical classification of PH is provided in *Box 23.51*.

a5th World Symposium on Pulmonary Hypertension, Nice, 2013.  
bNow called 'autoimmune rheumatic disease'.

ALK1, activin-like receptor kinase-1; BMPR, bone morphogenetic protein receptor type II; CAV1, caveolin-1; ENG, endoglin; HIV = human immunodeficiency virus; KCNK3, potassium channel super-family K member-3; SMAD9, mothers against decapentaplegic 9.

### Pathophysiology

The different groups are characterized by variable amounts of hypertrophy, proliferation and fibrotic changes in distal pulmonary arteries (pulmonary arterial hypertension, PAH;
pulmonary veno-occlusive disease, PVOD; pulmonary hypertension, PH, due to left heart disease; PH due to lung disease and/or hypoxia). Pulmonary venous changes are seen in PVOD and PH groups due to left heart disease, and the vascular bed may be destroyed in emphysematous or fibrotic areas seen in lung disease. In chronic thromboembolic pulmonary hypertension (CTEPH), organized thrombi are seen in the elastic pulmonary arteries. Patients with PH with unclear and/or multifactorial mechanisms have variable pathological findings.

Patients with progressive PH develop right ventricular hypertrophy, dilatation, heart failure and death.

### Pulmonary artery hypertension

#### Epidemiology

A French registry of 674 patients with PAH identified 39.2% with idiopathic pulmonary artery hypertension (IPAH), 3.9% with familial (or heritable) disease, 9.5% with drug and toxin (anorexigens) causes, 15.3% with autoimmune rheumatic disease, 11.3% with congenital heart disease, 10.4% with portal hypertension and 6.2% with HIV-associated disease. In familial or heritable PAH, mutations in the bone morphogenetic protein receptor type 2 (BMPR2) gene, are detected in over 70% of cases; other mutations are seen in patients with hereditary haemorrhagic telangiectasia (Osler–Weber–Rendu syndrome).

Drugs and toxins known to cause PAH include fenfluramine, dexfenfluramine, toxic rapeseed oil and the anorectic agents aminorex and benfluorex.

#### Clinical features of PAH

Patients with PAH may present with symptoms of dyspnoea, fatigue, weakness, angina, syncope or abdominal distension. Clinical signs of PAH and right heart hypertrophy include a left parasternal heave, a loud P2 heart sound, a soft pansystolic murmur with tricuspid regurgitation or early diastolic murmur with pulmonary regurgitation. Right heart failure leads to jugular venous distension, ascites, peripheral oedema and hepatomegaly. Clinical signs of associated diseases, such as systemic sclerosis or chronic liver disease, should be sought.

#### Investigation of PAH

- **Routine blood tests** include full blood count, renal and liver biochemistry, thyroid function tests, and serological assays for underlying autoimmune rheumatic diseases, HIV and hepatitis.
- **Chest X-ray** shows enlargement of the pulmonary arteries and the major branches, with marked tapering (pruning) of peripheral arteries. The lung fields are usually lucent and there may be right atrial and right ventricular enlargement. The chest X-ray may facilitate the diagnosis of PH due to left heart or chronic lung disease.
• **ECG** shows right ventricular hypertrophy and right atrial enlargement (P pulmonale).

• **Echocardiography** (Fig. 23.101) with tricuspid regurgitation can be used for determination of PAP using the simplified Bernoulli equation ($PAP = 4 \times (\text{tricuspid regurgitation velocity})^2 + \text{estimated right atrial pressure}$). Right atrial pressure can be assumed at 5–10 mmHg unless there is significant dilatation of the inferior vena cava with reduced respiratory variation. Mean $PAP = 0.61 \times \text{PA systolic pressure} + 2$ mmHg (although the Bernoulli equation may not be accurate in cases of severe tricuspid regurgitation).

![FIGURE 23.101 Pulmonary hypertension. A. Continuous wave Doppler echocardiography demonstrates markedly elevated tricuspid regurgitation velocity consistent with pulmonary hypertension. B. Parasternal short-axis echocardiogram with a dilated right ventricle (RV) and septal flattening (arrowed) in a patient with pulmonary hypertension. LV, left ventricle.](image)

- **CMR** may be useful in adult congenital heart disease and in assessing right ventricular function on serial assessment.

- **Abdominal liver ultrasound** is useful to exclude liver cirrhosis and portal hypertension.

- **Right heart catheterization** may be indicated as part of the clinical assessment to confirm
the diagnosis (elevated PAP), determine the pulmonary wedge pressure (PWP), calculate the cardiac output, and assess for pulmonary vascular resistance and reactivity. In PAH, a vasodilator challenge (inhaled nitric oxide, intravenous adenosine or epoprostenol) should be performed to identify patients who may benefit from vasodilator therapies. A responder is defined as a reduction in mean PAP of ≥10 mmHg to reach an absolute mean PAP of ≤40 mmHg with increased or unchanged cardiac output. These vasodilator challenges are not recommended in patients with other types of PH (types 2–5).

**Management of PAH**

- **Physical activity.** Patients should be encouraged to remain physically active but avoid exertion that precipitates severe dyspnoea, chest pain or pre-syncope.

- **Pregnancy.** Patients with PAH have a very high mortality rate during pregnancy (30–50%) and should be counselled against conception. Contraception may include barrier methods, progesterone-only pill or the Mirena coil.

- **Travel.** During plane travel, supplementary oxygen at 2 L/min may be appropriate for patients with reduced functional class and with resting hypoxia of <8 kPa.

- **Vaccination.** Vaccination should be given for influenza and pneumococcal pneumonia.

- **Elective surgery.** Epidural anaesthesia may be preferable to a general anaesthetic.

- **Oral anticoagulation.** There is evidence to support the use of oral anticoagulation in patients with IPAH, heritable PAH, and PAH due to anorexigens. The European target INR is 2.0–3.0.

- **Diuretics.** These are used in patients with right heart failure and fluid overload.

- **Digoxin.** This may be helpful in patients with tachyarrhythmias.

- **Calcium channel blockers.** These can be effective in high doses in selected patients with IPAH who demonstrate a response to a vasodilator challenge. Right heart catheterization should be repeated in 3–4 months to assess response to therapy.

- **Prostanoids.** Prostacyclin is a potent vasodilator that also inhibits platelet aggregation and cell proliferation. Synthetic prostacyclins are generally short-acting compounds requiring continuous intravenous or subcutaneous infusion or regular aerosol inhalation. They provide symptomatic relief and can improve exercise capacity; **epoprostenol** can improve survival in patients with both IPAH and APAH. Oral **selexipag** has been approved by the FDA for PAH treatment.

- **Endothelin receptor antagonists.** Endothelin-1 is a potent vasoconstrictor and mitogen that binds to endothelin A and B receptors in the pulmonary vasculature. Both dual antagonists (**bosentan**) and selective A receptor antagonists (**sitaxentan, ambrisentan**) can improve symptoms, exercise capacity and haemodynamics in patients with IPAH.

- **Phosphodiesterase type 5 inhibitors.** These produce vasodilatation in the pulmonary vasculature and reduce cellular proliferation. **Sildenafil** and **tadalafil** have been demonstrated to provide symptomatic relief and improve exercise capacity in patients with
IPAH.

• **Balloon atrial septostomy.** This technique may be considered as palliative therapy in severe cases of PH.

• **Cardiac transplantation.** This is used in patients with an adverse prognosis, although the 5-year survival following transplantation may be only 40–50%.

### Other pulmonary hypertension groups

Left-sided heart disease (systolic and diastolic heart failure) and valvular heart disease is frequently associated with PH, as is advanced chronic obstructive pulmonary disease (see pp. 1079–1085), pulmonary fibrosis and emphysema. Following acute pulmonary embolism, 0.5–2.0% of patients will develop chronic thromboembolic pulmonary hypertension (CTEPH).

### Pulmonary embolism

Thrombus, usually formed in the systemic veins or rarely in the right heart (<10% of cases), may dislodge and embolize into the pulmonary arterial system. Postmortem studies indicate that this is a very common condition (microemboli are found in up to 60% of autopsies) but it is not usually diagnosed this frequently in life. Ten per cent of clinical pulmonary emboli are fatal.

Most clots that cause clinically relevant pulmonary emboli actually come from the pelvic and abdominal veins, but femoral DVT, and even occasionally axillary thrombosis, can be the origin of the clot. Clot forms as a result of a combination of sluggish blood flow, local injury or compression of the vein and a hypercoagulable state. Emboli can also occur from tumour, fat (long bone fractures), amniotic fluid and foreign material during intravenous drug misuse. Risk factors are shown in **Box 16.35** and discussed on pages 575–578.

After pulmonary embolism, lung tissue is ventilated but not perfused, producing an intrapulmonary dead space and resulting in impaired gas exchange. After some hours, the non-perfused lung no longer produces surfactant. Alveolar collapse occurs and exacerbates hypoxaemia. The primary haemodynamic consequence of pulmonary embolism is a reduction in the cross-sectional area of the pulmonary arterial bed, which causes an elevation of pulmonary arterial pressure and a reduction in cardiac output. Right ventricular ischaemia can be detected with elevations of troponin and creatine kinase and is associated with adverse outcomes. Distal embolization leads to alveolar haemorrhage with haemoptysis, pleural inflammation and effusion (pulmonary infarction).

### Clinical features

Sudden onset of **unexplained dyspnoea** is the most common, and often the only, symptom of pulmonary embolism. **Pleuritic chest pain** and **haemoptysis** are present only when infarction has occurred.

On examination, the patient may be tachypnoeic with a localized pleural rub and, often,
coarse crackles over the area involved. An exudative pleural effusion (occasionally blood-stained) can develop. The patient may have a fever, and cardiovascular examination is typically normal.

**Massive pulmonary embolism**

Sudden collapse may occur with acute obstruction of the right ventricular outflow tract. The patient has severe central chest pain (cardiac ischaemia due to lack of coronary blood flow) and becomes shocked, pale and sweaty. Syncope may result if the cardiac output is transiently but dramatically reduced, and death may occur. On examination, the patient is tachypnoeic, and has a tachycardia with hypotension and peripheral shutdown. The JVP is raised with a prominent $a$-wave. There is a right ventricular heave, a gallop rhythm and a widely split second heart sound.

**Chronic recurrent pulmonary embolism**

This may present with dyspnoea, weakness, syncope on exertion and, occasionally, angina. Examination may reveal signs of right ventricular overload with a right ventricular heave and loud pulmonary second sound.

**Investigations**

- **Chest X-ray** is often normal, but linear atelectasis or blunting of a costophrenic angle (due to a small effusion) is not uncommon. Occasionally, a wedge-shaped pulmonary infarct, the abrupt cut-off of a pulmonary artery or a translucency of an under-perfused distal zone is seen. Patients with massive pulmonary embolism may have pulmonary oligaemia. Those with recurrent pulmonary emboli may have enlarged pulmonary arterioles with oligaemic lung fields.

- **ECG** findings include sinus tachycardia, right atrial dilatation with tall peaked P waves in lead II, right ventricular strain with right axis deviation and right bundle branch block, and T-wave inversion in the right precordial leads (*Fig. 23.102*). The ‘classic’ ECG pattern with an S wave in lead I, and a Q wave and inverted T waves in lead III (S1, Q3, T3), is rare.
Blood gases may be normal, but with significant pulmonary embolism there will be arterial hypoxaemia with a low arterial $CO_2$ level, i.e. a type I respiratory failure pattern.

Cardiac troponins and BNP may be elevated and are associated with an adverse outcome.

Plasma D-dimer (see p. 566) is elevated in patients with thromboembolism and a negative test excludes a diagnosis of pulmonary embolism. However, elevated levels may be detected in patients with cancer, those who are pregnant, and in hospitalized and elderly patients.

Radionuclide ventilation/perfusion scanning ($V/Q$ scan) is a good diagnostic investigation that is widely available. Pulmonary $^{99m}$Tc scintigraphy demonstrates under-perfused areas (Fig. 23.103), which, if not accompanied by a ventilation defect on a ventilation scintigram performed after inhalation of radioactive xenon gas (see p. 1070), is highly suggestive of a pulmonary embolus. There are limitations to the test, however. For example, a matched defect may arise with a pulmonary embolus that causes an infarct, or with emphysematous bullae. This test is therefore conventionally reported as a probability (low, medium or high) of pulmonary embolus and should be interpreted in the context of the history, examination and other investigations. A normal $V/Q$ scan has a negative predictive value of 97%.
Radionuclide ventilation/perfusion scanning. Ventilation (top) and perfusion (bottom) lung scans demonstrate an absence of perfusion in the right upper lobe, i.e. probable pulmonary embolism (arrowed).

- **Ultrasound scanning** can be performed for the detection of clots in pelvic or iliofemoral veins (see p. 1055). This may be very useful as a screening assessment in pregnant patients; a positive scan may preclude the need for further investigation with CT angiography (CTA) or $\dot{V}/\dot{Q}$ scanning.

- **Contrast-enhanced multidetector CT angiograms (CTA; Fig. 23.104)** can accurately diagnose and exclude pulmonary embolism, and modern scanners have a negative predictive value of 95–97%. In pregnancy, CTA exposes the mother to a greater radiation risk than a $\dot{V}/\dot{Q}$ scan but delivers a lower radiation dose to the fetus.
• **MRI** can provide similar results and may be appropriate if CTA is contraindicated.

• **Echocardiography** can be useful in acute pulmonary embolism to assess for evidence of right ventricular dysfunction and, in some cases, may demonstrate thrombus. In chronic recurrent pulmonary emboli, there may be right ventricular dilatation and hypertrophy with pulmonary arterial hypertension.

### Classification and investigation of acute pulmonary embolism

Clinical status at presentation can be used to divide patients into ‘high-risk’ and ‘not high-risk’, based on the presence of shock or hypotension (**Fig. 23.105A**).
FIGURE 23.105 Initial stratification of acute pulmonary embolism (PE). A. With shock or hypotension. B. Without shock or hypotension. *Systolic blood pressure <90 mmHg, or a systolic pressure drop of ≥40
High-risk patients should proceed to CTA; a positive test confirms the diagnosis. A negative test should lead to investigations for other causes of haemodynamic instability. Echocardiography may be useful if patients are too unstable for CTA. Right ventricular dysfunction or visible thrombi are consistent with pulmonary embolism; normal right ventricular function should suggest an alternative diagnosis.

In not high-risk patients, the clinical probability of pulmonary embolus should be determined using the Wells rule (Box 23.52).

- High-clinical-probability or PE-likely patients should proceed to multidetector contrast-enhanced CTA (see Fig. 23.104). A positive test confirms the diagnosis. A negative test that has high probability may require further investigation. (Patients with renal failure or contrast allergy can have V/Q scanning).
- Low- or intermediate-probability or PE-unlikely patients should have a D-dimer assay performed. A negative D-dimer rules out a pulmonary embolism. A positive D-dimer requires further investigation with CTA (Fig. 23.105B).

### Management

#### Acute management

- **High-flow oxygen** (60–100%) should be given to all patients, unless they have significant chronic lung disease. Patients with pulmonary infarcts require bed rest and analgesia.
- **Initial anticoagulation** with subcutaneous low-molecular-weight heparin or fondaparinux or intravenous unfractionated heparin should be given.
• **Intravenous fluids and even inotropic agents** to improve the pumping of the right heart are sometimes required in severe cases, and very ill patients will require care on the intensive therapy unit (see pp. 1157–1158).

• **Thrombolysis therapy** can improve pulmonary perfusion quicker than anticoagulation. It should be used in unstable patients and should be considered in stable patients with adverse features, such as right ventricular dysfunction. The Pulmonary Embolism Thrombolysis (PEITHO) trial compared tenecteplase and heparin versus placebo and heparin in 1006 patients with acute pulmonary embolism. Thrombolysis reduced the primary end-point (all-cause death or haemodynamic collapse or compromise) (2.6% versus 5.6%, P = 0.015).

• **Surgical embolectomy** is rarely necessary, but there may be no alternative when the haemodynamic circumstances are very severe.

**Prevention of further emboli**

Patients should be anticoagulated with vitamin K antagonists (e.g. warfarin) for a period of 3–6 months with a target INR of 2.0–3.0. More recently, non-vitamin-K-antagonist oral anticoagulants (NOACs; dabigatran, rivaroxaban and apixaban) have been used in patients with venous thromboembolism; they appear to be effective and possibly safer than standard vitamin K antagonists. Patients with cancer or pregnant women should be treated with long-term low-molecular-weight heparin. In high-risk patients in whom anticoagulation is absolutely contraindicated, a vena cava filter may be inserted via the femoral vein to above the level of the renal veins.

**Chronic thromboembolic pulmonary hypertension**

Chronic thromboembolic obstruction of the major pulmonary arteries has an incidence of 5 per million population in the UK. The mean age is 63 years, and males and females are equally affected. Patients may present with dyspnoea, haemoptysis and/or ankle oedema.

The clinical diagnosis of chronic thromboembolic pulmonary hypertension (CTEPH) is made following 3 months of adequate anticoagulation with an elevated PAP ≥25 mmHg, wedge pressure ≥15 mmHg associated with a segmental defect on V/Q scan, or pulmonary artery obstruction on CT or pulmonary angiography. Pulmonary endarterectomy is the treatment of choice. Medical treatment includes anticoagulation, oxygen and diuretics. If the patient is inoperable, riociguat (a vasodilator) is used under specialist care.

## Myocardial and Endocardial Disease

### Cardiac Tumours

#### Atrial myxoma

This is the most common primary cardiac tumour. It occurs at all ages and shows no sex preference. Although most myxomas are sporadic, some are familial or are part of a multiple system syndrome. Histologically, they are benign. The majority of myxomas are solitary, usually develop in the left atrium, and are polypoid, gelatinous structures attached by a pedicle to the atrial septum. The tumour may obstruct the mitral valve or may be a site of thrombi, which then embolize. It is also associated with constitutional symptoms: the patient may present with dyspnoea, syncope or a mild fever. The physical signs are a loud first heart sound, a tumour ‘plop’ (a loud third heart sound produced as the pedunculated tumour comes to an abrupt halt), a mid-diastolic murmur and signs due to embolization. A raised erythrocyte sedimentation rate (ESR) is usually present.

The diagnosis is easily made by echocardiography because the tumour is demonstrated as a dense, space-occupying lesion (*Fig. 23.106*). Surgical removal usually results in a complete cure.

**FIGURE 23.106** Atrial myxoma shown by a two-dimensional echocardiogram (long-axis view). The myxoma (X) is an echo-dense mass obstructing the mitral valve orifice. It was removed surgically. LV, left ventricle; LA, left atrium.

Myxomas may also occur in the right atrium or in the ventricles. Other primary cardiac
tumours include rhabdomyomas and sarcomas.

**Myocardial Disease**

Myocardial disease that is not due to ischaemic, valvular or hypertensive heart disease, or a known infiltrative, metabolic/toxic or neuromuscular disorder, may be caused by:

- an acute or chronic inflammatory pathology (myocarditis)
- idiopathic myocardial disease (cardiomyopathy).

**Myocarditis**

Acute inflammation of the myocardium has many causes (*Box 23.53*). Establishment of a definitive aetiology, with isolation of viruses or bacteria, is difficult in routine clinical practice.

---

**Box 23.53**

**Causes of myocarditis**

- Idiopathic
- Infective
  - Viral: Coxsackievirus, adenovirus, cytomegalovirus, echovirus, influenza, polio, hepatitis, HIV
  - Parasitic: *Trypanosoma cruzi, Toxoplasma gondii* (a cause of myocarditis in the newborn or immunocompromised)
  - Bacterial: streptococcus (most commonly, rheumatic carditis), diphtheria (toxin-mediated heart block common)
  - Spirochaetal: Lyme disease (heart block common), leptospirosis
  - Fungal
  - Rickettsial
- Toxic
  - Drugs: those causing hypersensitivity reactions, e.g. methyldopa, penicillin, sulphonamides, antituberculous, modafinil
  - Radiation: may cause myocarditis but pericarditis is more common
- Autoimmune
  - An autoimmune form with autoactivated T cells and organ-specific antibodies may occur
  - Giant cell myocarditis
- Alcohol
- Hydrocarbons
In Western societies, the most common cause of infective myocarditis is Coxsackie or adenoviral infection. Myocarditis in association with HIV infection is seen at postmortem in up to 20% of cases but causes clinical problems in less than 10% of cases. Chagas' disease, due to *Trypanosoma cruzi*, which is endemic in South America, is one of the most common causes of myocarditis worldwide. Additionally, toxins (including prescribed drugs), physical agents, hypersensitivity reactions and autoimmune conditions may also cause myocardial inflammation.

**Pathology**

In the acute phase, myocarditic hearts are flabby with focal haemorrhages; in chronic cases, they are enlarged and hypertrophied. Histologically (*Fig. 23.107*), an inflammatory infiltrate is present – lymphocytes predominating with viral causes, polymorphonuclear cells with bacterial causes, and eosinophils with allergic and hypersensitivity causes.

![Myocardial biopsies. A. Normal myocardium. B. Myocarditis, with increased interstitial inflammatory cells.](image)

**Clinical features**

Myocarditis may be an acute or chronic process; its clinical presentations range from an asymptomatic state associated with limited and focal inflammation, to *fatigue, palpitations, chest pain, dyspnoea* and *fulminant congestive cardiac failure* due to diffuse myocardial involvement. An episode of viral myocarditis, perhaps unrecognized and forgotten, may be the initial event that eventually culminates in an ‘idiopathic’ dilated cardiomyopathy. Physical examination includes soft heart sounds, a prominent third sound and often a tachycardia. A
pericardial friction rub may be heard.

**Investigations**

- **Chest X-ray.** This may show some cardiac enlargement, depending on the stage and virulence of the disease.
- **ECG.** The ECG demonstrates ST- and T-wave abnormalities and arrhythmias. Heart block may be seen with diphtheritic myocarditis, Lyme disease and Chagas' disease (see below).
- **Cardiac enzymes.** These are elevated.
- **Viral antibody titres.** These may be increased. However, since enteroviral infection is common in the general population, the diagnosis depends on the demonstration of acutely rising titres.
- **Endomyocardial biopsy.** Biopsy may show acute inflammation but false negatives are common by conventional criteria. Biopsy is of limited value outside specialized units.
- **Viral RNA.** DNA can be measured from biopsy material using polymerase chain reaction (PCR). Specific diagnosis requires demonstration of active viral replication within myocardial tissue.

**Management**

The underlying cause must be identified, treated, eliminated or avoided. Bed rest is recommended in the acute phase of the illness and athletic activities should be avoided for 6 months. Heart failure should be treated conventionally with the use of diuretics, ACE inhibitors/angiotensin II receptor antagonists, beta-blockers or spironolactone with or without digoxin. **Antibiotics** should be administered immediately where appropriate. Non-steroidal anti-inflammatory drugs (NSAIDs) are contraindicated in the acute phase of the illness but may be used in the late phase. The use of **corticosteroids** is controversial and no studies have demonstrated an improvement in left ventricular ejection fraction or survival following their use. The administration of high-dose intravenous **immunoglobulin**, on the other hand, appears to be associated with a more rapid resolution of the left ventricular dysfunction and improved survival. Effective antiviral, immunosuppressive (e.g. interferon-gamma) and **immunomodulating** (e.g. interleukin-10) agents are available to treat viral myocarditis.

**Giant cell myocarditis**

This is a severe form of myocarditis characterized by the presence of multinucleated giant cells within the myocardium. The cause is unknown but it may be associated with sarcoidosis, thymomas and autoimmune disease. It has a rapidly progressive course and a poor prognosis. Immunosuppression is recommended.

**Chagas' disease**

Chagas' disease is caused by the protozoan *Trypanosoma cruzi* and is endemic in South
America, where upwards of 20 million people are infected. Acutely, features of myocarditis are present with fever and congestive heart failure. Chronically, there is progression to a dilated cardiomyopathy with a propensity towards heart block and ventricular arrhythmias. Treatment is discussed on page 303. Amiodarone is helpful for the control of ventricular arrhythmias; heart failure is treated in the usual way (see pp. 985–987).

**Cardiomyopathy**

Cardiomyopathies are a group of diseases of the myocardium that affect the mechanical or electrical function of the heart. They are frequently genetic and a reclassification through the World Health Federation has endorsed the MOGE(S) nomenclature. This classification incorporates morphological phenotype, organ or system involvement, genetics, aetiological annotation and stage of clinical function. This will aid understanding of the complexity of the inherited cardiomyopathies with the hope of integrating genotype assessment to individualize therapy. Clinically, these diseases can be divided into hypertrophic cardiomyopathy (HCM), arrhythmogenic cardiomyopathies (ACs) and dilated cardiomyopathy (DCM).

Secondary cardiomyopathies cover a wide range of aetiologies: infiltrative (e.g. amyloidosis, Gaucher's disease); storage-related (e.g. haemochromatosis); drugs (e.g. alcohol); inflammatory (e.g. sarcoidosis); neuromuscular (e.g. Friedreich's ataxia); nutritional (e.g. beriberi); autoimmune (e.g. systemic lupus erythematosus); and cancer therapy (e.g. anthracyclines – doxorubicin).

**Inherited cardiomyopathies**

**Hypertrophic cardiomyopathy**

Hypertrophic cardiomyopathy (HCM) includes a group of inherited conditions that produce hypertrophy of the myocardium in the absence of an alternative cause (e.g. aortic stenosis or hypertension). It is the most common cause of sudden cardiac death in young people and affects 1 in 500 of the population. The majority of cases are familial autosomal dominant, due to mutations in the genes encoding sarcomeric proteins (*Fig. 23.108*). The most common causes of HCM are mutations of the β-myosin heavy chain MYH7 and myosin-binding protein C MYBPC3. Other mutations include troponin T and I, regulatory and essential myosin light chains, titin, α-tropomyosin, α-actin, α-myosin heavy chain and muscle LIM protein (although over 400 mutations have been identified.) There are non-sarcomeric protein mutations in genes that control cardiac metabolism, which result in glycogen storage diseases (Danon's, Pompe's and Fabry's diseases) that are indistinguishable from HCM.
Clinical features

HCM is characterized by variable myocardial hypertrophy that frequently involves the interventricular septum, and by disorganization (‘disarray’) of cardiac myocytes and myofibrils. Some 25% of patients have dynamic left ventricular outflow tract obstruction due to the combined effects of hypertrophy, systolic anterior motion (SAM) of the anterior mitral valve leaflet and rapid ventricular ejection. The salient clinical and morphological features of the disease vary according to the underlying genetic mutation. For example, marked hypertrophy is common with β-myosin heavy chain mutations, whereas mutations in troponin T may be associated with mild hypertrophy but a high risk of sudden death. The hypertrophy may not manifest before completion of the adolescent growth spurt, making the diagnosis difficult in children. HCM due to myosin-binding protein may not manifest until the sixth decade of life or later.

Symptoms

- Many cases are asymptomatic and are detected by family screening of an affected individual or by a routine ECG examination.
- Chest pain, dyspnoea, syncope or pre-syncope (typically with exertion), cardiac arrhythmias and sudden death are seen.
- Sudden death occurs at any age but the highest rates (up to 6% per annum) occur in
adolescents or young adults. Risk factors for sudden death are discussed below.

- **Dyspnoea** occurs due to impaired relaxation of the heart muscle or the left ventricular outflow tract obstruction that occurs in some patients. The systolic cavity remains small until the late stages of disease, when progressive dilatation may occur. If a patient develops atrial fibrillation, there is often a rapid deterioration in clinical status due to the loss of atrial contraction and the tachycardia – resulting in elevated left atrial pressure and acute pulmonary oedema.

### Signs

- Double apical pulsation (forceful atrial contraction producing a fourth heart sound).
- Jerky carotid pulse because of rapid ejection and sudden obstruction to left ventricular outflow during systole.
- Ejection systolic murmur due to left ventricular outflow obstruction late in systole; it can be increased by manoeuvres that decrease afterload, such as standing or Valsalva, and decreased by manoeuvres that increase afterload and venous return, such as squatting.
- Pansystolic murmur due to mitral regurgitation (secondary to SAM).
- Fourth heart sound (if not in atrial fibrillation).

### Investigations

- **ECG** abnormalities in HCM include left ventricular hypertrophy (see *Fig. 23.79*), ST- and T-wave changes, and abnormal Q waves, especially in the inferolateral leads.
- **Echocardiography** is usually diagnostic. In classical HCM, there is asymmetric left ventricular hypertrophy (involving the septum more than the posterior wall), systolic anterior motion of the mitral valve, and a vigorously contracting ventricle (*Fig. 23.109*). However, any pattern of hypertrophy may be seen, including concentric and apical hypertrophy.
Hypertrophic cardiomyopathy. A two-dimensional echocardiogram (short-axis view). The grossly thickened interventricular septum is shown, resulting in a small left ventricular cavity. This condition is associated with an abnormal anterior motion of the mitral valve during systole (arrows). LA, left atrium; LV, left ventricle.

- **CMR** can detect both the hypertrophy and abnormal myocardial fibrosis (*Fig. 23.110*).

**FIGURE 23.110** Cardiac magnetic resonance imaging in a patient with hypertrophic cardiomyopathy. A. Turbo spin-echo demonstrates marked thickening of the basal to mid-anterior wall and septum (*). B. Inversion recovery image post gadolinium demonstrates regional fibrosis with enhancement (+).

- **Genetic analysis**, where available, may confirm the diagnosis and provide prognostic information for the patient and relatives.

Management
The management of HCM includes treatment of symptoms and prevention of sudden cardiac death in the patient and relatives.

Risk factors for sudden death are as follows:

- massive left ventricular hypertrophy (>30 mm on echocardiography)
- family history of sudden cardiac death (<50 years old)
- non-sustained ventricular tachycardia on 24-hour Holter monitoring
- prior unexplained syncope
- abnormal blood pressure response on exercise (flat or hypotensive response).

The presence of these cardiac risk factors is associated with an increased risk of sudden death (Box 23.54), and patients with two or more should be assessed for ICD insertion. When the risk is less, amiodarone is an appropriate alternative.

### Box 23.54

**Causes of sudden cardiac death**

#### Coronary artery disease

- Acute myocardial infarction – STEMI
- Chronic ischaemic heart disease
- Following coronary artery bypass surgery
- After successful resuscitation for cardiac arrest
- Congenital anomaly of coronary arteries
- Coronary artery embolism
- Coronary arteritis

#### Non-coronary artery disease

- Hypertrophic cardiomyopathy
- Dilated cardiomyopathy (ischaemic or idiopathic)
- Arrhythmogenic right ventricular cardiomyopathy
- Congenital long QT syndrome
- Brugada syndrome
- Valvular heart disease (aortic stenosis, mitral valve prolapse) ± infective endocarditis
- Cyanotic heart disease (tetralogy of Fallot, transposition)
- Acyanotic heart disease (ventricular septal defect, patent ductus arteriosus)

**STEMI**, ST elevation myocardial infarction.

Chest pain and dyspnoea are treated with beta-blockers and verapamil, either alone or in
combination. An alternative agent is disopyramide if patients have left ventricular outflow tract obstruction. In some individuals with significant left outflow obstruction and symptoms, dual-chamber pacing is necessary. Alcohol (non-surgical) ablation of the septum has been investigated and appears to give good results in reduction of outflow tract obstruction and subsequent improvement in exercise capacity. This procedure carries risks, including the development of complete heart block and MI. Occasionally, surgical resection of septal myocardium may be indicated. Vasodilators should be avoided because they may aggravate left ventricular outflow obstruction or cause refractory hypotension.

**Arrhythmogenic cardiomyopathy/arrhythmogenic right ventricular cardiomyopathy**

Arrhythmogenic cardiomyopathy (ACM) is an uncommon (1 in 1000–5000 population) inherited condition that predominantly affects the right ventricle with fatty or fibro-fatty replacement of myocytes, leading to segmental or global dilatation *(Fig. 23.11)*. Left ventricular involvement has been reported in up to 75% of cases. The fibro-fatty replacement leads to ventricular arrhythmia and risk of sudden death in its early stages, and right ventricular or biventricular failure in its later stages.
Autosomal dominant ACM has been mapped to mutations in genes coding for desmosomal proteins. These are the cardiac ryanodine receptor RyR2 (also responsible for familial catecholaminergic polymorphic ventricular tachycardia, CPVT), desmoplakin, plakophilin-2 and mutations altering the regulatory sequences of the transforming growth factor-β gene.

There are two recessive forms: Naxos disease (associated with palmoplantar keratoderma and woolly hair), which is due to a mutation in junctional plakoglobin, and Carvajal syndrome, due to a mutation in desmoplakin.

### Clinical features

Most patients are asymptomatic. Symptomatic ventricular arrhythmia, syncope or sudden death occurs. Occasionally, presentation is with symptoms and signs of right heart failure, although this is more common in the later stages of the disease. Some patients may be detected through family screening, although frequently the morphological appearance of the right ventricle is normal, despite significant cardiac arrhythmias.
Investigations and diagnosis

- **ECG** is usually normal but may demonstrate T-wave inversion in the precordial leads related to the right ventricle ($V_1-V_3$). Small-amplitude potentials occurring at the end of the QRS complex (epsilon waves) may be present (Fig. 23.112), and incomplete or complete right bundle branch block is sometimes seen. Signal-averaged ECG may indicate the presence of late potentials, and the delayed depolarization of individual muscle cells; 24-hour Holter monitoring may demonstrate frequent extrasystoles of right ventricular origin or runs of non-sustained ventricular tachycardia.

![FIGURE 23.112](image1) Electrocardiogram from an adult with arrhythmogenic cardiomyopathy. The ECG demonstrates right bundle branch block and precordial T-wave insertion, with epsilon waves visible at the terminal of the QRS complex (arrowed).

- **Echocardiography** is frequently normal but with more advanced cases may demonstrate right ventricular dilatation and aneurysm formation; there may be left ventricular dilatation.

- **CMR** can assess the right ventricle more accurately and in some cases can demonstrate fibro-fatty infiltration (Fig. 23.113).

![FIGURE 23.113](image2) Arrhythmogenic cardiomyopathy (ACM). Inversion recovery magnetic resonance image post gadolinium demonstrates marked hyper-enhancement (arrowed) in the right ventricular free wall and infero-septum consistent with fibro-fatty replacement in right ventricle (RV) and left ventricle (LV).

- **Genetic testing** may soon be the diagnostic ‘gold standard’.

Clinical diagnosis is made using Task Force Criteria, which include structural abnormalities of the right ventricle and right ventricular outflow tract (dilatation and abnormal wall motion...
on echocardiography or MRI), fibro-fatty replacement of myocytes on tissue biopsy, repolarization and conduction abnormalities on ECG or signal-averaged ECG, ventricular tachycardia or frequent ventricular extrasystoles on Holter monitoring, family history of ACM in a first- or second-degree relative, or premature sudden death (<35 years) due to ACM.

### Management

Beta-blockers are first-line treatment for patients with non-life-threatening arrhythmias. Amiodarone or sotalol is used for symptomatic arrhythmias but for refractory or life-threatening arrhythmias an ICD is required. Occasionally, cardiac transplantation is indicated for either intractable arrhythmia or cardiac failure.

### Dilated cardiomyopathy

Dilated cardiomyopathy (DCM) has a prevalence of 7–12 in 100 000 and is characterized by dilatation of the ventricular chambers and systolic dysfunction with preserved wall thickness.

**Familial DCM** is predominantly autosomal dominant and can be associated with over 20 abnormal loci and genes ([Fig. 23.114](#)). Many of these are genes encoding cytoskeletal or associated myocyte proteins (dystrophin in X-linked cardiomyopathy; actin, desmin, troponin T, β-myosin heavy chain, sarcoglycans, vinculin and lamin a/c in autosomal dominant DCM; [Fig. 23.115](#)). Many of these have prominent associated features, such as skeletal myopathy or conduction system disease, and therefore differ from the majority of cases of DCM.

![FIGURE 23.114](#) Pedigree of a family with dilated cardiomyopathy. Blue symbols are affected family members. The arrow indicates the index case.
Sporadic DCM can be caused by multiple conditions:

- myocarditis – Coxsackievirus, adenoviruses, erythroviruses, HIV, bacteria, fungi, mycobacteria, parasitic (Chagas’ disease)
- toxins – alcohol, chemotherapy, metals (cobalt, lead, mercury, arsenic)
- autoimmune disorders
- endocrine disorders
- neuromuscular disorders.

Clinical features

DCM can present with heart failure, cardiac arrhythmias, conduction defects, thromboembolism or sudden death. Increasingly, evaluation of relatives of DCM patients is allowing identification of early asymptomatic disease, prior to the onset of these complications. Clinical evaluation should include a family history and construction of a pedigree where appropriate.

Investigations

- **Chest X-ray** demonstrates generalized cardiac enlargement.
- **ECG** may demonstrate diffuse non-specific ST-segment and T-wave changes. Sinus tachycardia, conduction abnormalities and arrhythmias (i.e. atrial fibrillation, ventricular premature contractions or ventricular tachycardia) are also seen.
- **Echocardiogram** reveals dilatation of the left and/or right ventricle with poor global contraction function (**Fig. 23.116**).
FIGURE 23.116 Dilated cardiomyopathy. A. Two-dimensional (apical four-chamber view) echocardiogram. B. M-mode echocardiogram. The heart has a ‘globular’ appearance with all four chambers dilated. The extremely impaired left ventricular function can be appreciated from the M-mode recording. Compare the systolic shortening fraction with that of Figure 23.23. IVS, interventricular septum; LA, left atrium; LV, left ventricle; LV(d), left ventricle (diastole); LV(s), left ventricle (systole); PVW, posterior ventricular wall; RA, right atrium.

• **CMR** may demonstrate other aetiologies of left ventricular dysfunction (e.g. previous MI) or show abnormal myocardial fibrosis (**Fig. 23.117**).
Dilated cardiomyopathy. Inversion recovery magnetic resonance scan post gadolinium demonstrates septal mid-wall hyper-enhancement (arrowed) consistent with fibrosis in a patient with dilated cardiomyopathy.

• **Coronary angiography** should be performed to exclude coronary artery disease in all individuals at risk (generally, patients >40 years, or younger if symptoms or risk factors are present).

• **Biopsy** is not normally indicated outside specialist care.

### Management

Treatment consists of the conventional management of heart failure with the option of cardiac resynchronization therapy and ICDs in patients with NYHA III/IV grading. Cardiac transplantation is appropriate for certain patients.

### Left ventricular non-compaction

Left ventricular non-compaction (LVNC) is associated with a sponge-like appearance of the left ventricle. The condition predominantly affects the apical portion of the left ventricle and may be associated with congenital heart abnormalities. LVNC is diagnosed by echocardiography, CMR or left ventricular angiography. The natural history of the condition is unresolved but includes congestive cardiac failure, thromboembolism, cardiac arrhythmias and sudden death. Familial and spontaneous cases have been described.

### Primary restrictive non-hypertrophic cardiomyopathy

This is a rare condition in which there is normal or decreased volume of both ventricles with bi-atrial enlargement, normal wall thickness, normal cardiac valves and impaired ventricular filling with restrictive physiology but near-normal systolic function. The restrictive physiology produces symptoms and signs of heart failure. Conditions associated with this form of cardiomyopathy include amyloidosis (most common), sarcoidosis, Loeffler's endocarditis and endomyocardial fibrosis; in the latter two conditions, there is myocardial and endocardial
fibrosis, associated with eosinophilia. The idiopathic form of restrictive cardiomyopathy may be familial.

Clinical features

Patients with restrictive cardiomyopathy may present with dyspnoea, fatigue and embolic symptoms. On clinical examination, there will be elevated JVP with diastolic collapse (Friedreich's sign) and elevation of venous pressure with inspiration (Kussmaul's sign), hepatic enlargement, ascites and dependent oedema. Third and fourth heart sounds may be present.

Investigations

- **Chest X-ray** may show pulmonary venous congestion. The cardiac silhouette can be normal or show cardiomegaly and/or atrial enlargement.
- **ECG** may demonstrate low-voltage QRS and ST-segment and T-wave abnormalities.
- **Echocardiography** shows symmetrical myocardial thickening and often a normal systolic ejection fraction, but impaired ventricular filling. In amyloid patients, the myocardium typically appears speckled with absent radial thickening, as demonstrated by ‘tramlines’ on M-mode echocardiography *(Fig. 23.118)*.
Amyloid.

A. Parasternal long-axis echocardiogram demonstrating left ventricular hypertrophy with reduced systolic function. The septum has a speckled appearance (arrowed). B. M-mode echocardiogram demonstrates reduced septal thickening with a ‘tramline’ appearance (arrowed). These features are suggestive of cardiac amyloid – confirmed on cardiac biopsy. LA, left atrium; LV, left ventricle.

- **CMR** may demonstrate abnormal myocardial fibrosis in amyloidosis or sarcoidosis.
- **Cardiac catheterization** and haemodynamic studies may help distinguish between restrictive cardiomyopathy and constrictive pericarditis, although volume loading may be required.
- **Endomyocardial biopsy** in this condition is often useful, in contrast to other cardiomyopathies, and may permit a specific diagnosis, such as amyloidosis, to be made.

## Management

There is no specific treatment. Cardiac failure and embolic manifestations should be treated. Cardiac transplantation is necessary in some severe cases, especially the idiopathic variety. In primary amyloidosis, combination therapy with melphalan plus prednisolone, with or without colchicine, may improve survival. However, patients with cardiac amyloidosis have a worse prognosis than those with other forms of the disease, and the disease often recurs after
transplantation. Liver transplantation may be effective in familial amyloidosis (due to production of mutant pre-albumin) and may lead to reversal of the cardiac abnormalities.

**Acquired cardiomyopathies**

**Stress (Tako-tsubo/octopus pot/apical ballooning syndrome) cardiomyopathy**

Patients with this condition present acutely with chest pain and breathlessness associated with ECG changes and elevated cardiac biomarkers consistent with acute MI. Diagnostic coronary angiography typically demonstrates unobstructed coronary arteries, with characteristic akinesia of the mid-apical segments of the left ventricle on ventriculography or echocardiography, and preserved basal function (*Fig. 23.119*). The pathophysiology is uncertain but disease may be due to transient catecholamine excess, coronary vasospasm, abnormalities of the coronary microcirculation and hypertrophy of the basal septum. The syndrome is more common in middle-aged to elderly women. Severe cases may have cardiogenic shock and pulmonary oedema. Patients with a significant left ventricular gradient may respond to cautious beta-blockade. Complete recovery of function is usual within 4–6 weeks but recurrences occur.

![Fig. 23.119 Tako-tsubo cardiomyopathy. Left ventricular angiography in a patient admitted with chest pain following emotional stress demonstrates apical ballooning (arrowed) consistent with Tako-tsubo cardiomyopathy. Diagnostic coronary angiography showed normal coronary arteries.](image)

**Peripartum cardiomyopathy**

This rare condition affects women in the last trimester of pregnancy or within 5 months of delivery. It presents as a dilated cardiomyopathy, is more common in obese, multiparous
women over 30 years old, and is associated with pre-eclampsia. Nearly half of patients will recover to normal function within 6 months but in some it can cause progressive heart failure and sudden death.

**Tachycardia cardiomyopathy**

Prolonged periods of supraventricular or ventricular tachycardia will lead to dilated cardiomyopathy. Cardioversion and ablation may be necessary to restore sinus rhythm and allow for recovery of cardiac function.

**Further reading**

**Pericardial Disease**

The pericardium acts as a protective covering for the heart. It consists of an outer fibrous pericardial sac and an inner serous pericardium; the latter is made up of the inner visceral epicardium that lines the heart and great vessels, and its reflection, the outer parietal pericardium that lines the fibrous sac. The normal amount of pericardial fluid is 20–49 mL and this fluid lubricates the surface of the heart. Presentations of pericardial disease include:

- acute and relapsing pericarditis
- pericardial effusion and cardiac tamponade
- constrictive pericarditis.

**Acute pericarditis**

This term refers to inflammation of the pericardium. Classically, fibrinous material is deposited into the pericardial space and pericardial effusion often occurs. Acute pericarditis has numerous aetiologies *(Box 23.55)*, although, in most cases, a cause is not identified (idiopathic).

**Box 23.55**

**Aetiology of pericarditis**

I. Infectious pericarditis
   - Viral (Coxsackievirus, echovirus, mumps, herpes, HIV)
   - Bacterial (staphylococcal, streptococcal, pneumococcal and meningococcal infections,
Viral pericarditis

The most common viral causes are Coxsackie B virus and echovirus. Viral pericarditis is usually painful but follows a short time course and rarely has long-term effects. Increasingly, HIV is implicated in the aetiology of pericarditis, both directly and via immunosuppression, which predisposes the subject to infective causes.

Bacterial pericarditis

This may rarely occur with septicaemia or pneumonia, may stem from an early postoperative infection after thoracic surgery or trauma, or may complicate endocarditis. *Staphylococcus aureus* is a frequent cause of purulent pericarditis in HIV patients. This form of pericarditis, especially staphylococcal, is fulminant and often fatal.

Other endemic infectious types of pericarditis include mycoplasmosis and Lyme pericarditis, which are often effusive and require pericardial drainage. The diagnosis is based on serological tests of pericardial fluid and identification of organisms in pericardial or myocardial biopsies.

Tuberculous pericarditis
This usually presents with chronic low-grade fever, particularly in the evening, associated with features of acute pericarditis, dyspnoea, malaise, night sweats and weight loss. Pericardial aspiration is often required to make the diagnosis. Constrictive pericarditis is a frequent outcome. Treatment is as for pulmonary tuberculosis (see pp. 1110–1113) with added prednisolone 60 mg daily for 2–6 weeks.

**Fungal pericarditis**

Pericarditis is a common complication of endemic fungal infections, such as histoplasmosis and coccidioidomycosis, but may be also caused by *Candida albicans*, especially in immunocompromised patients and drug addicts, or after cardiac surgery.

**Post-myocardial infarction pericarditis**

This occurs in about 20% of patients in the first few days following MI. It is more common with anterior MI and STEMI with high serum cardiac enzymes, but its incidence is reduced to 5–6% with thrombolysis. It may be difficult to differentiate this pain from recurrent angina when it occurs early (day 1–2 post infarct) but a good history of the pain and serial ECG monitoring are helpful. Pericarditis may also be present later on in the recovery phase after infarction. It is usually a feature of *Dressler syndrome*, an autoimmune response to cardiac damage occurring 2–10 weeks' post infarct. Autoimmune reaction to myocardial damage is the main aetiology, and antmyocardial antibodies can often be found. Recurrences are common. Differential diagnosis includes new MI or unstable angina.

**Malignant pericarditis**

*Carcinoma of the bronchus, carcinoma of the breast* and *Hodgkin's lymphoma* are the most common causes of malignant pericarditis. Leukaemia and malignant melanoma are also associated with pericarditis. A substantial pericardial effusion is very typical and is due to obstruction of the lymphatic drainage from the heart. The effusion is often haemorrhagic. Radiation and therapy for thoracic tumours may cause radiation injury to the pericardium, resulting in serous or haemorrhagic pericardial effusion and pericardial fibrosis. Absence of neoplastic cells in the pericardial fluid in these conditions often helps diagnosis.

**Uraemic pericarditis**

This is due to irritation of the pericardium by accumulating toxins. It can occur in 6–10% of patients with advanced kidney disease if dialysis is delayed. It is an indication for urgent dialysis, as it continues to be associated with significant morbidity and mortality.

**Clinical features**

Pericardial inflammation produces sharp central chest pain that is exacerbated by movement, respiration and lying down. It is typically relieved by sitting forwards. It may be referred to the neck or shoulders. The main differential diagnoses are angina and pleurisy. The classical
Clinical sign is a pericardial friction rub occurring in three phases that correspond to atrial systole, ventricular systole and ventricular diastole. It may also be heard as a biphasic ‘to-and-fro’ rub. The rub is heard best with the diaphragm of the stethoscope at the lower left sternal edge at the end of expiration with the patient leaning forwards. There is usually a fever, leucocytosis or lymphocytosis when pericarditis is due to viral or bacterial infection, rheumatic fever or MI. Features of a pericardial effusion may also be present. Large pericardial effusion can compress adjacent bronchi and lung tissue and may cause dyspnoea.

**Investigations**

ECG is diagnostic. There is widespread concave-upwards (saddle-shaped) ST elevation (Fig. 23.120), reciprocal ST depression in leads AVR and V\(_1\), and PR segment depression. These changes evolve over time, with resolution of the ST elevation, T-wave flattening/inversion and, finally, T-wave normalization. The early ECG changes must be differentiated from the ST elevation found in MI, which is limited to the infarcted area: for example, anterior or inferior. Sinus tachycardia may result from fever or haemodynamic embarrassment, and rhythm and conduction abnormalities may be present if myocardium is involved. Cardiac enzymes may be elevated if there is associated myocarditis (see pp. 1036–1037). Chest X-ray may demonstrate cardiomegaly (in cases with an effusion), which should be confirmed with echocardiography. CT and CMR may be helpful in cases with thickened (>4 mm) or inflamed (abnormal delayed enhancement) pericardium.
FIGURE 23.120 Electrocardiograms associated with pericarditis. A. Acute pericarditis. Note the raised ST segment, concave upwards (arrowed). B. Chronic phase of pericarditis associated with a pericardial effusion. Note the T-wave flattening and inversion, and the alternation of the QRS amplitude (QRS alternans). C. The same patient after evacuation of the pericardial fluid. Note that the QRS voltage has increased and the T waves have returned to normal.

Management

If a cause is found, this should be treated. Bed rest and oral NSAIDs (high-dose aspirin, indometacin or ibuprofen) are effective in most patients. Aspirin is the drug of choice for patients with a recent MI. Colchicine is also effective in combination with conventional therapy, as demonstrated in the COPE trial. Corticosteroids should be reserved for patients with a known immune cause, as their use is associated with an increased rate of recurrence.
Recurrent or relapsing pericarditis

About 20% of cases of acute pericarditis go on to develop idiopathic relapsing pericarditis, which may be incessant (recurring within 6 weeks during weaning off NSAIDs) or intermittent (recurs >6 weeks after the initial presentation). The first-line treatment is, again, oral NSAIDs. The trial of colchicine as first-choice therapy for recurrent pericarditis demonstrated that prolonged colchicine (for 6 months) was more effective than aspirin alone in reducing recurrence. In resistant cases, oral corticosteroids may be effective, and in some patients, pericardiectomy may be appropriate.

Pericardial effusion and cardiac tamponade

A pericardial effusion is a collection of fluid within the potential space of the serous pericardial sac (Fig. 23.121); it commonly accompanies an episode of acute pericarditis. When a large volume collects in this space, ventricular filling is compromised, leading to embarrassment of the circulation. This is known as cardiac tamponade.

Clinical features

Symptoms of a pericardial effusion commonly reflect the underlying pericarditis. On examination:

- Heart sounds are soft and distant.
• Apex beat is commonly obscured.
• A friction rub may be evident due to pericarditis in the early stages, but this becomes quieter as fluid accumulates and pushes the layers of the pericardium apart.
• Rarely, the effusion may compress the base of the left lung, producing an area of dullness to percussion below the angle of the left scapula (Ewart's sign).
• As the effusion worsens, signs of cardiac tamponade may become evident:
  – Raised JVP with sharp rise and y descent (Friedreich's sign)
  – Kussmaul's sign (rise in JVP/increased neck vein distension during inspiration)
  – Pulsus paradoxus (an exaggeration in the normal variation in pulse pressure seen with inspiration, such that there is a drop in systolic blood pressure of ≥10 mmHg)
  – Reduced cardiac output.

### Investigations

• **ECG** reveals low-voltage QRS complexes (<0.5 mV in limb leads) with sinus tachycardia and there may be electric alternans (alteration of QRS amplitude or axis between beats).

• **Chest X-ray (Fig. 23.121)** shows a large, globular or pear-shaped heart with sharp outlines. Typically, the pulmonary veins are not distended.

• **Echocardiography (Fig. 23.122)** is the most useful technique for demonstrating the effusion and looking for evidence of tamponade – late diastolic collapse of the right atrium, early diastolic collapse of the right ventricle, ventricular septum displacement into the left ventricle during inspiration, diastolic flow reversal in the hepatic veins during expiration, dilated inferior vena cava with <50% reduction during inspiration.
Two-dimensional echocardiogram (short-axis view) from a patient with a large pericardial effusion associated with pulmonary tuberculosis. The exudate is seen between the visceral and parietal layers of the pericardium and would give a false impression of cardiomegaly on a chest X-ray. Note the multiple fibrous strands within the effusion, showing that it is consolidating and will probably lead to constriction of cardiac function. LA, left atrium; LV, left ventricle; PE, pericardial effusion; RA, right atrium; RV, right ventricle.

- **Cardiac CT or MRI** is helpful if loculated pericardial effusions are suspected (post cardiac surgery).
- **Pericardiocentesis** is the removal of pericardial fluid with an aseptic technique under echocardiographic guidance (see Fig. 23.26). It is indicated when a tuberculous, malignant or purulent effusion is suspected.
- **Pericardial biopsy** may be needed if tuberculosis is suspected and pericardiocentesis is not diagnostic.

Other tests may be needed to identify underlying causes: for example, blood cultures or autoantibody screen.

**Management**

An underlying cause should be sought and treated if possible. Most pericardial effusions resolve spontaneously. However, when the effusion collects rapidly, tamponade may result. Pericardiocentesis is then indicated to relieve the pressure; a drain may be left in place temporarily to allow sufficient release of fluid. Pericardial effusions may re-accumulate, most commonly due to malignancy (in the UK). This may require pericardial fenestration: that is, creation of a window in the pericardium to allow the slow release of fluid into the surrounding tissues. This procedure may be performed either transcutaneously under local anaesthetic or using a conventional surgical approach.

**Constrictive pericarditis**

Certain causes of pericarditis, such as tuberculosis, haemopericardium, bacterial infection and rheumatic heart disease, result in the pericardium becoming thick, fibrous and calcified. This
may also develop late after open heart surgery, and fibrosis also occurs with the use of
dopamine agonists, such as cabergoline and pergolide. In many cases, these pericardial
changes do not cause any symptoms. If, however, the pericardium becomes so inelastic as to
interfere with diastolic filling of the heart, constrictive pericarditis is said to have developed.
As these changes are chronic, allowing the body time to compensate, this condition is not as
immediately life-threatening as cardiac tamponade, in which the circulation is more acutely
embarrassed.

Constrictive pericarditis should be distinguished from restrictive cardiomyopathy (see pp.
1041–1042). The two conditions are very similar in their presentation, but the former is fully
treatable, whereas most cases of the latter are not. In the later stages of constrictive
pericarditis, the sub-epicardial layers of myocardium may undergo fibrosis, atrophy and
calcification.

### Clinical features

The symptoms and signs of constrictive pericarditis occur due to:

- reduced ventricular filling (similar to cardiac tamponade, i.e. Kussmaul's sign, Friedreich's
  sign, pulsus paradoxus)
- systemic venous congestion (ascites, dependent oedema, hepatomegaly and raised JVP)
- pulmonary venous congestion (dyspnoea, cough, orthopnoea, paroxysmal nocturnal
dyspnoea), less commonly
- reduced cardiac output (fatigue, hypotension, reflex tachycardia)
- rapid ventricular filling (‘pericardial knock’ heard in early diastole at the lower left sternal
  border)
- atrial dilatation (30% of cases have atrial fibrillation).

### Investigations

- **Chest X-ray** shows a relatively small heart in view of the symptoms of heart failure.
  Pericardial calcification may be present in up to 50%. A lateral chest film may be useful for
detecting calcification that is missed on a postero-anterior film. However, a calcified
pericardium is not necessarily a constricted one.
- **ECG** reveals low-voltage QRS complexes with generalized T-wave flattening or inversion.
- **Echocardiography** shows thickened, calcified pericardium, and small ventricular cavities
  with normal wall thickness. Doppler studies may be useful.
- **CT and CMR** are used to assess pericardial anatomy and thickness (≥4 mm) (see *Fig. 23.28*).
- **Endomyocardial biopsy** may be helpful in distinguishing constrictive pericarditis from
  restrictive cardiomyopathy in difficult cases.
• **Cardiac catheterization** will usually reveal equal end-diastolic pressures in the left and right ventricles, owing to pericardial constriction.

Restrictive cardiomyopathy is a close mimic of constrictive pericarditis and all the above tests may help to distinguish the two conditions.

**Management**

The treatment for chronic constrictive pericarditis is complete resection of the pericardium. This is a risky procedure with a high complication rate due to the presence of myocardial atrophy in many cases at the time of surgery. Thus, early pericardiectomy is suggested in non-tuberculous cases, before severe constriction and myocardial atrophy have developed.

In cases of tuberculous constriction, the presence of pericardial calcification implies chronic disease. Early pericardiectomy with antituberculous drug cover is used in these cases. If there is no calcification, a course of antituberculous therapy should be attempted first. If the patient's haemodynamic state remains static or deteriorates after 4–6 weeks of therapy, pericardiectomy is recommended.

**Further reading**

**Systemic Hypertension**

High blood pressure (hypertension) is a major cause of premature vascular disease, leading to cerebrovascular events, ischaemic heart disease and peripheral vascular disease. Blood pressure (BP) is normally distributed in the population and mortality rises with increasing BP. The prevalence of hypertension may be 30–45% of the general population.

**Diagnosis**

BP should be measured in a quiet room; the patient should be seated, with an outstretched and supported arm. An automated machine with an appropriate cuff size is recommended. If postural hypotension (reduction in systolic BP of ≥20 mmHg) is suspected, then BP should be repeated after 1 minute of standing. In the UK, NICE recommends that ambulatory blood pressure monitoring (ABPM) is offered to patients with a clinic BP of ≥140/90 mmHg to confirm the diagnosis of hypertension. Home blood pressure monitoring (HBPM) can also be used.
• **Stage 1 hypertension** – clinic BP ≥140/90 mmHg and daytime average ABPM or HBPM ≥135/85 mmHg.

• **Stage 2 hypertension** – clinic BP ≥160/100 mmHg and daytime average ABPM or HBPM ≥150/95 mmHg.

• **Severe hypertension** – clinic systolic BP ≥180 mmHg and/or diastolic BP ≥110 mmHg.

Patients with a diagnosis of hypertension should have their cardiovascular risk assessed using an appropriate calculator. NICE recommends QRISK®2-2015 but the European Society of Cardiology/European Association for Cardiovascular Prevention and Rehabilitation's ‘Heartscore’ is an alternative.

### Investigations

• **Urinalysis** for protein, albumin : creatinine ratio and haematuria.

• **Blood tests** for glucose, electrolytes, creatinine, estimated glomerular filtration rate (eGFR), and total and HDL cholesterol.

• **Fundoscopy** to detect hypertensive retinopathy:
  – Grade 1 – tortuosity of the retinal arteries with increased reflectiveness (silver wiring)
  – Grade 2 – grade 1 plus the appearance of arteriovenous nipping, produced when thickened retinal arteries pass over the retinal veins
  – Grade 3 – grade 2 plus flame-shaped haemorrhages and soft (‘cotton wool’) exudates due to small infarcts
  – Grade 4 – grade 3 plus papilloedema (blurring of the optic disc; *[Fig. 23.123](#)*).
A 12-lead ECG to detect left ventricular hypertrophy (see Fig. 23.79).

The clinical history and examination may suggest a secondary cause of hypertension (Box 23.56), and referral to a specialist for specific investigations is recommended.

(From The Task Force for the management of arterial hypertension of the European Society of Hypertension)
Management

**Lifestyle intervention**

The following lifestyle changes are recommended in patients with hypertension:

- **diet**: high consumption of vegetables and fruits and low-fat diet
- **regular physical exercise** (30 min of moderate-intensity aerobic exercise 5–7 days/week)
- **reduction of alcohol intake** (<140 g/week men, <80 g/week women)
- **reduction of dietary sodium intake** (5–6 g/day) and use of low-sodium salt
- **smoking cessation**
- **weight reduction** (BMI 25 kg/m², waist circumference <102 cm men, <88 cm women).

**Pharmacological therapy**

NICE guidance *(Fig. 23.124)* recommends that treatment should be offered to all people under 80 years of age with stage 1 hypertension and at least one of the following risk factors:

- target organ damage *(Fig. 23.125)*
- cardiovascular disease
- renal disease
- diabetes
- 10-year cardiovascular risk ≥20%.
FIGURE 23.124 Hypertension treatment algorithm. *Thiazide-like diuretic if a calcium-channel blocker is not tolerated or is contraindicated. ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker. (From National Institute for Health and Care Excellence 2011 CG127 Hypertension: The Clinical Management of Primary Hypertension in Adults. London: NICE, with permission.)
Patients under 40 years old with no risk factors should be referred to a specialist to exclude secondary causes of hypertension. All patients with stage 2 hypertension should be offered treatment. Using clinic BP, the target for treated patients is <140/90 mmHg in patients below 80 years of age, and <150/90 mmHg in patients of 80 years and above. In patients with ‘white-coat’ hypertension (Fig. 23.126), ABPM or HBPM may be more appropriate, with targets of <135/85 mmHg (below 80 years) and <145/85 mmHg (80 years and above). A recent study (SPRINT) found that in patients with hypertension but without diabetes, reducing systolic BP to a target of <120 mmHg reduced the rates of fatal and non-fatal cardiovascular events and death from any cause. A more recent study suggests a systolic BP of <130 mmHg is optimal in people with co-morbidities of renal, cardiovascular diseases and diabetes.
Step 1
First-line therapy for patients under 55 years is an ACE inhibitor, such as enalapril, or a low-cost ARB, such as candesartan. In young women of childbearing potential, treatment with beta-blockers may be preferred (Box 23.57). Patients aged 55 years and above, and black African or Caribbean patients, should be treated with a calcium-channel blocker, such as amlodipine (a thiazide-like diuretic should be used in patients with heart failure or those who develop troublesome ankle oedema).

**Step 2**

If BP control is inadequate, then the combination of an ACE-inhibitor or ARB with a calcium-channel blocker is recommended (or a thiazide-like diuretic as above).

**Step 3**

At this point, therapy should be reviewed (including compliance and optimal dosage). Triple therapy of an ACE inhibitor or ARB with a calcium-channel blocker and a thiazide-like diuretic is recommended.
Step 4
If BP remains >140/90 mmHg on three agents, then the patient should be referred for specialist advice. In those with preserved renal function and resistant hypertension, spironolactone 25 mg daily can be added if the serum potassium is ≤4.5 mmol/L. If the potassium is >4.5 mmol/L, an increased dose of thiazide-like diuretic can be used with monitoring of electrolytes. Alpha- or beta-blockers can be used if these measures are not effective.

Management of severe or malignant hypertension
Patients with severe hypertension (diastolic pressure >140 mmHg), malignant hypertension (grade 3 or 4 retinopathy) and hypertensive encephalopathy or those with severe hypertensive complications, such as cardiac failure, should be admitted to hospital for immediate initiation of treatment. However, it is unwise to reduce the BP too rapidly, since this may lead to cerebral, renal and retinal ischaemia or MI, and the BP response to therapy must be carefully monitored, preferably in a high-dependency unit. In most cases, the aim is to reduce the diastolic BP to 100–110 mmHg over 24–48 hours. This is usually achieved with oral medication, such as amlodipine. The BP can then be normalized over the next 2–3 days. When rapid control of BP is required (e.g. in an aortic dissection), the agent of choice is intravenous sodium nitroprusside. Alternatively, an infusion of labetalol can be used. The infusion dosage must be titrated against the BP response.

Management of resistant hypertension
A patient with resistant hypertension is defined as having inadequate BP control on three or more antihypertensive drugs. Following investigations for any underlying cause, endovascular renal denervation of the sympathetic nerves, performed with a single electrode radio-frequency catheter, has shown to be effective in further reduction of BP, although results are variable.

Peripheral Vascular Disease

Peripheral Arterial Disease

Peripheral vascular disease (PVD) is commonly caused by atherosclerosis and usually affects the aorto-iliac or infra-inguinal arteries. It is present in 7% of middle-aged men and 4.5% of middle-aged women, but these patients are more likely to die of MI or stroke than lose their leg.

Limb ischaemia

Limb ischaemia may be classified as chronic or acute.

Chronic lower limb ischaemia

Common risk factors are:
• smoking
• diabetes
• hypercholesterolaemia
• hypertension.

Premature atherosclerosis in patients aged <45 years may be associated with thrombophilia and hyperhomocysteinaemia.

Clinical features

Symptoms

Peripheral arterial disease can be described using the Fontaine classification:
• Stage I – asymptomatic
• Stage II – intermittent claudication
• Stage III – rest pain/nocturnal pain
• Stage IV – necrosis/gangrene.
Patients with *intermittent claudication* complain of exertional discomfort, most commonly in the calf, which is relieved by rest. Patients with aorto-iliac disease may experience pain in the buttock, hip or thigh and may notice erectile dysfunction. The ‘claudication distance’ may be reproducible.

Patients with *rest pain* experience severe, unremitting pain in the foot, which stops a patient from sleeping. It is partially relieved by dangling the foot over the edge of the bed or standing on a cold floor.

Patients with severe PVD or critical lower limb ischaemia may have ulceration or *necrosis* of the tissue (*gangrene*).

**Signs**
The lower limbs are cold with dry skin and lack of hair. Pulses may be diminished or absent. Ulceration may occur in association with dark discoloration of the toes or gangrene. The abdomen should be examined for a possible aneurysm.

**Differential diagnosis**
Symptoms may be confused with those of:
- spinal canal claudication (but all pulses are present)
- osteoarthritis hip/knee (knee pain often at rest)
- peripheral neuropathy (associated with numbness and tingling)
- popliteal artery entrapment (young patients who may have normal pulses)
- venous claudication (bursting pain on walking with a previous history of a DVT)
- fibromuscular dysplasia
- Buerger's disease (young males, heavy smokers).

**Investigations**
An estimation of the anatomical level of disease may be possible with the examination of pulses. The severity of disease is indicated by the *ankle/brachial pressure index* (ABPI). This is a measurement of the cuff pressure at which blood flow is detectable by Doppler in the posterior tibial or anterior tibial arteries compared to the brachial artery (ankle/brachial pressure). Intermittent claudication is associated with an ABPI of 0.5–0.9. Values of <0.5 are associated with critical limb ischaemia. The sensitivity of the test may be improved by a fall in ABPI after exercise. If the arteries are heavily calcified and incompressible – that is, in renal or diabetic disease, the ABPI will be falsely elevated. In these patients, toe pressure values are more sensitive. Diagnostic imaging includes the following options:

- **Digital subtraction angiography** (DSA) provides an arterial map (Fig. 23.127) but requires peripheral arterial cannulation and exposes the individual to iodinated contrast; it should be reserved for use in patients immediately prior to intervention.
Duplex ultrasound using B-mode ultrasound and colour Doppler can provide an accurate anatomical map of the lower limbs with sensitivity of 87% and specificity of 94% compared to angiography, although it is operator-dependent.

Three-dimensional contrast-enhanced MR angiography provides excellent imaging of both legs with a single contrast injection without exposure to ionizing radiation. Sensitivity of 97% and specificity of 96% are reported.

CT angiography is an effective alternative to MRA, although extensive calcification may obscure stenoses. CTA requires ionizing radiation and iodinated contrast media.

**Management**

**Medical**

All patients with PVD need aggressive risk factor management. They should be encouraged to stop smoking and require smoking cessation advice. Individuals with diabetes mellitus need regular chiropody care and diabetic management. Hypercholesterolaemia should be treated, as this reduces disease progression. The Heart Protection Study showed that even the reduction of a normal cholesterol level reduces mortality from cardiovascular disease. Patients with peripheral arterial disease and a total cholesterol >3.5 mmol/L should receive statin therapy. Low-dose aspirin reduces the risk of MI and stroke in patients with PVD. Patients should be encouraged to exercise and to avoid obesity.
Pharmacological

• **Cilostazol** is a phosphodiesterase III inhibitor that increases levels of cAMP, produces vasodilatation and reversibly inhibits platelet aggregation. At a dose of 100 mg twice daily, it can increase walking distance in patients with short-distance claudication.

• **Naftidrofuryl** is a vasodilator agent that inhibits vascular and platelet 5-hydroxytryptamine$_2$ (5-HT$_2$) receptors and can reduce lactic acid levels. At a dose of 1–200 mg three times a day, it may increase walking distance and improve quality of life.

• **Oxpentifylline, inositol nicotinate and cinnarizine** are not recommended for patients with claudication.

Surgical/radiological

Vascular intervention for stable claudication is not generally recommended except in patients with severe or disabling symptoms. **Percutaneous transluminal angioplasty** is the first option and is carried out via a catheter inserted into the femoral artery. The long-term patency rates decrease as the angioplasty becomes more distal. The long-term results of angioplasty appear to be similar to those of a continued exercise programme. Arterial stents may be deployed in recurrent iliac disease, and drug-eluting stents allowing long-term patency are being used – with paclitaxel, for example. **Bypass procedures** may be performed using Dacron, polytetrafluoroethylene (PTFE) or autologous veins. Bypasses to distal vessels have poorer long-term patencies. Prosthetic grafts have equal patencies in above-knee bypasses but are inferior to grafts to veins below the knee. In severe ischaemia with unreconstructable arterial disease, an **amputation** may be necessary. An amputation may lead to loss of independence, only 70% of below-knee and 30% of above-knee amputees achieving full mobility.

Acute lower limb ischaemia

Clinical features

Symptoms

Patients complain of the ‘five Ps’: **pain**, the fact that the leg looks white (**pallor**), **paraesthesia**, **paralysis** and the sensation that it is **perishingly** cold. The pain is unbearable and normally requires opioids for relief.

Signs

The limb is cold, with mottling or marbling of the skin. Pulses are diminished or absent. The sensation and movement of the leg are reduced in severe ischaemia. Patients may develop a compartment syndrome with pain in the calf on compression.
Aetiologist

Acute limb ischaemia (ALI) may occur because of embolic or thrombotic disease. *Embolic disease* is commonly due to cardiac thrombus and cardiac arrhythmias. Rheumatic fever is now an uncommon cause and the frequency of cardiac embolic ALI is also on the decline. Emboli may also occur secondary to aneurysm thrombus or thrombus on atherosclerotic plaques. Emboli from atrial myxomas are rare.

ALI is now often due to *thrombotic disease*. Acute thrombus usually forms on a chronic atherosclerotic stenosis in a patient who has previously reported symptoms of claudication. Thrombus may also form in normal vessels in individuals who are hypercoagulable because of malignancy or thrombophilia defects. Prosthetic or venous grafts may also thrombose either *de novo* or secondary to a developing stenosis, which may be in the graft or in the native vessels. Popliteal aneurysms may thrombose or embolize distally. *Acute upper limb ischaemia* may be caused by similar processes or occur secondary to external compression with a cervical rib/band.

**Investigations**

Investigations are similar to those described for chronic lower limb disease.

**Management**

**Medical**

Management is dependent on the degree of ischaemia. Patients showing improvement may be treatable with heparin and appropriate treatment of the underlying cause. Patients with emboli following MI or atrial fibrillation need long-term warfarin.

**Surgical/radiological**

Patients with mild to moderate ischaemic symptoms who have an occluded graft may need graft thrombolysis. Intra-arterial thrombolysis may reveal an underlying stenosis within a graft or native vessel that could be treated with angioplasty. Patients with an embolus may benefit from its surgical removal (embolectomy). A bypass graft may be required after occlusion of a popliteal aneurysm or acute-on-chronic lower limb arterial disease. When an ischaemic limb is revascularized, the sudden improvement in blood flow can cause reperfusion injury, with release of toxic metabolites into the circulation. In muscle compartments, the consequent oedema may lead to a ‘compartment syndrome’, which requires fasciotomies (release of the fascia to prevent muscle damage). An amputation may be warranted in unreconstructable or severe ischaemia. In patients dying from other causes, acute limb ischaemia may occur and intervention may then be inappropriate.

**Aneurysmal disease**
Aneurysms are classified as true and false. An aneurysm is defined if there is a permanent dilatation of the artery to twice the normal diameter. In true aneurysms, the arterial wall forms the wall of the aneurysm. The arteries most frequently involved are the abdominal aorta, the iliac, popliteal and femoral arteries, and the thoracic aorta (in decreasing frequency). In false aneurysms (pseudoaneurysms), the surrounding tissues form the wall of the aneurysm. False aneurysms can occur following femoral artery puncture. A haematoma is formed because of inadequate compression of the entry site and continued bleeding into the surrounding compressed soft tissue forms the wall of this aneurysm.

**Abdominal aortic aneurysm**

Abdominal aortic aneurysms (AAAs) occur most commonly below the renal arteries (infra-renal). The incidence increases with age, AAAs being present in 5% of the population >60 years. They arise five times more frequently in men, and in 1 in 4 male children of an affected individual. Aneurysms may occur secondary to atherosclerosis, infection (syphilis, *Escherichia coli*, *Salmonella*) and trauma, or may be genetic (Marfan syndrome, Ehlers–Danlos syndrome).

**Screening**

In England and Wales, the prevalence of AAA is 3–4% of men ≥65 years old, and approximately 6000 deaths occur each year from a ruptured aortic aneurysm. The mortality rate for elective surgery is ≤3.5%, compared to 50% for an emergency repair. There are fixed risk factors – age, male gender, strong family history – and modifiable risk factors – smoking, hypertension, hypercholesterolaemia.

The UK recommendation is that screening should be offered to men aged 65–74 years, who will receive an abdominal ultrasound.

- **Normal** or <3 cm aorta will not require treatment or further scans.
- **Small** (3–4.4 cm) aorta will require annual ultrasound surveillance and a GP review to optimize lifestyle.
- **Medium** (4.5–5.4 cm) aorta requires quarterly ultrasound surveillance and cardiovascular secondary prevention therapy.
- **Large** (≥5.5 cm) aorta will be referred for assessment and possible elective repair.

Screening of female patients is not recommended, as the prevalence is much lower.

**Clinical features**

**Symptoms**

Most aneurysms are asymptomatic and are found on routine abdominal examination or plain X-ray, or during urological investigations. Rapid expansion or rupture of an AAA may cause **severe pain** (epigastric pain radiating to the back). A ruptured AAA causes **hypotension**,
tachycardia, profound anaemia and sudden death. The symptoms of rupture may mimic renal colic, diverticulitis and severe lower abdominal or testicular pain. Gradual erosion of the vertebral bodies may cause non-specific back pain. The aneurysm may embolize distally. Inflammatory aneurysms can obstruct adjacent structures, such as the ureter, duodenum and vena cava. Rarely, patients with aneurysms can present with severe haematemesis secondary to an aortoduodenal fistula.

**Signs**
The aorta is retroperitoneal and in overweight patients there may be no overt signs. An aneurysm is suspected if a pulsatile, expansile abdominal mass is felt. The presence of an AAA should alert a clinician to the possibility of popliteal aneurysms. Patients may present with ‘trash feet’, dusky discoloration of the digits secondary to emboli from the aortic thrombus.

**Management**
As with any operation, the management of an asymptomatic aneurysm depends on the balance of operative risk and conservative management. The UK Small Aneurysm Trial showed that patients with infra-renal AAAs did best with an operation if the aneurysm was:
- ≥5.5 cm diameter
- expanding at a rate of >1 cm/year
- symptomatic.

**Medical**
Patients with aneurysmal disease need careful control of hypertension, smoking cessation and lipid-lowering medication. Patients with AAAs <5.5 cm are followed up by regular ultrasound surveillance.

**Surgical repair**
Standard therapy is open surgical repair with insertion of a Dacron or Gore-Tex graft.

**Endovascular stent**
Endovascular stent insertion (via the femoral or iliac arteries) is a non-surgical approach to AAA repair. The Endovascular Aneurysm Repair (EVAR) studies (stent versus open surgical repair) and EVAR 2 (stent versus medical therapy in patients unsuitable for open repair) investigated the role of endovascular stents in patients with an AAA ≥5.5 cm on CT. In EVAR, the 30-day mortality rate was 1.7% with stenting versus 4.7% with surgery ($p = 0.009$) but the long-term mortality rate was similar in both groups at 4 years. In EVAR 2, the 30-day mortality rate with stenting was 9%. Long-term mortality rate was similar in both stent and medical therapy groups. A meta-analysis of three randomized control trials demonstrated a 30-day mortality rate of 2% for stent-graft repair versus 5% for open surgical repair; there were also
reductions in intensive treatment unit and in-hospital stays with stent-graft repair.

**Laparoscopic surgery**
An alternative to open surgical repair or endovascular stenting is laparoscopic repair, which is performed with hand-assisted laparoscopic surgery (HALS, requiring a midline mini-laparotomy) or total laparoscopic surgery (TLS). In non-randomized controlled trials, both methods were associated with reduced length of stay, although the operating times were longer.

**Prognosis**
After repair, patients with an AAA should return to normal activity within a few months.

**Thoraco-abdominal aneurysm**
The ascending, arch or descending thoracic aorta may become aneurysmal. Ascending thoraco-abdominal aneurysms (TAAs) occur most commonly in patients with Marfan syndrome or hypertension. Descending or arch TAAs occur secondary to atherosclerosis and are now rarely due to syphilis.

**Clinical features**
Most aneurysms are asymptomatic and are found on routine chest X-ray or cardiological investigation. Rapid expansion may cause severe pain (chest pain radiating to the upper back) and rupture is associated with hypotension, tachycardia and death. Chest symptoms from expansion may include stridor (compressed bronchial tree), haemoptysis (aortobronchial fistula) and hoarseness (compression of the recurrent laryngeal nerve). Aorto-oesophageal fistula uncommonly causes haematemesis.

**Investigations**
- **CT or MRI scan** is used for assessment of a TAA.
- **Aortography** may be helpful for assessing the position of the key branches in relation to the aneurysm.
- **Transoesophageal echocardiography** can be useful for identifying an aortic dissection.

**Management**
If the aneurysm is >6 cm, then operative repair or stenting may be appropriate, but these can be technically difficult and carry a high risk of mortality and paraplegia. EVAR is, at present, the procedure of choice for isolated descending thoracic aneurysms.

**Acute aortic syndromes**
Acute aortic syndromes include aortic dissection, intramural haematoma (IMH) and penetrating aortic ulcers. Aortic dissection usually begins with a tear in the intima. Blood penetrates the diseased medial layer and then cleaves the intimal laminal plain, leading to dissection. IMH is considered a precursor of dissection, in which there is rupture of the vasa vasorum in the aortic media with aortic wall infarction. IMH is typically in the descending thoracic aorta. Deep penetrating aortic plaques may lead to IMH, dissection or ulceration/perforation. There is a predisposition to aortic dissection in patients with autoimmune rheumatic disorders and Marfan and Ehlers–Danlos syndromes.

Aortic dissection can be classified according to the timing of diagnosis from the origin of symptoms: acute <2 weeks, subacute 2–8 weeks and chronic >8 weeks, with mortality and extension decreasing with time. It can also be classified anatomically:

- **Type A** involves the aortic arch and aortic valve proximal to the left subclavian artery origin. This category includes De Bakey type I (extends to the abdominal aorta) and De Bakey type II (localized to the ascending aorta).

- **Type B** involves the descending thoracic aorta distal to the left subclavian artery origin. This category includes De Bakey type III (Fig. 23.128).

![Classification of aortic aneurysms.](image)
Clinical features

Symptoms
Most patients present with a sudden onset of severe and central chest pain that often radiates to the back and down the arms, mimicking MI. The pain is often described as tearing in nature and may be migratory.

Signs
Patients may be shocked and may have neurological symptoms secondary to loss of blood supply to the spinal cord. They may develop aortic regurgitation, coronary ischaemia and cardiac tamponade. Distal extension may produce acute kidney failure, acute lower limb ischaemia or visceral ischaemia. Peripheral pulses may be absent.

Investigations
The mediastinum may be widened on chest X-ray; urgent CT scan, transoesophageal echocardiography or MRI will confirm the diagnosis (see Fig. 23.100).

Management
At least 50% of patients are hypertensive and may require urgent antihypertensive medication to reduce blood pressure to <120 mmHg; intravenous beta-blockers (labetalol, metoprolol) and vasodilators (GTN) are used. Type A dissections should undergo surgery (arch replacement) if the patient is fit enough, as medical management carries a high mortality (50% within 2 weeks). Type B dissections carry a better prognosis and have a survival rate of 89% at 1 month; initially, these patients should be managed medically unless they develop complications. Endovascular intervention with stents may be indicated in individuals with rapidly expanding dissections (>1 cm/year), critical diameter (>5.5 cm), refractory pain or malperfusion syndrome, blunt chest trauma, penetrating aortic ulcers or IMH. Patients will require long-term follow-up with CT or MRI.

Other types of peripheral arterial disease

Raynaud's phenomenon or Raynaud's disease
Raynaud's phenomenon consists of spasm of the digital arteries, usually precipitated by cold and relieved by heat. If there is no underlying cause, it is known as Raynaud's disease. This affects 5% of the population, mostly women. The disorder is usually bilateral and fingers are affected more commonly than toes.
Vasoconstriction causes skin *pallor* followed by *cyanosis* due to sluggish blood flow, then redness secondary to hyperaemia. The duration of the attacks is variable but they can sometimes last for hours. Numbness, a burning sensation and severe pain occur as the fingers warm up. In chronic, severe disease tissue, *infarction* and *digital loss* can occur.

### Diagnosis

Primary Raynaud's disease needs to be differentiated from secondary treatable causes leading to Raynaud's phenomenon. These are the rheumatic autoimmune disorders, such as systemic sclerosis. It can be associated with atherosclerosis or occupations that involve the use of vibrating tools. Ergot-containing drugs and beta-blockers, as well as smoking, can aggravate symptoms.

### Management

Patients should avoid cold provocation by wearing gloves and warm clothes, and stop smoking. Vasodilators can be prescribed but are often unacceptable, as cerebral vasodilatation causes severe headaches. Sympathectomy or prostacyclin infusion can be helpful in severe disease.

### Takayasu's disease

This is rare, except in Japan. It is known as the pulseless disease or aortic arch syndrome. It is of unknown aetiology and occurs in females. There is a vasculitis involving the aortic arch, as well as other major arteries. A systemic illness is also present, with pain and tenderness over the affected arteries. Absent peripheral pulses and hypertension are common. Corticosteroids help the constitutional symptoms. Eventually, heart failure and strokes may occur but most patients survive for at least 5 years. Treatment may involve a surgical bypass to improve perfusion of the affected areas.

### Thromboangiitis obliterans (Buerger's disease)

This disease, involving the small vessels of the lower limbs, occurs in young men who smoke. It is thought by some workers to be indistinguishable from atheromatous disease. However, pathologically, there is inflammation of the arteries, and sometimes veins, which may indicate a separate disease entity. Clinically, it presents with severe claudication and rest pain, leading to gangrene. A thrombophlebitis is sometimes present. Treatment is as for all peripheral vascular disease, but patients must stop smoking.

### Cardiovascular syphilis

This gives rise to:
• uncomplicated aortitis
• aortic aneurysms, usually in the ascending part
• aortic valvulitis with regurgitation
• stenosis of the coronary ostia.

The diagnosis is confirmed by serology. Treatment is with penicillin. Aneurysms and valvular disease are treated as necessary by the usual methods.

Peripheral Venous Disease

**Varicose veins**

Varicose veins are a common problem, sometimes giving rise to pain. They are treated by injection with ultrasound-guided foam sclerotherapy or thermal ablation with, for example, endovenous lasers or surgery.

**Venous thrombosis**

Thrombosis can occur in any vein but the veins of the leg and the pelvis are the most common sites.

**Superficial thrombophlebitis**

This commonly involves the saphenous veins and is often associated with varicosities. Occasionally, the axillary vein is involved, usually as a result of trauma. There is local superficial inflammation of the vein wall, with secondary thrombosis.

The clinical picture is of a painful, tender, cord-like structure with associated redness and swelling.

The condition usually responds to symptomatic treatment with rest, elevation of the limb and analgesics (e.g. NSAIDs). The Comparison of Arixtra in Lower Limb Superficial Vein Thrombosis with Placebo (CALISTO) trial demonstrated that a 45-day course of subcutaneous fondaparinux 2.5 mg daily, compared with placebo, significantly reduced the rate of thromboembolic events (pulmonary embolism and deep vein thrombosis) from 1.3% to 0.2%, and limited the extension of superficial vein thrombosis to the saphenofemoral junction from 3.4% to 0.3% with no increased risk of bleeding.

**Deep vein thrombosis**

A thrombus forms in the vein, and any inflammation of the vein wall is secondary to this.

Thrombosis commonly occurs after periods of immobilization but it can occur in normal individuals for no obvious reasons. The precipitating factors are discussed on pages 992–993. A deep vein thrombosis (DVT) in the legs occurs in 50% of patients after prostatectomy (without prophylactic heparin) or following a cerebral vascular event. In addition, 10% of
patients with an MI have a clinically detected DVT.

Thrombosis can occur in any vein of the leg or pelvis, but is found particularly in veins of the calf. It is often undetected; autopsy figures give an incidence of over 60% in hospitalized patients. Axillary vein thrombosis occasionally occurs, sometimes related to trauma, but usually for no obvious reason.

### Clinical features

The individual may be asymptomatic, presenting with clinical features of pulmonary embolism (see pp. 1031–1035).

A major presenting feature is pain in the calf, often with swelling, redness and engorged superficial veins. The affected calf is often warmer and there may be ankle oedema. Homan’s sign (pain in the calf on dorsiflexion of the foot) is often present, but is not diagnostic and occurs with all lesions of the calf.

Thrombosis in the iliofemoral region can present with severe pain, but there are often few physical signs apart from occasional swelling of the thigh and/or ankle oedema.

Complete occlusion, particularly of a large vein, can lead to a cyanotic discoloration of the limb and severe oedema, which can, very rarely, lead to venous gangrene.

Pulmonary embolism can occur with any DVT but is more frequent from an iliofemoral thrombosis and is rare with thrombosis confined to veins below the knee. In 20–30% of patients, spread of thrombosis can occur proximally without clinical evidence, so careful monitoring of the leg, usually by ultrasound, is required.

### Investigations

Clinical diagnosis is unreliable, but combined with D-dimer level, it has a sensitivity of 80%. Confirmation of an iliofemoral thrombosis can usually be made with B mode venous compression, ultrasonography or Doppler ultrasound with a sensitivity and specificity over 90%.

Below-knee thromboses can be detected reliably only by venography with non-invasive techniques, ultrasound, fibrinogen scanning and impedance plethysmography, having a sensitivity of only 70%. A venogram is performed by injecting a vein in the foot with contrast, which will detect virtually all thrombi that are present.

### Management

The main aim of therapy is to prevent pulmonary embolism, and all patients with thrombi above the knee must be anticoagulated. Anticoagulation of below-knee thrombi is now recommended for 6 weeks, as 30% of patients will have an extension of the clot proximally. Bed rest is advised until the patient is fully anticoagulated. The patient should then be mobilized, with an elastic stocking giving graduated pressure over the leg.

Low-molecular-weight heparins (see p. 578) have replaced unfractionated heparin, as they
are more effective and do not require monitoring; there is also less risk of bleeding. DVTs are being treated at home with low-molecular-weight heparin. Warfarin is started immediately and the heparin stopped when the INR is in the target range. The duration of warfarin treatment is debatable: 3 months is the period usually recommended, but 4 weeks is long enough if a definite risk factor (e.g. bed rest) has been present. Recurrent DVTs need permanent anticoagulants. The target INR should be 2.5. Anticoagulants do not lyse the thrombus that is already present. Unfractionated heparin should only be used if LMWH is unavailable.

**Thrombolytic therapy** (see pp. 577–578) is occasionally used for patients with a large iliofemoral thrombosis.

### Prognosis

Destruction of the deep vein valves produces a clinically painful, swollen limb that is made worse by standing and is accompanied by oedema and, sometimes, venous eczema. It occurs in approximately half of the patients with clinically symptomatic DVT, and it means that elastic support stockings are then required for life.

### Prevention

An estimated 25 000 people in the UK die every year from a preventable hospital-acquired venous thromboembolism (VTE). In January 2010, NICE provided guidelines on the assessment and prevention of VTE in patients admitted to hospital (see p. 580):

- All patients should be assessed on admission to hospital (and again within 24 h or when a change occurs in the patient's clinical condition).
- Medical patients are at risk if they have reduced mobility for ≥3 days or if their mobility is reduced and they have one or more risk factors for VTE (**Box 23.58**).

### Box 23.58

**Risk factors for venous thromboembolism (VTE)**

- Active cancer or cancer treatment
- Age >60 years
- Critical care admission
- Long distance flight ± dehydration
- Known thrombophilias
- Obesity (BMI >30 kg/m²)
- Significant medical co-morbidities (e.g. heart disease; metabolic, endocrine or respiratory pathologies; acute infectious diseases; inflammatory conditions)
- Personal history or first-degree relative with a history of VTE
• Use of hormone replacement therapy or oestrogen-containing contraceptive therapy
• Varicose veins with phlebitis
• Pregnancy/childbirth
  BMI, body mass index.

(From http://guidance.nice.org.uk/CG92/QuickRefGuide/pdf/English.)

• Surgical and trauma patients are at risk if they:
  – undergo a surgical procedure with a combined anaesthetic and surgery of >90 min (60 min if surgery is to the pelvis or lower limb)
  – are admitted with an acute inflammatory or intra-abdominal condition
  – have significantly reduced mobility
  – have one or more risk factors for VTE.

Patients at risk should be considered for pharmacological prophylaxis (fondaparinux or low-molecular-weight heparin or unfractionated heparin if there is renal impairment), unless they have a risk factor for bleeding (Box 23.59) that outweighs the benefits of VTE prophylaxis. Patients should also be encouraged to mobilize where possible and mechanical VTE (anti-embolism) stockings (thigh or knee length), foot impulse devices, and intermittent pneumatic compression devices (thigh or knee length) may be appropriate in certain patients. On discharge, patients should be provided with advice on the signs and symptoms of VTE; if pharmacological or mechanical prophylaxis has been prescribed, advice should be given on its usage. (Antithrombins are now being used in orthopaedic surgery; see p. 580.)

Box 23.59

Risk factors for bleeding

- Active bleeding
- Acquired bleeding disorders (e.g. acute liver failure)
- Concurrent use of anticoagulants (e.g. warfarin with INR >2)
- Lumbar puncture/epidural/spinal anaesthesia within the previous 4 h or expected within 12 h
- Acute stroke
- Thrombocytopenia (platelets <75 × 10⁹/L)
- Uncontrolled systolic hypertension (≥230/120 mmHg)
- Untreated inherited bleeding disorders (haemophilia and von Willebrand's disease)

INR, International Normalized Ratio.

Introduction

The main role of the respiratory system is to extract oxygen from the external environment and to dispose of waste gases, principally carbon dioxide. This requires the lungs to function as efficient bellows, bringing in fresh air and delivering it to the alveoli, and expelling used air at
an appropriate rate. Gas exchange is achieved by exposing thin-walled capillaries to the alveolar gas and matching ventilation to blood flow through the pulmonary capillary bed. In doing this, the lungs expose a large area of tissue, which can be damaged by dusts, gases and infective agents. Host defence is therefore a key priority for the lung and is achieved by a combination of structural and immunological defences.

**Anatomy of the Respiratory System**

**The nose, pharynx and larynx**

See pages 1317 and 1319.

**The trachea, bronchi and bronchioles**

The trachea is 10–12 cm in length. It lies slightly to the right of the midline and divides at the carina into right and left main bronchi. The carina lies under the junction of the manubrium sterni and the second right costal cartilage. The right main bronchus is more vertical than the left and, hence, inhaled material is more likely to end up in the right lung.

The right main bronchus divides into the upper lobe bronchus and the intermediate bronchus, which further subdivides into the middle and lower lobe bronchi. On the left, the main bronchus divides into upper and lower lobe bronchi only. Each lobar bronchus further divides into segmental and sub-segmental bronchi. There are about 25 divisions in all between the trachea and the alveoli.

The first seven divisions are bronchi that have:

- walls consisting of cartilage and smooth muscle
- an epithelial lining with cilia and goblet cells
- submucosal mucus-secreting glands
- endocrine cells – Kulchitsky or amine precursor and uptake decarboxylation (APUD) cells containing 5-hydroxytryptamine (5-HT, serotonin).

The next 16–18 divisions are bronchioles that have:

- no cartilage and a muscular layer that progressively becomes thinner
- a single layer of ciliated cells but very few goblet cells
- granulated Clara cells that produce a surfactant-like substance.

The ciliated epithelium is a key defence mechanism. Each cell bears approximately 200 cilia beating at 1000 beats per minute (b.p.m.) in organized waves of contraction. Each cilium consists of nine peripheral parts and two inner longitudinal fibrils in a cytoplasmic matrix (*Fig. 24.1*). Nexin links join the peripheral pairs. Dynein arms consisting of adenosine triphosphatase (ATPase) protein project towards the adjacent pairs. Bending of the cilia results from a sliding movement between adjacent fibrils powered by an ATP-dependent shearing force developed by the dynein arms (see also pp. 92–93). Absence of dynein arms leads to immotile cilia. Mucus, which contains macrophages, cell debris, inhaled particles and
bacteria, is moved by the cilia towards the larynx at about 1.5 cm/min (the ‘mucociliary escalator’; see below).

![Cross-section of a cillum](image1.png)

**FIGURE 24.1** Cross-section of a cillum. Nine outer microtubular doublets and two central single microtubules are linked by spokes, nexin links and dynein arms.

The bronchioles finally divide within the acinus into smaller respiratory bronchioles that have alveoli arising from the surface ([Fig. 24.2](image2.png)). Each respiratory bronchiole supplies approximately 200 alveoli via alveolar ducts. The term ‘small airways’ refers to bronchioles of <2 mm; the average lung contains about 30 000 of these.

**FIGURE 24.2** Branches of a terminal bronchiole ending in the alveolar sacs.

**The alveoli**
There are approximately 300 million alveoli in each lung. Their total surface area is 40–80 m².
The epithelial lining consists mainly of **type I pneumocytes (Fig. 24.3)**. These cells have an extremely thin layer of cytoplasm, which only offers a thin barrier to gas exchange. Type I cells are connected to each other by tight junctions that limit the movements of fluid in and out of the alveoli. Alveoli are not completely airtight; many have holes in the alveolar wall, allowing communication between alveoli of adjoining lobules (pores of Kohn).

**FIGURE 24.3** The structure of alveoli, showing the pneumocytes and capillaries.

**Type II pneumocytes** are slightly more numerous than type I cells but cover less of the epithelial lining. They are found generally in the borders of the alveolus and contain distinctive lamellar vacuoles, which are the source of surfactant. Type I pneumocytes are derived from type II cells. Large alveolar macrophages are present within the alveoli and assist in defending the lung.

**The lungs**

The lungs are separated into lobes by invaginations of the pleura, which are often incomplete. The right lung has three lobes, whereas the left lung has two. The positions of the oblique fissures and the right horizontal fissure are shown in **Figure 24.4**. The upper lobe lies mainly in front of the lower lobe and therefore physical signs on the right side in the front of the chest are due to lesions of the upper lobe or the middle lobe.
Each lobe is further subdivided into bronchopulmonary segments by fibrous septa that extend inwards from the pleural surface. Each segment receives its own segmental bronchus.

The bronchopulmonary segment is further divided into individual lobules approximately 1 cm in diameter and generally pyramidal in shape, the apex lying towards the bronchiole that supplies it. Within each lobule, a terminal bronchus supplies an acinus; within this structure, further divisions of the bronchioles eventually give rise to the alveoli.

The pleura

The pleura is a layer of connective tissue covered by a simple squamous epithelium. The visceral pleura covers the surface of the lung, lines the interlobar fissures, and is continuous at the hilum with the parietal pleura, which lines the inside of the hemithorax. At the hilum, the visceral pleura continues alongside the branching bronchial tree for some distance before reflecting back to join the parietal pleura. In health, the pleurae are in apposition, apart from a small quantity of lubricating fluid.

The diaphragm

The diaphragm is covered by parietal pleura above and peritoneum below. Its muscle fibres arise from the lower ribs and insert into the central tendon. Motor and sensory nerve fibres go separately to each half of the diaphragm via the phrenic nerves. Fifty per cent of the muscle fibres are of the slow-twitch type with a low glycolytic capacity; they are relatively resistant to fatigue.

Pulmonary vasculature and lymphatics

The lung has a dual blood supply, receiving deoxygenated blood from the right ventricle via the pulmonary artery and oxygenated blood via the bronchial circulation.

The pulmonary artery divides to accompany the bronchi. The arterioles accompanying the respiratory bronchioles are thin-walled and contain little smooth muscle. The pulmonary venules drain laterally to the periphery of the lobules, pass centrally in the interlobular and
Intersegmental septa, and eventually join to form the four main pulmonary veins.

The bronchial circulation arises from the descending aorta. These bronchial arteries supply tissues down to the level of the respiratory bronchiole. The bronchial veins drain into the pulmonary veins, forming part of the normal physiological shunt.

Lymphatic channels lie in the interstitial space between the alveolar cells and the capillary endothelium of the pulmonary arterioles.

The tracheobronchial lymph nodes are arranged in five main groups: pulmonary, bronchopulmonary, subcarinal, superior tracheobronchial and paratracheal. For practical purposes, these form a continuous network of nodes from the lung substance up to the trachea.

**Nerve supply to the lung**

The innervation of the lung remains incompletely understood. Parasympathetic and sympathetic fibres (from the vagus and sympathetic chain, respectively) accompany the pulmonary arteries and the airways. Airway smooth muscle is innervated by vagal afferents, postganglionic muscarinic vagal efferents and vagally derived non-adrenergic non-cholinergic (NANC) fibres, which use a range of neurotransmitters including substance P, neurokinins A and B, calcitonin gene-related peptide, vasoactive intestinal polypeptide, and various adenine and guanine phosphates. Three muscarinic receptor subtypes have been identified: $M_1$ receptors on parasympathetic ganglia, a smaller number of $M_2$ receptors on muscarinic nerve terminals, and $M_3$ receptors on airway smooth muscle. The parietal pleura is innervated from intercostal and phrenic nerves but the visceral pleura has no innervation.

**Further reading**

**Physiology of the Respiratory System**

**The nose**

The major functions of nasal breathing are:

- to heat and moisten the air
- to remove particulate matter.

About 10 000 L of air are inhaled daily. The relatively low flow rates and turbulence of inspired air in the nose mean that few particles >10 microns ($\mu$m) in diameter pass through the nose. Particles deposited on the nasal mucosa are removed within 15 minutes, compared with 60–120 days for particles that reach the alveoli. Nasal secretion contains immunoglobulin A (IgA) antibodies, lysozyme and interferons. In addition, the cilia of the nasal epithelium move the mucous gel layer rapidly back to the oropharynx, where it is swallowed. Bacteria have little chance of settling in the nose. Mucociliary protection is less effective against viral
infections because viruses bind to receptors on epithelial cells. The majority of rhinoviruses bind to an adhesion molecule, intercellular adhesion molecule 1 (ICAM-1), which is shared by neutrophils and eosinophils. Many noxious gases, such as SO$_2$, are almost completely removed by nasal breathing.

**Breathing**

Lung ventilation can be considered in two parts:

- the mechanical process of inspiration and expiration
- the control of respiration to a level appropriate for metabolic needs.

**The mechanical process**

The lungs have an inherent elastic property that causes them to tend to collapse away from the thoracic wall, generating a negative pressure within the pleural space. The strength of this retractive force relates to the volume of the lung: at higher lung volumes the lung is stretched more, and a greater negative intrapleural pressure is generated. *Lung compliance* is a measure of the relationship between this retractive force and lung volume. At the end of a quiet expiration, the retractive force exerted by the lungs is balanced by the tendency of the thoracic wall to spring outwards. At this point, respiratory muscles are resting. The volume of air remaining in the lung after a quiet expiration is called the *functional residual capacity (FRC)*.

Inspiration from FRC is an active process: a negative intrapleural pressure is created by descent of the diaphragm and movement of the ribs upwards and outwards through contraction of the intercostal muscles. During tidal breathing in healthy individuals, inspiration is almost entirely due to contraction of the diaphragm. More vigorous inspiration requires the use of accessory muscles of ventilation (sternomastoid and scalene muscles). Respiratory muscles are similar to other skeletal muscles but are less prone to fatigue. However, inspiratory muscle fatigue contributes to respiratory failure in patients with severe chronic airflow limitation and in those with primary neurological and muscle disorders.

At rest or during low-level exercise, expiration is passive and results from the natural tendency of the lung to collapse.

Forced expiration involves activation of accessory muscles, chiefly those of the abdominal wall, which help to push up the diaphragm.

**The control of respiration**

Coordinated respiratory movements result from rhythmical discharges arising in an anatomically ill-defined group of interconnected neurones in the reticular substance of the brainstem, known as the respiratory centre. Motor discharges from the respiratory centre travel via the phrenic and intercostal nerves to the respiratory musculature.

Ventilation is controlled by a combination of neurogenic and chemical factors (*Fig. 24.5*). In healthy individuals, the main driver for respiration is the arterial pH, which is closely related to the partial pressure of carbon dioxide in arterial blood. Oxygen levels in arterial blood are
usually above the level that triggers respiratory drive. Typical normal values are shown in Box 24.1.

**FIGURE 24.5** Chemical and neurogenic factors in the control of ventilation. The strongest stimulant to ventilation is a rise in $P_aCO_2$, which increases $[H^+]$ in cerebrospinal fluid. Sensitivity to this may be lost in chronic obstructive pulmonary disease. In these patients, hypoxaemia is the chief stimulus to respiratory drive; oxygen treatment may therefore reduce respiratory drive and lead to a further rise in $P_aCO_2$. An increase in $[H^+]$ due to metabolic acidosis, as in diabetic ketoacidosis, will increase ventilation with a fall in $P_aCO_2$, causing deep sighing (Kussmaul) respiration. The respiratory centre is depressed by severe hypoxaemia and sedatives (e.g. opiates).

### Box 24.1

**Normal values for respiratory physiology**

In a typical normal adult at rest:

- Pulmonary blood flow is about 5 L/min
- This carries 11 mmol/min (250 mL/min) of $O_2$ to tissues
- Ventilation is about 6 L/min
- This removes 9 mmol/min (200 mL/min) of $CO_2$ from the body
- Normal pressure of oxygen in arterial blood ($P_aO_2$) is 11–13 kPa
- Normal pressure of carbon dioxide in arterial blood ($P_aCO_2$) is 4.8–6.0 kPa

Breathlessness on physical exertion is normal and not considered a symptom unless the level
of exertion is very light, such as when walking slowly. Surveys of healthy Western populations reveal that over 20% of the general population report themselves as breathless on relatively minor exertion. Although breathlessness is a very common symptom, the sensory and neural mechanisms underlying it remain obscure. The sensation of breathlessness is derived from at least three sources:

- **Changes in lung volume.** These are sensed by receptors in thoracic wall muscles signalling changes in their length.
- **Tension developed by contracting muscles.** This is sensed by Golgi tendon organs.
- **Central perception of the sense of effort.**

### The airways of the lungs

From the trachea to the periphery, the airways decrease in size but increase in number. Overall, the cross-sectional area available for airflow increases as the total number of airways increases. The airflow rate is greatest in the trachea and slows progressively towards the periphery (since the velocity of airflow depends on the cross-sectional area). In the terminal airways, gas flow occurs solely by diffusion. The resistance to airflow is very low (0.1–0.2 kPa/L in a normal tracheobronchial tree), steadily increasing from the small to the large airways.

Airways expand as the lung volume increases. At full inspiration (**total lung capacity**, TLC) they are 30–40% larger in calibre than at full expiration (**residual volume**, RV). In chronic obstructive pulmonary disease (COPD), the small airways are narrowed but this can be partially compensated by breathing closer to TLC.

### Control of airway tone

Bronchomotor tone is maintained by vagal efferent nerves and can be reduced by atropine or β-adrenoceptor agonists. Adrenoceptors on the surface of bronchial muscles respond to circulating catecholamines; there is no direct sympathetic innervation. Airway tone shows a **circadian rhythm**, which is greatest at 04.00 and lowest in the mid-afternoon. Tone can be increased transiently by inhaled stimuli acting on epithelial nerve endings, which trigger reflex bronchoconstriction via the vagus. These stimuli include cigarette smoke, solvents, inert dust and cold air. Airway responsiveness to these stimuli increases following respiratory tract infections, even in healthy subjects. In asthma, the airways are very irritable and as the circadian rhythm remains the same, asthmatic symptoms are usually worse in the early morning.

### Airflow

Movement of air through the airways results from a difference between atmospheric pressure and the pressure in the alveoli; alveolar pressure is negative in inspiration and positive in expiration. During quiet breathing, the pleural pressure is negative throughout the breathing cycle. With vigorous expiratory efforts (e.g. cough), the pleural pressure becomes positive (up
to 10 kPa). This compresses the central airways, but the smaller airways do not close off because the driving pressure for expiratory flow (alveolar pressure) is also increased.

Alveolar pressure \( (P_{ALV}) \) is equal to the pleural pressure \( (P_{PL}) \) plus the elastic recoil pressure \( (P_{EL}) \) of the lung.

When there is no airflow (i.e. during a pause in breathing), the tendency of the lungs to collapse (the positive recoil pressure) is exactly balanced by an equivalent negative pleural pressure.

As air flows from the alveoli towards the mouth, there is a gradual drop of pressure owing to flow resistance (Fig. 24.6A).

\[
P_{ALV} = P_{PL} + P_{EL}
\]

\[
P_{ALV} = 0 + 0.5 = 0.5
\]

\[
P_{ALV} = 2.5 + 2 + 0.5 = 5
\]

\[
P_{ALV} = 2.2 + 2.0 + 0.2 = 4.4
\]

FIGURE 24.6 Ventilatory forces. A. During resting at functional residual capacity. B. During forced expiration in normal subjects. C. During forced expiration in a patient with chronic obstructive pulmonary disease (COPD). The respiratory system is represented as a piston with a single alveolus and the collapsible part of the airways within the piston (see text). C, collapse point; \( P_{ALV} \), alveolar pressure; \( P_{EL} \), elastic recoil pressure; \( P_{PL} \), pleural pressure.

In forced expiration, as mentioned above, the driving pressure raises both the alveolar
pressure and the intrapleural pressure. Between the alveolus and the mouth, there is a point (C in Fig. 24.6B) where the airway pressure equals the intrapleural pressure, and the airway collapses. However, this collapse is temporary, as the transient occlusion of the airway results in an increase in pressure behind it (i.e. upstream), and this raises the intra-airway pressure so that the airways open and flow is restored. The airways thus tend to vibrate at this point of ‘dynamic collapse’.

As lung volume decreases during expiration, the elastic recoil pressure of the lungs decreases and the ‘collapse point’ moves upstream (i.e. towards the smaller airways; see Fig. 24.6C). Where there is pathological loss of recoil pressure (as in COPD), the ‘collapse point’ is located even further upstream and causes expiratory flow limitation. The measurement of the forced expiratory volume in 1 second (FEV₁) is a useful clinical index of this phenomenon. To compensate, patients with COPD often ‘purse their lips’ in order to increase airway pressure so that their peripheral airways do not collapse. During inspiration, the intrapleural pressure is always less than the intraluminal pressure within the intrathoracic airways, so increasing effort does not limit airflow. Inspiratory flow is limited only by the power of the inspiratory muscles.

**Flow–volume loops**

The relationship between maximal flow rates and lung volume is demonstrated by the maximal flow–volume (MFV) loop (Fig. 24.7A).
FIGURE 24.7 Flow–volume loops. A, B. Maximal flow–volume loops, showing the relationship between maximal flow rates on expiration and inspiration. A. Normal subject. B. Severe airflow limitation. Flow–volume loops during tidal breathing at rest (starting from the functional residual capacity, FRC) and during exercise are also shown. The highest flow rates are achieved when forced expiration begins at total lung capacity (TLC) and represent the peak expiratory flow rate (PEFR). As air is blown out of the lung, so the flow rate decreases until no more air can be forced out, a point known as the residual volume (RV). Because inspiratory airflow is only dependent on effort, the shape of the maximal inspiratory flow–volume loop is quite different, and inspiratory flow remains at a high rate throughout the manoeuvre. C, D. Flow–volume loops in large airway (tracheal) obstruction, showing plateauing of maximal expiratory flow. C. Extrathoracic tracheal obstruction with a proportionally greater reduction of maximal inspiratory (as opposed to expiratory) flow rate. D. Intrathoracic large airway obstruction; the expiratory plateau is more pronounced and inspiratory flow rate is less reduced than in (C). In severe airflow limitation, the ventilatory demands of exercise cannot be met (compare A, B), greatly reducing effort tolerance.

In subjects with healthy lungs, maximal flow rates are rarely achieved even during vigorous exercise. However, in patients with severe COPD, limitation of expiratory flow occurs even during tidal breathing at rest (Fig. 24.7B). To increase ventilation, these patients have to breathe at higher lung volumes and allow more time for expiration, both of which reduce the tendency for airway collapse. To compensate, they increase flow rates during inspiration, where there is relatively less flow limitation.

The volume that can be forced in from the residual volume in 1 second (FIV₁) will always be greater than that which can be forced out from TLC in 1 second (FEV₁). Thus, the ratio of FEV₁ to FIV₁ is <1. The only exception to this occurs when there is significant obstruction to the airways outside the thorax, such as tracheal tumour or retrosternal goitre. Expiratory airway narrowing is prevented by tracheal resistance and expiratory airflow becomes more effort-dependent. During forced inspiration, this same resistance causes such negative intraluminal pressure that the trachea is compressed by the surrounding atmospheric pressure. Inspiratory flow thus becomes less effort-dependent, and the ratio of FEV₁ to FIV₁ is >1. This
phenomenon, and the characteristic flow–volume loop, is diagnostic of extrathoracic airways obstruction (*Fig. 24.7C*).

**Ventilation and perfusion relationships**

For optimum gas exchange there must be a match between ventilation of the alveoli ($\dot{V}$) and their perfusion ($\dot{Q}$). However, in reality there is variation in the ($\dot{V}/\dot{Q}$) ratio in both normal and diseased lungs (*Fig. 24.8*). In the normal lung, both ventilation and perfusion are greater at the bases than at the apices, but the gradient for perfusion is steeper, so the net effect is that ventilation exceeds perfusion towards the apices, while perfusion exceeds ventilation at the bases. Other causes of $\dot{V}/\dot{Q}$ mismatch include direct shunting of deoxygenated blood through the lung without passing through alveoli (e.g. the bronchial circulation) and areas of lung that receive no blood (e.g. anatomical deadspace, bullae and areas of under-perfusion during acceleration and deceleration, e.g. in aircraft and high-performance cars).

An increased physiological shunt results in arterial hypoxaemia since it is not possible to compensate for some of the blood being under-oxygenated by increasing ventilation of the well-perfused areas. An increased physiological deadspace just increases the work of
breathing and has less impact on blood gases since the normally perfused alveoli are well ventilated. In more advanced disease this compensation cannot occur, leading to increased alveolar and arterial $PCO_2$ ($P_aCO_2$), together with hypoxaemia, which cannot be compensated for by increasing ventilation.

Hypoxaemia occurs more readily than hypercapnia because of the different ways in which oxygen and carbon dioxide are carried in the blood. Carbon dioxide is carried in three forms (in bicarbonate, in carbamino compounds and in simple solution), but the volume carried is proportional to the partial pressure of CO$_2$. Oxygen is carried in chemical combination with haemoglobin in the red blood cells, with a non-linear relationship between the volume carried and the partial pressure (see Fig. 24.5). Alveolar hyperventilation reduces the alveolar $PCO_2$ ($P_ACO_2$) and diffusion leads to a proportional fall in the carbon dioxide content of the blood ($P_aCO_2$). However, as the haemoglobin is already saturated with oxygen, increasing the alveolar $PO_2$ through hyperventilation will not increase blood oxygen content. This means that hypoxaemia due to physiological shunting cannot be compensated for by hyperventilation.

In individuals who have mild degrees of $V_A/Q$ mismatch, the $P_aO_2$ and $P_aCO_2$ will still be normal at rest. Increasing the requirements for gas exchange by exercise will widen the $V_A/Q$ mismatch and the $P_aO_2$ will fall. $V_A/Q$ mismatch is by far the most common cause of arterial hypoxaemia.

**Alveolar stability**

Pulmonary alveoli are polygonal spaces within a sponge-like matrix. Surface tension acting at the curved internal surface tends to cause the alveoli to decrease in size. The surface tension within the alveoli would make the lungs extremely difficult to distend were it not for the presence of surfactant, an insoluble lipoprotein largely consisting of dipalmitoyl lecithin, which forms a thin monomolecular layer at the air–fluid interface. Surfactant is secreted by type II pneumocytes within the alveolus and reduces surface tension so that alveoli remain stable.

Fluid surfaces covered with surfactant exhibit a phenomenon known as hysteresis; that is, the surface-tension-lowering effect of the surfactant can be improved by a transient increase in the size of the surface area of the alveoli. During quiet breathing, small areas of the lung undergo collapse, but it is possible to re-expand these rapidly by a deep breath: hence the importance of sighs or deep breaths as a feature of normal breathing. Failure of this mechanism, such as in patients with fractured ribs, gives rise to patchy basal lung collapse. Surfactant levels may be reduced in a number of lung diseases (e.g. pneumonia). Lack of surfactant plays a central role in the respiratory distress syndrome of the newborn. Severe reduction in perfusion of the lung impairs surfactant activity and this may explain the characteristic areas of collapse associated with pulmonary embolism.
Defence mechanisms of the respiratory tract

Pulmonary disease often results from a failure of the normal host defence mechanisms of the healthy lung (Fig. 24.9). These can be divided into physical, physiological, humoral and cellular mechanisms.

**Physical and physiological mechanisms**

**Humidification**
This prevents dehydration of the epithelium.

**Particle removal**
Over 90% of particles >10 µm in diameter are removed in the nostril or nasopharynx. This includes most pollen grains, which are typically >20 µm in diameter. Particles between 5 and 10 µm become impacted at the carina. Particles of <1 µm tend to remain airborne, thus the particles capable of reaching the deep lung are those in the 1–5 µm range.

**Particle expulsion**
This is effected by coughing, sneezing or gagging.
Respiratory tract secretions

The mucus of the respiratory tract is a gelatinous substance consisting of water and highly glycosylated proteins (mucins). The mucus forms a thick gel that is relatively impermeable to water and floats on a liquid or sol layer found around the cilia of the epithelial cells (Fig. 24.9). The gel layer is secreted from goblet cells and mucous glands as distinct globules that coalesce increasingly in the central airways to form a more or less continuous mucus blanket.

In addition to the mucins, the gel contains various antimicrobial molecules (lysozyme, defensins), specific antibodies (IgA) and cytokines, which are secreted by cells in airways and are incorporated into the mucus gel. Bacteria, viruses and other particles become trapped in the mucus and are either inactivated or simply expelled before they can do any damage. Under normal conditions, the tips of the cilia engage with the undersurface of the gel phase and by coordinated movement they push the mucus blanket upwards and outwards to the pharynx, where it is either swallowed or coughed up. While it only takes 30–60 minutes for mucus to be cleared from the large bronchi, it can be several days before mucus is cleared from respiratory bronchioles. One of the major long-term effects of cigarette smoking is a reduction in mucociliary transport. This contributes to recurrent infection and prolongs contact with carcinogenic material. Air pollutants, local and general anaesthetics, and products of bacterial and viral infection also reduce mucociliary clearance.

Congenital defects in mucociliary transport lead to recurrent infections and eventually to bronchiectasis. For example, in the ‘immotile cilia’ syndrome there is an absence of the dynein arms in the cilia themselves, while in cystic fibrosis there is ciliary dyskinesia and abnormally thick mucus.

The respiratory microbiome

It has always been thought that the lower respiratory tract is sterile. Recent evidence has shown that there is a resident bacterial flora that is very similar to that of the mouth. The composition of the respiratory microbiome is determined by three factors:

• **microbial immigration**, e.g. by inhalation, or microaspiration from the gastrointestinal tract

• **the local growth conditions** for the bacteria, e.g. temperature, pH, nutrients, concentration and activation of local inflammatory cells, and epithelial cell interactions

• **microbial elimination** by the usual mechanisms, i.e. the mucociliary escalator, coughing, and the innate and adaptive humoral mechanisms.

All of these factors will change in both acute and chronic lung conditions when there is an increase in pathological bacteria. This respiratory tract dysbiosis causes a disregulation of the local immune response and favours the growth of bacteria: for example, in the exacerbation of chronic diseases in which inflammation is perpetuated. The background composition of the bacterial microbiome in different conditions might favour exacerbations.

Humoral and cellular mechanisms
Non-specific soluble factors

- **α-Antitrypsin** (α₁-antiprotease; see p. 479) in lung secretions is derived from plasma. It inhibits chymotrypsin and trypsin, and neutralizes proteases including neutrophil elastase.

- **Antioxidant defences** include enzymes such as superoxide dismutase and low-molecular-weight antioxidant molecules (ascorbate, urate) in the epithelial lining fluid. In addition, lung cells are protected by an extensive range of intracellular defences, especially members of the glutathione S-transferase superfamily.

- **Lysozyme** is an enzyme found in granulocytes that has bactericidal properties.

- **Lactoferrin** is synthesized from epithelial cells and neutrophil granulocytes, and has bactericidal properties.

- **Interferons** are produced by most cells in response to viral infection and are potent modulators of lymphocyte function.

- **Complement** in secretions is also derived from plasma. In association with antibodies, it plays a major role in cytotoxicity.

- **Surfactant protein A** (SPA) is one of four species of surfactant proteins that opsonize bacteria/particles, enhancing phagocytosis by macrophages.

- **Defensins** are bactericidal peptides present in the azurophil granules of neutrophils.

- **Dimeric secretory IgA** targets specific antigens (see p. 392).

Innate and adaptive immunity

These mechanisms act as a defence against microbes, inorganic substances such as asbestos, particulate matter such as dust, and other antigens. They act by aiding opsonization so that macrophages can better ingest foreign material.

With infection, neutrophils migrate out of pulmonary capillaries into the air spaces and phagocytose and kill microbes with, for example, antimicrobial proteins (lactoferrin), degradative enzymes (elastase) and oxidant radicals. In addition, neutrophil extracellular traps ensnare and kill extracellular bacteria. Neutrophils also generate a variety of mediators, e.g. tumour necrosis factor alpha (TNF-α), interleukin 1 (IL-1), and chemokines that activate dendritic cells and B cells, and produce the T-cell-activating cytokine IL-12, which enhances neutrophil-mediated defence during pneumonia. Dendritic cells are antigen-presenting cells and are key to the adaptive immune response (see pp. 128–132).

Microbes are detected by host cells by pattern recognition receptors, such as toll-like receptors. These act via nuclear factor kappa B (NF-κB) transcription factors in the epithelial cells to produce adhesion molecules, chemokines and colony stimulating factors to initiate inflammation. Inflammation is necessary for innate immunity and host defence but can lead to lung damage; there is a fine line between defence and injury.

Clinical Approach to the Patient with Respiratory Disease

Clinical features of respiratory disease

**Runny, blocked nose and sneezing**

Nasal symptoms are extremely common; ‘runny nose’ (rhinorrhoea), nasal blockage and attacks of sneezing can be caused by allergic rhinitis (see p. 1075) and by common colds (pp. 1075–1076).

Nasal secretions are usually thin and runny in allergic rhinitis but thicker and discoloured with viral infections. Nose bleeds and blood-stained nasal discharge are common and rarely indicate serious pathology. However, a blood-stained nasal discharge associated with nasal obstruction and pain may be the presenting feature of a nasal tumour (see p. 1318). Nasal polyps typically present with nasal blockage and loss of smell.

**Cough**

Cough (see also pp. 1089–1090) is the most common symptom of lower respiratory tract disease. It is caused by mechanical or chemical stimulation of cough receptors in the epithelium of the pharynx, larynx, trachea, bronchi and diaphragm. Afferent receptors go to the cough centre in the medulla, where efferent signals are generated to the expiratory musculature. Smokers often have a morning cough with a little sputum. A productive cough is the cardinal feature of chronic bronchitis, while dry coughing, particularly at night, can be a symptom of asthma or acid reflux. Cough also occurs in asthmatics after mild exertion or following forced expiration. Cough can occur without any definable pathology; psychological causes may be blamed but there is only limited evidence.

A worsening cough is the most common presenting symptom of lung cancer. The normal explosive character of the cough is lost when a vocal cord is paralysed, usually as a result of lung cancer infiltrating the left recurrent laryngeal nerve – sometimes termed a bovine cough. Cough can be accompanied by stridor in whooping cough or in laryngeal or tracheal obstruction.

**Sputum**

Approximately 100 mL of mucus is produced daily in a healthy, non-smoking individual. This flows gradually up the airways, through the larynx, and is then swallowed. Excess mucus is
expectorated as sputum. Cigarette smoking is the most common cause of excess mucus production.

Mucoid sputum is clear and white but can contain black specks resulting from the inhalation of carbon. Yellow or green sputum is due to the presence of cellular material, including bronchial epithelial cells, or neutrophil or eosinophil granulocytes. Yellow sputum is not necessarily due to infection, as eosinophils in the sputum, as seen in asthma, can give the same appearance. The production of large quantities of yellow or green sputum is characteristic of bronchiectasis.

**Haemoptysis** (blood-stained sputum) varies from small streaks of blood to massive bleeding.

• The most common cause of mild haemoptysis is acute infection, particularly in exacerbations of COPD, but it should not be attributed to this without investigation.
• Other common causes are pulmonary infarction, bronchial carcinoma and tuberculosis.
• In lobar pneumonia, the sputum is usually rusty in appearance rather than frankly blood-stained.
• Pink, frothy sputum is seen in pulmonary oedema.
• In bronchiectasis, the blood is often mixed with purulent sputum.
• Massive haemoptysis (>200 mL of blood in 24 h) is usually due to bronchiectasis or tuberculosis.
• Uncommon causes of haemoptysis include idiopathic pulmonary haemosiderosis, Goodpasture syndrome, microscopic polyangiitis, trauma, blood disorders and benign tumours.

Haemoptysis should always be investigated. Although a diagnosis can often be made from a chest X-ray, a normal chest X-ray does not exclude disease. However, if the chest X-ray is normal, CT scanning and bronchoscopy are diagnostic in only about 5% of patients with haemoptysis.

**Firm plugs of sputum** may be coughed up by patients suffering from an exacerbation of allergic bronchopulmonary aspergillosis. Sometimes such sputum looks like casts of inflamed bronchi.

---

**Breathlessness**

**Dyspnoea** is a sense of awareness of increased respiratory effort that is unpleasant and that is recognized by the patient as being inappropriate. Patients often complain of tightness in the chest; this must be differentiated from angina.

**Breathlessness** should be assessed in relation to the patient's lifestyle. For example, a moderate degree of breathlessness will be totally disabling if the patient has to climb many flights of stairs to reach home.

**Orthopnoea** (see p. 939) is breathlessness on lying down. While it is classically linked to heart failure, it is partly due to the weight of the abdominal contents pushing the diaphragm up
into the thorax. Such patients may also become breathless on bending over.

*Tachypnoea* and *hyperpnoea* are, respectively, an increased rate of breathing and an increased level of ventilation. These may be appropriate responses (e.g. during exercise).

*Hyperventilation* is inappropriate overbreathing. This may occur at rest or on exertion, and results in a lowering of the alveolar and arterial $PCO_2$ (see p. 916).

*Paroxysmal nocturnal dyspnoea* (see p. 939) is acute episodes of breathlessness at night, typically due to heart failure.

### Wheezing

Wheezing is a common complaint and results from airflow limitation due to any cause. The symptom of wheezing is not diagnostic of asthma; other causes include vocal chord dysfunction, bronchiolitis and COPD. Conversely, wheeze may be absent in the early stages of asthma.

### Chest pain

The most common type of chest pain reported in respiratory disease is a localized sharp pain, often termed pleuritic. It is made worse by deep breathing or coughing and the patient can usually localize it. Localized anterior chest pain with tenderness of a costochondral junction is caused by costochondritis. Shoulder tip pain suggests irritation of the diaphragmatic pleura, while central chest pain radiating to the neck and arms is likely to be cardiac. Retrosternal soreness is associated with tracheitis, while malignant invasion of the chest wall causes a constant, severe, dull pain.

### Examination of the respiratory system

The nose
See page 1318.

The chest

**Inspection**

Assessment should be made of mental alertness, cyanosis, breathlessness at rest, use of accessory muscles, any deformity or scars on the chest and movement on both sides. $CO_2$ intoxication causes coarse tremor or flap of the outstretched hands. Prominent veins on the chest may imply obstruction of the superior vena cava.

*Cyanosis* (see p. 940) is a dusky colour of the skin and mucous membranes, due to the presence of $>50\, g/L$ of desaturated haemoglobin. When it has a central cause, cyanosis is visible on the tongue (especially the underside) and lips. Patients with central cyanosis will also be cyanosed peripherally. Peripheral cyanosis without central cyanosis is caused by a
reduced peripheral circulation and is noted on the fingernails and skin of the extremities with associated coolness of the skin.

*Finger clubbing* is present when the normal angle between the base of the nail and the nail fold is lost. The base of the nail is fluctuant owing to increased vascularity, and there is an increased curvature of the nail in all directions, with expansion of the end of the digit. Some causes of clubbing are given in *Box 24.2*. Clubbing is not a feature of uncomplicated COPD.

**Box 24.2**

**Some causes of finger clubbing**

**Respiratory**
- Bronchial carcinoma, especially epidermoid (squamous cell) type (major cause)
- Chronic suppurative lung disease:
  - Bronchiectasis
  - Lung abscess
  - Empyema
- Idiopathic lung fibrosis
- Pleural and mediastinal tumours (e.g. mesothelioma)
- Cryptogenic organizing pneumonia

**Cardiovascular**
- Cyanotic heart disease
- Subacute infective endocarditis
- Atrial myxoma

**Miscellaneous**
- Congenital – no disease
- Cirrhosis
- Inflammatory bowel disease

**Palpation and percussion**

The position of the trachea and apex beat should be checked. The supraclavicular fossa is examined for enlarged lymph nodes. The distance between the sternal notch and the cricoid cartilage (3–4 finger-breadths in full expiration) is reduced in patients with severe airflow limitation. Chest expansion should be checked; a tape measure may be used if precise or serial measurements are needed, such as in *ankylosing spondylitis*. Local discomfort over the sternochondral joints suggests costochondritis. In rib fractures, compression of the chest laterally and anteroposteriorly produces localized pain. On percussion, liver dullness is
usually detected anteriorly at the level of the sixth rib. Liver and cardiac dullness disappear when the lungs are over-inflated (Box 24.3).

**Auscultation**

The patient is asked to take deep breaths through the mouth. Inspiration should be more prolonged than expiration. Normal breath sounds are caused by turbulent flow in the larynx and sound harsher anteriorly over the upper lobes (particularly on the right). Healthy lungs filter out most of the high-frequency component, and the resulting sounds are called vesicular.

If the lung is consolidated or collapsed, the high-frequency hissing components of breath are not attenuated, and can be heard as ‘bronchial breathing’. Similar sounds may be heard over areas of localized fibrosis or bronchiectasis. Bronchial breathing is accompanied by whispering pectoriloquy (whispered, high-pitched sounds can be heard distinctly through a stethoscope).
Added sounds

**Wheeze.** Wheeze results from vibrations in the collapsible part of the airways when apposition occurs as a result of the flow-limiting mechanisms. Wheeze is usually heard during expiration and is commonly but not invariably present in asthma and COPD. In acute severe asthma, wheeze may not be heard, as airflow may be insufficient to generate the sound. Wheezes may be monophonic (single large airway obstruction) or polyphonic (narrowing of many small airways). An end-inspiratory wheeze or ‘squeak’ may be heard in obliterative bronchiolitis.

**Crackles.** These brief crackling sounds are probably produced by opening of previously closed bronchioles; early inspiratory crackles are associated with diffuse airflow limitation, while late inspiratory crackles are characteristically heard in pulmonary oedema, lung fibrosis and bronchiectasis.

**Pleural rub.** This creaking or groaning sound is usually well localized. It indicates inflammation and roughening of the pleural surfaces, which normally glide silently over one another.

**Vocal resonance.** Healthy lung attenuates high-frequency notes, as compared to the lower-pitched components of speech. Consolidated lung has the reverse effect, transmitting high frequencies well; the spoken word then takes on a bleating quality. Whispered (and therefore high-pitched) speech can be clearly heard over consolidated areas, as compared to healthy lung. Low-frequency sounds such as ‘ninety-nine’ are well transmitted across healthy lung to produce vibration that can be felt over the chest wall. Consolidated lung transmits these low-frequency noises less well, and pleural fluid severely dampens or obliterates the vibrations altogether. Tactile vocal fremitus is the palpation of this vibration, usually by placing the edge of the hand on the chest wall. For all practical purposes, this duplicates the assessment of vocal resonance and is not routinely performed as part of the chest examination.

Cardiovascular system examination

This gives additional information about the lungs (see pp. 940–943).

Additional bedside tests

Since so many patients with respiratory disease have airflow limitation, airflow should be routinely measured using a peak flow meter or spirometer. This is a much more useful assessment of airflow limitation than any physical sign.

Investigation of respiratory disease

Imaging

Imaging is essential in the investigation of most chest symptoms. Some diseases, such as tuberculosis or lung cancer, may be undetectable on clinical examination but are obvious on the chest X-ray. Conversely, asthma or chronic bronchitis may be associated with a normal chest X-ray. Always try to obtain previous images for comparison.
**Chest X-ray**

See *Box 24.4*.

---

**Box 24.4**

**The chest X-ray**

**Check**

- *Centring of the image*. The distance between each clavicular head and the spinal processes should be equal.
- *Penetration*. Check the image is not too dark and adjust the contrast.
- *View*:
  - *Postero-anterior (PA) views* are used for routine images; the X-ray source is behind the patient.
  - *Anteroposterior (AP) views* are used only in patients who are unable to stand or cannot be taken to the radiology department; the cardiac outline appears bigger and the scapulae cannot be moved out of the way.
  - *Lateral views* were used to localize pathology but have been replaced by CT scans.

**Look at**

- Shape and bony structure of the chest wall
- Centrality of the trachea
- Elevation/flatness of the diaphragm
- Shape, size and position of the heart
- Shape and size of the hilar shadows
- Shape and size of any lung abnormalities
- Vascular shadowing

---

**Collapse and consolidation**

Simple pneumonia is easy to recognize (see *Fig. 24.33*) but a careful search should be made for any evidence of collapse (*Fig. 24.10; Box 24.5*). Loss of volume or crowding of the ribs is the best indicator of lobar collapse. The lung lobes collapse in characteristic directions. The lower lobes collapse downwards and towards the mediastinum; the left upper lobe collapses forwards against the anterior chest wall; and the right upper lobe collapses upwards and inwards, giving the appearance of an arch over the remaining lung. The right middle lobe collapses anteriorly and inwards, obscuring the right heart border. If a whole lung collapses, the mediastinum will shift towards the side of the collapse. Uncomplicated consolidation does not cause mediastinal shift or loss of lung volume, so any of these features should raise the suspicion of an endobronchial obstruction.
FIGURE 24.10 Collapse of the left upper lobe. Chest X-ray showing a triangular shadow in the left upper zone, next to the mediastinum.

Box 24.5

Causes of lung collapse

- Enlarged tracheobronchial lymph nodes due to malignant disease or tuberculosis
- Inhaled foreign bodies (e.g. peanuts) in children, usually in the right main bronchus
- Bronchial casts or plugs (e.g. allergic bronchopulmonary aspergillosis)
- Retained secretions – postoperatively and in debilitated patients

Pleural effusion

Pleural effusions (see Fig. 24.45) need to be larger than 500 mL to cause much more than blunting of the costophrenic angle. On an erect film, they produce a characteristic shadow with a curved upper edge rising into the axilla. If they are very large, the whole of one hemithorax may be opaque, with mediastinal shift away from the effusion.

Fibrosis

Localized fibrosis produces streaky shadowing, and the accompanying loss of lung volume causes mediastinal structures to move to the same side. More generalized fibrosis can lead to a honeycomb appearance (see p. 1115), seen as diffuse shadows containing multiple circular translucencies a few millimetres in diameter.

Round shadows
Lung cancer is the most common cause of large round shadows but many other causes are recognized (Box 24.6).

### Box 24.6

**Causes of round shadows (>3 cm) in the lung**

- Carcinoma
- Metastatic tumours (usually multiple shadows)
- Lung abscess (usually with fluid level)
- Encysted interlobar effusion (usually in horizontal fissure)
- Hydatid cysts (often with a fluid level)
- Arteriovenous malformations (usually adjacent to a vascular shadow)
- Aspergilloma
- Rheumatoid nodules
- Tuberculoma (may be calcification within the lesion)

**Rare causes**

**Bronchial carcinoid**
- Cylindroma
- Chondroma
- Lipoma

**Other shadows related to mediastinum**
- Pericardium
- Oesophagus
- Spinal cord

Seen on lateral chest X-ray

---

**Miliary mottling**

This term, derived from the Latin for millet, describes numerous minute opacities, 1–3 mm in size. The most common causes are tuberculosis, pneumoconiosis, sarcoidosis, idiopathic pulmonary fibrosis and pulmonary oedema (see Fig. 23.15), although pulmonary oedema is usually perihilar and accompanied by larger, fluffy shadows. Pulmonary microlithiasis is a rare but striking cause of miliary mottling.

**Computed tomography**

Computed tomography (CT) provides excellent images of the lungs and mediastinal structures (Fig. 24.11). It is essential in staging bronchial carcinoma by demonstrating tumour size, nodal involvement, metastases and invasion of mediastinum, pleura or chest wall. CT-guided needle biopsy allows samples to be obtained from peripheral masses. Staging scans should assess liver and adrenals, which are common sites for metastatic disease. Mediastinal structures are shown more clearly after injecting intravenous contrast medium.
FIGURE 24.11  Computed tomography scans of the lung. A. Lung setting – showing normal lung markings. 1, right hilum; 2, mediastinum; 3, left hilum; 4, lung vessels; 5, left main bronchus; 6, right main bronchus; 7, peripheral lung vessels. B. Mediastinal (soft tissue) setting – showing normal mediastinal structures following intravenous contrast enhancement. 1, rib; 2, descending left pulmonary artery; 3, scapula; 4, subcutaneous fat; 5, left main bronchus; 6, descending aorta; 7, spinal canal; 8, vertebral body; 9, oesophagus; 10, right main bronchus; 11, right pulmonary artery; 12, muscle; 13, right superior pulmonary
C. Post-contrast scan – showing large right upper zone carcinoma (1) with enlarged lymph nodes (2) in the mediastinum surrounding the trachea.

**High-resolution CT** (HRCT) samples lung parenchyma with 1–2 mm thickness scans at 10–20 mm intervals and is used to assess diffuse inflammatory and infective parenchymal processes. It is valuable in:

- evaluation of diffuse disease of the lung parenchyma, including sarcoidosis, hypersensitivity pneumonitis, occupational lung disease, and any other form of interstitial pulmonary fibrosis
- diagnosis of bronchiectasis; HRCT has a sensitivity and specificity of >90%
- distinction of emphysema from diffuse parenchymal lung disease or pulmonary vascular disease as a cause of a low gas transfer factor with otherwise normal lung function
- suspected opportunistic lung infection in immunocompromised patients
- diagnosis of lymphangitis carcinomatosa.

**Multi-slice CT** scanners can produce detailed images in two or three dimensions in any plane. This detail is particularly useful for the detection of pulmonary emboli. Pulmonary nodules and airway disease are more easily defined, reducing the need for HRCT.

**Magnetic resonance imaging**

Magnetic resonance imaging (MRI) with electrocardiography (ECG) gating allows accurate imaging of the heart and aortic aneurysms, and MRI has been used in staging lung cancer, for assessing tumour invasion in the mediastinum, chest wall and at the lung apex, because it produces good images in the sagittal and coronal planes. Vascular structures can be clearly differentiated, as flowing blood produces a signal void on MRI. MRI is less valuable than CT in assessing the lung parenchyma.

**Positron emission tomography**

Tumours take up labelled fluorodeoxyglucose (FDG), which emits positrons that can be imaged. In bronchial carcinoma, positron emission tomography (PET) scanning combined with CT is the investigation of choice for assessing lymph nodes and metastatic disease, and helps to differentiate benign from malignant tumours.

**Scintigraphic imaging**

Isotopic lung scans were used widely for the detection of pulmonary emboli but are now performed less often owing to widespread use of CT pulmonary angiography.

**Perfusion scan**

*Macro-aggregated human albumin* labelled with technetium-99m ($^{99m}$Tc) is injected intravenously. The particles impact in pulmonary capillaries, where they remain for a few hours. A gamma camera is then used to detect the deposition of the particles. The resultant pattern indicates the distribution of pulmonary blood flow; cold areas occur where there is
defective blood flow (e.g. in pulmonary emboli).

**Ventilation–perfusion scan**

*Xenon-133 gas* is inhaled and its distribution is detected at the same time as the perfusion scan. Areas affected by pulmonary embolism will have reduced perfusion relative to ventilation (see pp. 1032–1033). Other lung diseases (e.g. asthma or pneumonia) impair both ventilation and perfusion. Unfortunately, a pulmonary embolus can affect the lung substance (e.g. atelectasis), leading to reduced ventilation. Nevertheless, this is a better technique than perfusion scanning alone.

**Ultrasound**

Ultrasound (USS) is useful for diagnosing and aspirating small pleural effusions, and for placing intercostal drains safely. USS-guided biopsy is used for lung masses that abut the pleura. Endobronchial USS is increasingly being used to assess mediastinal lymphadenopathy and to stage lung cancer.

**Respiratory function tests**

In clinical practice, airflow limitation can be assessed by relatively simple tests that have good intra-subject repeatability ([Box 24.7](#)). Results must be compared with predicted values for healthy subjects, as normal ranges vary with sex, age and height. Moreover, there is considerable variation between healthy individuals of the same size and age; the standard deviation for the peak expiratory flow rate is approximately 50 L/min, and for the FEV<sub>1</sub> it is approximately 0.4 L. Repeated measurements of lung function are useful for assessing the progression of disease in individual patients.

CT, computed tomography; FEV, forced expiratory volume; FEV₁, forced expiratory volume in 1 s; FVC, forced vital capacity; PEFR, peak expiratory flow rate.

**Tests of ventilatory function**
These tests are used mainly to assess the degree of airflow limitation during expiration.

**Spirometry**
The patient takes a maximum inspiration followed by a forced expiration (for as long as possible) into the spirometer. The spirometer measures the 1-second forced expiratory volume (FEV₁) and the total volume of exhaled gas (forced vital capacity, FVC). Both FEV₁ and FVC are related to height, age and sex (*Fig. 24.12*).
In airflow limitation, the FEV₁ is reduced as a percentage of FVC. In normal health, the FEV₁/FVC ratio is around 75%. With increasing airflow limitation, FEV₁ falls proportionately more than FVC, so the FEV₁/FVC ratio is reduced. With restrictive lung disease, FEV₁ and FVC are reduced proportionately and the FEV₁/FVC ratio remains normal or may even increase because of enhanced elastic recoil.

In chronic airflow limitation (particularly in COPD and asthma), the total lung capacity (TLC) is usually increased, yet there is nearly always some reduction in the FVC. This is because collapse of small airways causes obstruction to airflow before the normal residual volume (RV) is reached. This trapping of air within the lung is a characteristic feature of these diseases.

**Peak expiratory flow rate**

Peak expiratory flow rate (PEFR) is an extremely simple and cheap test. Subjects take a full inspiration to total lung capacity and then blow out forcefully into the peak flow meter (Fig. 24.13). The best of three attempts is recorded.
Although reproducible, PEFR is mainly dependent on the flow rate in larger airways and it may be falsely reassuring in patients with moderate airflow limitation. PEFR is mainly used to diagnose asthma, and to monitor exacerbations of asthma and response to treatment. Regular measurements of peak flow rates on waking, during the afternoon, and before going to bed demonstrate the wide diurnal variations in airflow limitation that characterize asthma and allow objective assessment of response to treatment (Fig. 24.14).

**Other ventilatory function tests**
Measurement of airways resistance in a body box (plethysmograph) is more sensitive but the equipment is expensive and the necessary manoeuvres are too exhausting for many patients with
chronic airflow limitation.

**Flow–volume loops**

Plotting flow rates against expired volume (flow–volume loops; see Fig. 24.7) shows the site of airflow limitation within the lung. At the start of expiration from TLC, maximum resistance is from the large airways, and this affects the flow rate for the first 25% of the curve. As air is exhaled, lung volume reduces and the flow rate becomes dependent on the resistance of smaller airways. In COPD, where the disease mainly affects the smaller airways, expiratory flow rates at 50% or 25% of the vital capacity are disproportionately reduced when compared with flow rates at larger lung volumes. Flow–volume loops will also show obstruction of large airways: for example, tracheal narrowing due to tumour or retrosternal goitre.

**Lung volumes**

The subdivisions of lung volume are shown in Figure 24.15. Tidal volume and vital capacity can be measured using a simple spirometer, but alternative techniques are needed to measure TLC and RV. TLC is measured by inhaling air containing a known concentration of helium and measuring its dilution in the exhaled air. RV can be calculated by subtracting the vital capacity from the TLC.

![FIGURE 24.15](image)

TLC measurements using this technique are inaccurate if there are large cystic spaces in the lung because helium cannot diffuse into them. Under these circumstances, the thoracic gas volume can be measured more accurately using a body plethysmograph (see above). The difference between measurements made by these two methods shows the extent of non-communicating air space within the lungs.
**Transfer factor**

To measure the efficiency of gas transfer across the alveolar–capillary membrane, carbon monoxide is used as a surrogate, since its diffusion rate is similar to oxygen. A low concentration of carbon monoxide is inhaled and the rate of absorption calculated. In normal lungs, the transfer factor accurately reflects the diffusing capacity of the lungs for oxygen and depends on the thickness of the alveolar–capillary membrane. In lung disease, the diffusing capacity ($D_{CO}$) is also affected by the ventilation–perfusion relationship. To control for differences in lung volume, the uptake of carbon monoxide is expressed relative to lung volume as a transfer coefficient ($K_{CO}$).

Gas transfer is reduced in patients with severe degrees of emphysema and fibrosis, but also in heart failure and anaemia. Although relatively non-specific, gas transfer is particularly useful in the detection and monitoring of diseases affecting the lung parenchyma (e.g. idiopathic pulmonary fibrosis, sarcoidosis and asbestosis).

**Measurement of blood gases**

This technique is described on pages 1161–1162.

Measurement of the partial pressures of oxygen and carbon dioxide in arterial blood is essential in managing respiratory failure and severe asthma, when repeated measurements are often the best guide to therapy.

*Peripheral oxygen saturation* ($S_pO_2$) can be continuously measured using an oximeter with either ear or finger probes. Pulse oximetry has become an essential part of the routine monitoring of patients in hospital and clinics. It is also useful in exercise testing and reduces the need to measure arterial blood gases.

**Exhaled nitric oxide**

Nitric oxide (NO) is produced by the bronchial epithelium and increases in asthma and other forms of airway inflammation. Measuring exhaled NO can guide therapy in asthma that is difficult to control.

**Haematological and biochemical tests**

It is useful to measure:

- haemoglobin, to detect anaemia or polycythaemia
- packed cell volume (secondary polycythaemia occurs with chronic hypoxia)
- routine biochemistry (often disturbed in carcinoma and infection)
- D-dimer to detect intravascular coagulation; a negative test makes pulmonary embolism very unlikely.

Other blood investigations sometimes required include $\alpha_1$-antitrypsin levels, *Aspergillus* antibodies, viral and mycoplasma serology, autoantibody profiles and specific IgE measurements.
Sputum
Sputum should be inspected for colour:
• Yellowish-green indicates inflammation (infection or allergy).
• Blood suggests a neoplasm or pulmonary infarct (see ‘Haemoptysis’, p. 1066).
  Microbiological studies (e.g. Gram stain and culture) are rarely helpful in upper respiratory tract infections or in acute or chronic bronchitis. They are of value in:
• pneumonia
• tuberculosis
• unusual clinical problems
• Aspergillus lung disease.

Sputum cytology
This is useful in the diagnosis of bronchial carcinoma and asthma. Its advantages are speed, cheapness and its non-invasive nature.
  However, not everyone can produce sputum and a reliable cytologist is needed. Sputum can be induced by inhalation of nebulized hypertonic saline (5%). Better samples can be obtained by bronchoscopy and bronchial washings (see p. 1074).

Exercise tests
The predominant symptom in respiratory medicine is breathlessness. The degree of disability produced by breathlessness can be assessed by asking the patient to walk for 6 minutes along a measured track. This has been shown to be a reproducible and useful test once the patient has undergone an initial training walk to overcome the learning effect. Additional information can be obtained by using pulse oximetry during exercise to assess desaturation.
  More sophisticated cardiopulmonary exercise tests are useful in investigating unexplained breathlessness. These involve measurement of oxygen uptake (\(\dot{V}O_2\)), work performed, heart rate, blood pressure and serial ECGs.

Pleural aspiration
Diagnostic aspiration is necessary for all but very small effusions. Nowadays, this is usually done under ultrasound guidance, using full aseptic precautions. A needle is inserted under local anaesthesia through an intercostal space towards the top of the area identified on ultrasound. Fluid is withdrawn and the presence of any blood is noted. Samples are sent for cytology, protein estimation, lactate dehydrogenase (LDH) and bacteriological examination, including culture and Ziehl–Neelsen/auramine staining for tuberculosis. Large amounts of fluid can be aspirated through a large-bore needle to help relieve extreme breathlessness.

Pleural biopsy
Pleural biopsy used to be performed at the bedside but is now generally done under direct
vision using video-assisted thoracoscopy (VATS).

**Intercostal drainage**

This is carried out when large effusions are present, producing severe breathlessness, or for drainage of an empyema *(Box 24.8)*. Drains should be inserted with ultrasound guidance. Pleurodesis is performed for recurrent/malignant effusion. Occasionally, a *long-term pleural drain* may be needed for recurrent effusions.

---

**Box 24.8**

**Intercostal drainage**

Explain the nature of the procedure to the patient and obtain written consent.

**Technique**

1. Identify the site for aspiration (using ultrasound in most cases).
2. Carefully sterilize the skin over the aspiration site.
3. Anaesthetize the skin, muscle and pleura with 2% lidocaine.
4. Make a small incision and insert an 8–12 French gauge drain, using the Seldinger technique. A needle is used to enter the pleural space, and then withdrawn over a guide wire over which the catheter is then inserted. (A larger-calibre catheter is needed for drainage of empyema, or a 28 French gauge Argyle catheter.)
5. Attach to a three-way tap and 50 mL syringe, and aspirate up to 1000 mL. Stop aspiration if the patient becomes uncomfortable; shock may ensue if too much fluid is withdrawn too quickly.
6. If the drain is to stay in, secure it to skin with suture and sterile dressing.
7. Attach the drain to an underwater seal drainage bottle and allow fluid to drain. Clamp the drain and release periodically, especially if patient becomes uncomfortable (usually up to 1000 mL at a time before clamping for a few hours).
8. Perform a chest X-ray to check the position of the drain.

**Pleurodesis**

- Instil lidocaine 3 mg/kg and then talc 4–5 g in 50 ml sodium chloride 0.9% solution into the pleural cavity to achieve pleurodesis in recurrent/malignant effusion.

---

**Mediastinoscopy**

Mediastinoscopy is used in the diagnosis of mediastinal masses and in the staging of nodal disease in carcinoma of the bronchus. An incision is made just above the sternum and a mediastinoscope inserted by blunt dissection. Mediastinoscopy is needed much less often now, since the introduction of endobronchial ultrasound (EBUS).

**Fibreoptic bronchoscopy**
See Box 24.9 and Figure 24.16.

Box 24.9

Fibreoptic bronchoscopy

This enables the direct visualization of the bronchial tree as far as the sub-segmental bronchi under a local anaesthetic. Obtain informed written consent after explaining the nature of the procedure.

Indications

- Lesions requiring biopsy seen on chest X-ray
- Haemoptysis
- Stridor
- Positive sputum cytology for malignant cells with no chest X-ray abnormality
- Collection of bronchial secretions for bacteriology, especially tuberculosis
- Recurrent laryngeal nerve paralysis of unknown aetiology
- Infiltrative lung disease (to obtain a transbronchial biopsy)
- Investigation of collapsed lobes or segments and aspiration of mucus plugs

Disadvantages

- All patients require sedation to tolerate the procedure
- Minor and transient cardiac dysrhythmias occur in up to 40% of patients on passage of the bronchoscope through the larynx. Monitoring is required
- Oxygen supplementation is required in patients with $P_aO_2 < 8$ kPa
- Fibreoptic bronchoscopy should be performed with care in the very sick, and transbronchial biopsies avoided in ventilated patients owing to the increased risk of pneumothorax
- Massive bleeding may occur after biopsy of vascular lesions or carcinoid tumours. Rigid bronchoscopy may be required to allow adequate access to the bleeding point for haemostasis
Under local anaesthesia and sedation, the central airways can be visualized down to sub-segmental level and biopsies taken for histology. More distal lesions may be sampled by washing or blind brushing. Diffuse inflammatory and infective lung processes may be sampled by bronchoalveolar lavage and transbronchial biopsy. The yield is best in sarcoidosis, lymphangitis carcinomatosa and hypersensitivity pneumonitis. Other fibrotic lung diseases rarely yield diagnostic samples so it may be preferable to perform open or thoracoscopic lung biopsy. EBUS enables direct sampling of lymph nodes for diagnostic staging of lung cancer.

**Video-assisted thoracoscopic lung biopsy**

Video-assisted thoracoscopic (VATS) lung biopsy has largely replaced open thoracotomy when a lung biopsy is required (see p. 1115).

**Skin-prick tests**

Allergen solutions are placed on the skin (usually the volar surface of the forearm) and the epidermis is broken using a 1 mm tipped lancet. A separate lancet should be used for each allergen. If the patient is sensitive to the allergen, a weal develops. The weal diameter is measured after 10 minutes. A weal of at least 3 mm diameter is regarded as positive, provided that the control test is negative. The results should always be interpreted in the light of the history. Skin tests are not affected by bronchodilators or corticosteroids but antihistamines should be discontinued at least 48 hours before testing.

**Smoking**
Prevalence

Cigarette smoking is declining in the Western world. In 1974 in the UK, 51% of men and 41% of women smoked cigarettes – nearly half the adult population. Now, about 21% of men and 19% of women aged 16 years and over smoke. The highest rates are in people aged 20–24 (28% of women and 30% of men in this age group smoke). The highest rates of cigarette consumption per capita are in Serbia, Bulgaria, Greece and Russia. In global terms, the USA ranks 51st and the UK ranks 73rd, close to the rates in Sweden, Canada and the Netherlands. Smoking continues to increase in many developing countries, particularly among women.

Toxic effects

Cigarette smoke contains polycyclic aromatic hydrocarbons and nitrosamines, which are potent carcinogens. It causes release of enzymes from neutrophil granulocytes and macrophages that are capable of destroying elastin and leading to lung damage. Pulmonary epithelial permeability increases, even in symptomless cigarette smokers, and correlates with the concentration of carboxyhaemoglobin in blood. This altered permeability may allow easier access for carcinogens.

The dangers

Cigarette smoking is addictive and harmful to health (Box 24.10). People usually start smoking in adolescence for psychosocial reasons and, once they smoke regularly, the pharmacological properties of nicotine encourage persistence, by their effect on the smoker's mood. Very few cigarette smokers (<2%) can limit themselves to occasional or intermittent smoking.

</tbody>
</table>
• An increase in fetal and neonatal mortality
• An increase in asthma

Passive smoking
• Risk of asthma, pneumonia and bronchitis in infants of smoking parents
• An increase in cough and breathlessness in smokers and non-smokers with COPD and asthma
• An increase in cancer risk

Significant dose–response relationships exist between cigarette consumption, airway inflammation and lung cancer mortality (Box 24.11). Sputum production and airflow limitation increase with daily cigarette consumption, and effort tolerance decreases. Smoking 20 cigarettes daily for 20 years increases the lifetime risk of lung cancer by about 10 times compared to a lifelong non-smoker. Smoking and asbestos exposure are synergistic risk factors for lung cancer, with a combined risk of about 90 times that of unexposed non-smokers.

Box 24.11
Effects of smoking on the lung

Large airways
• Increase in submucosal gland volume
• Increase in number of goblet cells
• Chronic inflammation
• Metaplasia and dysplasia of the surface epithelium

Small airways
• Increase in number and distribution of goblet cells
• Airway inflammation and fibrosis
• Epithelial metaplasia/dysplasia
• Carcinoma

Parenchyma
• Proximal acinar scarring
• Increase in alveolar macrophage numbers
• Emphysema (centri-acinar, pan-acinar)

Cigarette smokers who change to cigars or pipe-smoking can reduce their risk of lung cancer. However, pipe- and cigar-smokers remain at greater risk of lung cancer than lifelong
Environmental tobacco smoke (‘passive smoking’) has been shown to increase the frequency and severity of asthma attacks in children and may also increase the incidence of asthma. It is also associated with a small but definite increase in lung cancer. Worldwide, second-hand smoke was estimated to affect 40% of children, 33% of non-smoking males and 35% of non-smoking females in 2004. This caused a 1% worldwide mortality and 0.7% of the total worldwide burden of disease in disability-adjusted life years (DALYs).

**Stopping smoking**

If the entire population could be persuaded to stop smoking, the effect on healthcare use would be enormous. National campaigns, bans on advertising and a substantial increase in the cost of cigarettes are the best ways of achieving this at the population level. Smoking bans in the workplace and public spaces have also helped. Meanwhile, active encouragement to stop smoking remains a useful approach for individuals. Smokers who want to stop should have access to smoking cessation clinics to provide behavioural support. Nicotine replacement therapy (NRT) and bupropion are effective aids to smoking cessation in those smoking more than 10 cigarettes/day. Both should be used only in smokers who commit to a target stop date, and the initial prescription should be for 2 weeks beyond the target stop date. NRT is the preferred choice; there is no evidence that combined therapy offers any advantage. Therapy should be changed after 3 months if abstinence is not achieved.

Varenicline is an oral partial agonist on the $\alpha_4\beta_2$ subtype of the nicotinic acetylcholine receptor. It stimulates the nicotine receptor and reduces withdrawal symptoms and also the craving for cigarettes. A 12-week course quadruples the chance of stopping smoking; its main side-effects are nausea and sometimes severe depression. Cytisine, which has high affinity for the same receptor, also aids smoking cessation. Electronic cigarettes (battery-operated vaporizer) are a useful alternative for ex-smokers who miss the physical process of handling cigarettes and inhaling nicotine. While E-cigarettes are not harmless, they are much less harmful than ordinary cigarettes.

**Further reading**

Diseases of the Upper Respiratory Tract

Rhinitis

The common cold (acute coryza)
This highly infectious illness (see p. 253) is due to a variety of respiratory viruses: for example, the rhinoviruses (most common), coronaviruses and adenoviruses. Infectivity from close personal contact (nasal mucus on hands) or droplets is high in the early stages of the infection, and spread is facilitated by overcrowding and poor ventilation. There are at least 100 different antigenic strains of rhinovirus, making it difficult for the immune system to confer protection. The incubation period varies from 12 hours to 5 days.

The clinical features are tiredness, slight pyrexia, malaise, and a sore nose and pharynx. Sneezing and profuse, watery nasal discharge are followed by thick mucopurulent secretions that may persist for up to a week. Secondary bacterial infection occurs in only a minority of cases.

Other forms of rhinitis
Rhinitis is defined clinically as sneezing attacks, nasal discharge or blockage occurring for more than an hour on most days:
• for a limited period of the year (seasonal or intermittent rhinitis)
• throughout the whole year (perennial or persistent rhinitis).

Seasonal rhinitis
This is the most common allergic disorder. It is often called ‘hayfever’, but as this implies that only grass pollen is responsible, it is better described as seasonal (or intermittent) allergic rhinitis. Worldwide prevalence rates vary from 2% to 20%. Prevalence is maximal in the second decade, and up to 30% of UK teenagers and young adults are affected each June and July.

Nasal irritation, sneezing and watery rhinorrhea occur, but many also suffer from itching of the eyes and soft palate, and occasionally even itching of the ears because of the common innervation of the pharyngeal mucosa and the ear. In addition, approximately 20% suffer from seasonal wheezing. The common seasonal allergens are shown in Figure 24.17.
Since pollination of plants that give rise to high pollen counts varies from country to country, seasonal rhinoconjunctivitis and accompanying wheeze may occur at different times of year in different regions.

**Perennial rhinitis**

In about 50% of patients with perennial rhinitis, symptoms of sneezing and watery rhinorrhea predominate, whilst the other half complain mostly of nasal blockage. The patient may lose the senses of smell and taste but rarely has eye or throat symptoms. Sinusitis occurs in about 50% of cases, due to mucosal swelling that obstructs drainage from the sinuses. Perennial rhinitis is most frequent in the second and third decades, decreasing with age, and can be divided into four main types.

**Perennial allergic rhinitis**

The most common cause is allergy to the faecal particles of the house-dust mite, *Dermatophagoides pteronyssinus* or *D. farinae*; these are under 0.5 mm in size, invisible to the naked eye (*Fig. 24.18*), and found in dust throughout the house, particularly in older, damp dwellings. Mites live off desquamated human skin scales and the highest concentrations (4000 mites/g of surface dust) are found in human bedding. Their faecal particles are approximately 20 μm in diameter (*Fig. 24.18*), and impact in the nose rather than the lungs, unless the patient breathes through the mouth.
The next most common allergens come from domestic pets (especially cats) and are proteins derived from urine or saliva spread over the surface of the animal, as well as skin protein. Allergy to urinary protein from small mammals is a major cause of morbidity among laboratory workers.

Industrial dust, vapours and fumes cause occupationally related perennial rhinitis more often than asthma.

The presence of perennial rhinitis makes the nose more reactive to non-specific stimuli, such as cigarette smoke, washing powders, household detergents, strong perfumes and traffic fumes. Although patients often think they are allergic to these stimuli, these are irritant responses and do not involve antibodies.

**Perennial non-allergic rhinitis with eosinophilia**

No extrinsic allergic cause can be identified, either from the history or on skin testing, but eosinophilic granulocytes are present in nasal secretions. Most of these patients are intolerant of aspirin/non-steroidal anti-inflammatory drugs (NSAIDs).

**Vasomotor rhinitis**

These patients with perennial rhinitis have no demonstrable allergy or nasal eosinophilia. Watery secretions and nasal congestion are triggered by, for example, cold air, smoke, perfume or newsprint, possibly because of an imbalance of the autonomic nerves controlling the erectile tissue (sinusoids) in the nasal mucosa.
Nasal polyps
These are round, smooth, soft, semi-translucent, pale or yellow, glistening structures attached to the sinus mucosa by a relatively narrow stalk or pedicle, occurring in patients with allergic or vasomotor rhinitis. The mechanism(s) of their formation is not known. They contain mast cells, eosinophils and mononuclear cells in large numbers and cause nasal obstruction, loss of smell and taste, and mouth breathing, but rarely sneezing, since the mucosa of the polyp is largely denervated.

Pathogenesis of rhinitis
Sneezing, increased secretion and changes in mucosal blood flow are mediated both by efferent nerve fibres and by released mediators (see p. 1094). Mucus production results largely from parasympathetic stimulation. Blood vessels are under both sympathetic and parasympathetic control. Sympathetic fibres maintain tonic contraction of blood vessels, keeping the sinusoids of the nose partially constricted and aiding nasal patency. Stimulation of the parasympathetic system dilates these blood vessels. This stimulation varies spontaneously in a cyclical fashion so that air intake alternates slowly over several hours from one nostril to the other. The erectile cavernous nasal sinusoids can be influenced by emotion and hence affect nasal patency.

B cells produce IgE antibody against allergens. IgE binds to mast cells via high-affinity cell surface receptors, whose crosslinking causes degranulation and release of histamine, proteases (tryptase, chymase), prostaglandins (PGDs), cysteinyl leukotrienes (LTC₄, LTD₄, LTE₄) and cytokines. These mediators cause the acute symptoms of sneezing, itch, rhinorrhea and nasal congestion. Sneezing results from stimulation of afferent nerve endings (mostly via histamine) and begins within minutes of an allergen entering the nose. This is followed by nasal exudation and secretion, and eventually nasal blockage, peaking 15–20 minutes after allergen exposure. These latter symptoms are driven by increased epithelial permeability, mostly due to histamine.

Additionally, allergens are presented to T cells via antigen-presenting cells (dendritic cells). This causes release of IL-4 and IL-13, which further stimulate the B cells, and also IL-5, IL-9 and granulocyte macrophage colony stimulating factor (GM-CSF), switching from a Th1 to a Th2 response to activate and recruit eosinophils, basophils, neutrophils and T lymphocytes. These cause chronic swelling and irritation, leading to nasal obstruction, hyper-reactivity and anosmia.
Investigations and diagnosis

The allergic factors causing rhinitis can usually be identified from the history. Skin-prick testing is used to support the history. A positive test does not necessarily mean that an allergen causes the respiratory disease. However, if there is a compatible clinical history, it is more likely to be relevant. Allergen-specific IgE antibodies can be measured in blood but such tests are much more expensive than skin tests and should be used only in patients who cannot be skin-tested for some reason (e.g. dermatographism, active eczema or inability to stop antihistamines for 3 days before skin tests).

Management

Allergen avoidance

Removal of a household pet or total enclosure of industrial processes releasing sensitizing agents can lead to cure of rhinitis and, indeed, asthma. However, pollen avoidance is impossible. Contact may be diminished by wearing sunglasses, driving with the car windows shut, avoiding walks in the countryside (particularly in the late afternoon, when the number of pollen grains is highest at ground level), and keeping bedroom windows shut at night. These measures are rarely sufficient in themselves to control symptoms. Exposure to pollen is generally lower in coastal regions, where sea breezes carry pollen grains inland.

The house-dust mite infests most areas of the house, but particularly the bedroom. Mite allergen exposure can be reduced by enclosing bedding in fabric specifically designed to prevent the passage of mite allergen, while allowing water vapour through. This is comfortable and also reduces symptoms. Acaricides are less effective and cannot be recommended. Increased room ventilation and reduced soft furnishings, including carpets, curtains and soft toys, can all help to reduce the mite load. However, the value of house-dust mite control measures in asthma has been challenged (see pp. 1096–1097).

H₁ antihistamines

Antihistamines remain the most common therapy for rhinitis; most can be purchased directly over the counter in the UK. They are particularly effective against sneezing and itching of the eyes and palate, but are less effective against rhinorrhea and have little influence on nasal blockage. First-generation antihistamines (chlorphenamine, hydroxyzine) cause sedation and loss of concentration in all patients (including those who are not aware of the problem) and should no longer be used. Second-generation drugs, such as loratadine (10 mg once daily), desloratadine (5 mg daily), cetirizine (10 mg daily) and fexofenadine (120 mg daily), are at least as potent and do not cause sedation.

Decongestants

Drugs with sympathomimetic activity (α-adrenergic agents) are widely used to treat nasal
obstruction. They may be taken orally or, more commonly, as nasal drops or sprays (e.g. ephedrine nasal drops). Xylometazoline and oxymetazoline are widely used because they have a prolonged action and tachyphylaxis does not develop. Secondary nasal hyperaemia can occur some hours later as a rebound effect and rhinitis medicamentosa can develop if patients take increasing quantities of decongestant to overcome this phenomenon. Although local decongestants are an effective treatment for vasomotor rhinitis, patients must be warned about rebound nasal obstruction and should use the drugs carefully. Ideally, such preparations should be prescribed for only a limited period to open the nasal airways and allow better access for other local therapy, such as topical corticosteroids.

**Anti-inflammatory drugs**

Sodium cromoglicate and nedocromil sodium act by blocking an intracellular chloride channel and influence mast cell and eosinophil activation and nerve function. Topical sodium cromoglicate and nedocromil sodium can be very effective in allergic conjunctivitis but are of limited value in allergic rhinitis.

**Corticosteroids**

The most effective treatment for rhinitis is a topical corticosteroid preparation (e.g. beclometasone, fluticasone propionate, fluticasone furoate or mometasone furoate spray). Topical steroids should be started before the beginning of seasonal symptoms. The combination of a topical corticosteroid with a non-sedating antihistamine taken regularly is particularly effective. Patients should be carefully instructed in how to use the nasal steroid device to achieve optimal drug deposition. In selected cases, an α-adrenergic agonist may help to decongest the nose prior to taking the topical corticosteroid. Patients often worry about possible side-effects; nasal steroids can cause epistaxis, but the amount used is insufficient to cause systemic effects.

If other therapy has failed, seasonal and perennial rhinitis respond readily to a short course (maximum 2 weeks) of treatment with oral prednisolone 5–10 mg daily. Nasal polyps may respond to oral corticosteroids and their recurrence may be prevented by continuous use of topical corticosteroids.

**Leukotriene antagonists**

In patients who do not respond to antihistamines or topical steroids, a leukotriene antagonist (e.g. montelukast 10 mg daily in the evening) may be helpful, especially in those with a history of NSAID sensitivity or concomitant asthma.

**Immunotherapy**

This is used for patients with seasonal allergic rhinitis who have not responded to standard drugs. Both oral and injectable vaccines are available (see p. 143). Other forms of desensitizing vaccines are under development.
Sinusitis
See page 1319.

Pharyngitis
The most common viruses causing pharyngitis are adenoviruses, of which there are about 32 serotypes. Endemic adenovirus infection causes the common sore throat, in which the oropharynx and soft palate are reddened and the tonsils are inflamed and swollen. Within 1–2 days, the tonsillar lymph nodes enlarge. Occasionally, localized epidemics occur due to adenovirus serotype 8, particularly in schools during summer, with episodes of fever, conjunctivitis, pharyngitis and lymphadenitis of the neck glands. The disease is self-limiting and requires only symptomatic treatment without antibiotics.

Over several decades, the proportion of sore throats due to bacterial infections, such as haemolytic streptococcus, has fallen. Many different pathogens have been implicated in pharyngitis but most do not require specific treatment. Persistent and severe tonsillitis should be treated with phenoxyethylpenicillin 500 mg four times a day or cefaclor 250 mg three times daily. Amoxicillin and ampicillin should be avoided if there is a possibility of infectious mononucleosis (see p. 258), as they are likely to cause drug rashes in this context.

Acute laryngotracheobronchitis

Acute laryngitis is an occasional but striking complication of upper respiratory tract infections, particularly those caused by parainfluenza viruses and measles. The condition is most severe in children under the age of 3 years. Inflammatory oedema extends to the vocal cords and the epiglottis, causing narrowing of the airway; there may be associated tracheitis or tracheobronchitis. The voice becomes hoarse, with a barking cough (croup), and there is audible stridor. Progressive airways obstruction may occur, with recession of the soft tissue of the neck and abdomen during inspiration and, in severe cases, central cyanosis. Steam inhalations are not helpful. Nebulized adrenaline (epinephrine) gives short-term relief. Oral or intramuscular corticosteroids (e.g. dexamethasone) should be given with oxygen and adequate fluids. If steroids are used, endotracheal intubation is rarely necessary. Rarely, a tracheostomy is required.

Acute epiglottitis

H. influenzae type b (Hib) can cause life-threatening infection of the epiglottis, usually in children under 5 years of age. The child becomes extremely ill with a high fever, and severe airflow obstruction may rapidly occur. This is a life-threatening emergency and requires urgent endotracheal intubation and intravenous antibiotics (e.g. ceftazidime 25–150 mg/kg). Chloramphenicol (50–100 mg/kg) is also used in some countries. The epiglottis, which is red
and swollen, should not be inspected until facilities to maintain the airways are available.

Other manifestations of Hib infection are meningitis, septic arthritis and osteomyelitis. A highly effective vaccine is now available, which is given to infants at 2, 3 and 4 months, with their primary immunizations against diphtheria, tetanus and pertussis (DTP). In many countries, this programme has reduced death rates from Hib infections virtually to zero.

**Influenza**

The influenza virus belongs to the orthomyxovirus group and exists in two main forms, A and B. Influenza B is associated with localized outbreaks of mild disease, whereas influenza A causes worldwide pandemics (see p. 254).

**Clinical features**

The incubation period of influenza is usually 1–3 days. The illness starts abruptly with a fever, shivering and generalized aching in the limbs. This is associated with severe headache, soreness of the throat and a dry cough that can persist for several weeks. Diarrhoea occurs in 70% of cases of H5N1 (‘bird flu’). Influenza infection can be followed by a prolonged period of debility and depression that may take weeks or months to clear.

**Complications**

Secondary bacterial infection is common following influenza virus infection, particularly with *Streptococcus pneumoniae* and *Haemophilus influenzae*. Secondary pneumonia caused by *Staphylococcus aureus* is rarer, but more serious, and carries a mortality of up to 20%. Post-infectious encephalomyelitis is rare after influenza infection.

**Diagnosis and management**

Laboratory diagnosis is not usually necessary, but a definitive diagnosis can be established by demonstrating a four-fold increase in complement-fixing antibody or haemagglutinin antibody measured at onset and after 1–2 weeks, or by demonstrating the virus in throat or nasal secretions.

*Management* is by bed rest and paracetamol, with antibiotics to prevent secondary infection in those with chronic bronchitis, or cardiac or renal disease.

Neuraminidase inhibitors help to shorten the duration of symptoms in patients with influenza, if given within 48 hours of the first symptom. The cost–benefit of zanamivir and oseltamivir remains unproven but these are currently recommended in the UK for patients with suspected influenza over the age of 65 and ‘at-risk’ adults, as part of a strategy to reduce admissions to hospital when influenza is circulating in the community.
Prophylaxis

Protection by influenza vaccines is effective in only about 70% of people and lasts only for about a year. New vaccines have to be prepared to cover each change in viral antigenicity and are therefore in limited supply at the start of an epidemic. Nevertheless, routine vaccination is recommended for all individuals over 65 years of age and also for younger people with chronic heart disease, chronic lung disease (including asthma), chronic kidney disease or diabetes mellitus and for those who are immunosuppressed. During pandemics, key hospital and health service personnel should also be vaccinated. Influenza vaccine should not be given to individuals who are allergic to egg protein, as some are manufactured in chick embryos.

Inhalation of foreign bodies

Children inhale foreign bodies, such as peanuts, more commonly than do adults. In adults, inhalation may occur after excess alcohol or under general anaesthesia (loose teeth or dentures).

When the foreign body is large, it may impact in the trachea. The person chokes and then becomes silent; death ensues unless the material is quickly removed (Box 24.12).

Box 24.12

Treatment of inhaled foreign bodies (Heimlich manœuvre)

Emergency

The Heimlich manœuvre is used to expel the obstructing object:

1. Stand behind the patient.
2. Encircle the upper part of the patient's abdomen just below the rib cage with your arms.
3. Give a sharp, forceful squeeze, forcing the diaphragm sharply into the thorax. This should expel sufficient air from the lungs to force the foreign body out of the trachea.

Non-emergency

Rigid bronchoscopy should be performed.

More often, impaction occurs in the right main bronchus and produces:

- choking
- persistent monophonc wheeze
- persistent suppurative pneumonia
- lung abscess (common).
Diseases of the Lower Respiratory Tract

Lower respiratory tract infection accounts for approximately 10% of the worldwide burden of morbidity and mortality. Some 75% of all antibiotic usage is for these diseases, despite the fact that they are mainly due to viruses.

**Acute bronchitis**

Acute bronchitis in previously healthy subjects is often viral. Bacterial infection with *Strep. pneumoniae* or *H. influenzae* is a common sequel to viral infections, and is more likely to occur in cigarette smokers or people with COPD.

The illness begins with an irritating, non-productive cough, together with discomfort behind the sternum. There may be associated chest tightness, wheezing and shortness of breath. Later, the cough becomes productive, with yellow or green sputum. There is a mild fever and a neutrophil leucocytosis; wheeze with occasional crackles can be heard on auscultation. In otherwise healthy adults, the disease improves spontaneously in 4–8 days without them becoming seriously ill.

Antibiotics are often given (e.g. amoxicillin 250 mg three times daily), but it is not known whether this hastens recovery in otherwise healthy individuals and they should not be given in most cases.

**Chronic obstructive pulmonary disease**

Chronic obstructive pulmonary disease (COPD) is predicted to become the third most common cause of death and fifth most common cause of disability worldwide by 2020.

COPD is an overarching diagnosis that brings together a variety of clinical syndromes associated with airflow limitation and destruction of the lung parenchyma.

COPD is associated with a number of co-morbidities, e.g. ischaemic heart disease, hypertension, diabetes, heart failure and cancer, suggesting that it may be part of a generalized systemic inflammatory process.

**Definition**
COPD has been described as ‘a disease state characterized by airflow limitation that is not fully reversible. The airflow limitation is usually both progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases.’

### Epidemiology and aetiology

COPD is caused by long-term exposure to toxic particles and gases. In developed countries, cigarette smoking accounts for over 90% of cases. In developing countries, other factors are also implicated, such as inhalation of smoke from biomass heating fuels and cooking in poorly ventilated areas. However, only 10–20% of heavy smokers develop COPD, indicating individual susceptibility. The development of COPD is proportional to the number of cigarettes smoked per day; the risk of death from COPD in patients smoking 30 cigarettes daily is 20 times that of a non-smoker. Autopsy studies have shown substantial numbers of centri-acinar emphysematous spaces in the lungs of 50% of British smokers over the age of 60 years, independently of whether significant respiratory disease was diagnosed before death.

Climate and air pollution are lesser causes of COPD, but mortality from COPD increases dramatically during periods of heavy atmospheric pollution (see pp. 56–57). Urbanization, social class and occupation may also play a part in the aetiology but these effects are difficult to separate from that of smoking. Some animal studies suggest that diet could be a risk factor for COPD but this has not been proven in humans.

The socioeconomic burden of COPD is considerable. In the UK, COPD causes approximately 18 million lost working days annually for men and 2.1 million lost working days for women, accounting for approximately 7% of all days of absence from work due to sickness. Nevertheless, the number of COPD admissions to UK hospitals has been falling steadily over the last 30 years.

### Pathophysiology

The most consistent pathological finding in COPD is increased numbers of mucus-secreting goblet cells in the bronchial mucosa, especially in the larger bronchi (Fig. 24.19). In more advanced cases, the bronchi become overtly inflamed and pus is seen in the lumen. The role of the resident microbiome (see p. 1065) in exacerbations of COPD is as yet unknown.
Microscopically, there is infiltration of the walls of the bronchi and bronchioles with acute and chronic inflammatory cells; lymphoid follicles may develop in severe disease. In contrast to asthma, the lymphocytic infiltrate is predominantly CD8⁺. The epithelial layer may become ulcerated and, with time, squamous epithelium replaces the columnar cells. The inflammation is followed by scarring and thickening of the walls, which narrows the small airways (Fig. 24.20).
The small airways are particularly affected early in the disease, initially without the development of any significant breathlessness. This initial inflammation of the small airways is reversible and accounts for the improvement in airway function if smoking is stopped early. In later stages, the inflammation continues, even if smoking is stopped.

Further progression of the airways disease leads to progressive squamous cell metaplasia and fibrosis of the bronchial walls. The physiological consequence of these changes is the development of airflow limitation. If the airway narrowing is combined with emphysema (causing loss of the elastic recoil of the lung with collapse of small airways during expiration), the resulting airflow limitation is even more severe.

Emphysema is defined as abnormal, permanent enlargement of air spaces distal to the terminal bronchiole, accompanied by destruction of their walls and without obvious fibrosis. Enlargement of the distal air spaces (i.e. emphysema) is thought to be a secondary result of small airway inflammation and destruction. It is classified according to the site of damage:

- **Centri-acinar emphysema.** Distension and damage of lung tissue is concentrated around the respiratory bronchioles, whilst the more distal alveolar ducts and alveoli tend to be well preserved. This form of emphysema is extremely common; when of modest extent, it is not necessarily associated with disability. Severe centri-acinar emphysema is associated with substantial airflow limitation.

- **Pan-acinar emphysema.** This is less common but is the type associated with $\alpha_1$-antitrypsin deficiency (see p. 1081). Distension and destruction affect the whole acinus, and in severe cases the lung is just a collection of bullae. Severe airflow limitation and $V_a/Q$ mismatch occur.

- **Irregular emphysema.** There is scarring and damage that affect the lung parenchyma patchily, independent of acinar structure.
Emphysema leads to expiratory airflow limitation and air trapping. The loss of lung elastic recoil results in an increase in total lung capacity (TLC). Premature closure of airways limits expiratory flow while the loss of alveoli decreases capacity for gas transfer. 

$\dot{V}_a/\dot{Q}$ mismatch is partly due to damage and mucus plugging of smaller airways from chronic inflammation, and partly due to rapid closure of smaller airways in expiration owing to loss of elastic support. The mismatch leads to a fall in $P_{a}O_2$ and increased work of respiration.

$CO_2$ excretion is less affected by $\dot{V}_a/\dot{Q}$ mismatch and many patients have low-normal $P_{a}CO_2$ values due to increasing alveolar ventilation in an attempt to correct their hypoxia (‘pink puffers’). Other patients fail to maintain their respiratory effort and then their $P_{a}CO_2$ levels increase. In the short term, this rise in $CO_2$ leads to stimulation of respiration, but in the longer term, these patients often become insensitive to $CO_2$ and come to depend on hypoxaemia to drive ventilation. Such patients appear less breathless and, because of renal hypoxia, they start to retain fluid and increase erythrocyte production (leading eventually to polycythaemia). In consequence, they become bloated, plethoric and cyanosed, the typical appearance of the ‘blue bloater’. Attempts to abolish hypoxaemia by administering oxygen can make the situation much worse by decreasing respiratory drive in these patients who depend on hypoxia to drive their ventilation.

The classic Fletcher and Peto studies (Fig. 24.21) showed a loss of 50 mL per year in FEV$_1$ in patients with COPD compared with 20 mL per year in healthy people. A more recent study has shown a 40 mL loss per year but only in 38% of the patients studied. Biomarkers to predict the rate of decline have been unhelpful, although serum levels of Clara cell secretory protein 16 (CC16) has been proposed as a possible indicator; it is an indication of acute or chronic bronchial epithelium injury.

![FIGURE 24.21 Influence of smoking on airflow limitation](From Fletcher CM, Peto R. The natural history of chronic airflow obstruction. *British Medical Journal* 1977; 1:1649.)

Three mechanisms have been suggested to explain airflow limitation in small airways (<2 mm in diameter).
• **Loss of elasticity** and alveolar attachments of airways due to emphysema. This reduces the elastic recoil and the airways collapse during expiration.

• **Inflammation and scarring**, which cause the small airways to narrow.

• **Mucus secretion**, which blocks the airways.

  Each of these narrows the small airways and causes air trapping, leading to hyperinflation of the lungs, $V_a/Q$ mismatch, increased work of breathing and breathlessness.

### Pathogenesis

**Cigarette smoking**

Bronchoalveolar lavage and biopsies of the airways of smokers show increased numbers of neutrophil granulocytes. These granulocytes can release elastases and proteases, which may help to produce emphysema. It has been suggested that an imbalance between protease and antiprotease activity causes the damage. Alpha$_1$-antitrypsin is a major serum antiprotease, which can be inactivated by cigarette smoke (see below).

Mucous gland hypertrophy in the larger airways is thought to be a direct response to persistent irritation resulting from the inhalation of cigarette smoke. The smoke has an adverse effect on surfactant, favouring over-distension of the lungs.

**Infections**

Patients with COPD cope badly with respiratory infections, which are often the precipitating cause of acute exacerbations of the disease. However, it is less clear whether infection is responsible for the progressive airflow limitation that characterizes disabling COPD. Prompt use of antibiotics and routine vaccinations against influenza and pneumococci are appropriate.

**Alpha$_1$-antitrypsin deficiency**

Alpha$_1$-antitrypsin (see also pp. 479–480) is a proteinase inhibitor that is produced in the liver; it is secreted into the blood and diffuses into the lung. Here it inhibits proteolytic enzymes such as neutrophil elastase, which are capable of destroying alveolar wall connective tissue. In alpha$_1$-antitrypsin deficiency, the protein accumulates in the liver, leading to low levels in the lung.

More than 75 alleles of the alpha$_1$-antitrypsin gene have been described. The three main phenotypes are MM (normal), MZ (heterozygous deficiency) and ZZ (homozygous deficiency). About 1 child in 5000 in the UK is born with the homozygous deficiency, but not all develop chest disease. Those who do develop breathlessness under the age of 40 years have radiographic evidence of basal emphysema and are usually, but not always, cigarette smokers. Hereditary deficiency of alpha$_1$-antitrypsin accounts for about 2% of UK emphysema cases. A small minority develop liver disease (see p. 480).
Clinical features

Symptoms
The characteristic symptoms of COPD are productive cough with white or clear sputum, wheeze and breathlessness, usually following many years of a smoker's cough. Colds seem to ‘settle on the chest’ and frequent infective exacerbations occur, with purulent sputum. Symptoms can be worsened by cold or damp weather and atmospheric pollution. With advanced disease, breathlessness is severe, even after mild exercise such as getting dressed. Systemic effects include hypertension, osteoporosis, depression, weight loss and reduced muscle mass with general weakness.

Signs
In mild COPD, there may be no signs or just quiet wheezes throughout the chest. In severe disease, the patient is tachypnoeic, with prolonged expiration. The accessory muscles of respiration are used and there may be intercostal indrawing on inspiration and pursing of the lips on expiration (see p. 1061). Chest expansion is poor, the lungs are hyperinflated, and there is loss of the normal cardiac and liver dullness.

Patients who remain responsive to CO$_2$ are usually breathless and rarely cyanosed. Heart failure and oedema are rare features, except as terminal events. In contrast, patients who become insensitive to CO$_2$ are often oedematous and cyanosed but not particularly breathless. Those with hypercapnia may have peripheral vasodilatation, a bounding pulse, and when the $P_a$CO$_2$ is above about 10 kPa, a coarse flapping tremor of the outstretched hands. Severe hypercapnia causes confusion and progressive drowsiness. Papilloedema may be present but this is neither specific nor sensitive as a diagnostic feature.

Respiratory failure
The later stages of COPD are characterized by the development of respiratory failure. For practical purposes, this is defined as either a $P_a$O$_2$ <8 kPa (60 mmHg) or a $P_a$CO$_2$ >7 kPa (53 mmHg).

Chronic alveolar hypoxia and hypercapnia lead to constriction of the pulmonary arterioles and pulmonary hypertension. Cardiac output is normal or increased but salt and fluid retention occurs as a result of renal hypoxia.

Pulmonary hypertension
Patients with advanced COPD may develop pulmonary hypertension (cor pulmonale), which is defined as symptoms and signs of fluid overload secondary to lung disease. The fluid retention and peripheral oedema are due to failure of excretion of sodium and water by the hypoxic kidney rather than heart failure. It is characterized by pulmonary hypertension and right ventricular hypertrophy. On examination, the patient is centrally cyanosed (owing to the lung disease), and later becomes more breathless and develops ankle oedema. Initially, there may
be a prominent parasternal heave, due to right ventricular hypertrophy, and a loud pulmonary second sound. In very severe pulmonary hypertension, the pulmonary valve becomes incompetent. With severe fluid overload, tricuspid incompetence may develop with a greatly elevated jugular venous pressure (JVP), ascites and upper abdominal discomfort due to liver swelling.

**Diagnosis**

This is usually clinical *(Box 24.13)* and based on a history of breathlessness and sputum production in a chronic smoker. In the absence of a history of cigarette smoking, asthma is a more likely explanation, unless there is a family history suggesting α1-antitrypsin deficiency.

<sup>a</sup>FEV<sub>1</sub> levels post bronchodilator therapy.

(Modified from Global Initiative for Chronic Obstructive Lung Disease (GOLD), 2016. [www.goldcopd.com](http://www.goldcopd.com).)

No individual clinical feature is diagnostic. The patient may have signs of hyperinflation and typical pursed lip respiration. There may be signs of overinflation of the lungs (e.g. loss of liver dullness on percussion), but this also occurs in other diseases such as asthma. Conversely, centri-acinar emphysema may be present without signs of overinflation. The chest may become ‘barrel-shaped’ but this can also result from osteoporosis of the spine in older men without emphysema.

**Investigations**

- **Lung function tests** show evidence of airflow limitation (see Figs 24.7 and 24.12). The FEV<sub>1</sub>:FVC ratio is reduced and the PEFR is low. In many patients, the airflow limitation is partly reversible (usually a change in FEV<sub>1</sub> of <15%), and it can be difficult to distinguish between COPD and asthma. Lung volumes may be normal or increased; carbon monoxide gas transfer factor is low when significant emphysema is present.
- **Chest X-ray** is often normal, even when the disease is advanced. The classic features are overinflation of the lungs with low, flattened diaphragms, and sometimes the presence of
large bullae. Blood vessels may be ‘pruned’, with large proximal vessels and relatively little blood visible in the peripheral lung fields.

- **High resolution CT (HRCT) scans** are useful, particularly when the plain chest X-ray is normal.

- **Haemoglobin level and packed cell volume** can be elevated as a result of persistent hypoxaemia (secondary polycythaemia; see p. 550).

- **Blood gases** are often normal at rest but patients desaturate on exercise. In more advanced cases, there is resting hypoxaemia and there may also be hypercapnia.

- **Sputum examination** is not useful in ordinary cases. *Strep. pneumoniae* and *H. influenzae* are the only bacterial common organisms to produce acute exacerbations. Occasionally, *Moraxella catarrhalis* may cause infective exacerbations. Many acute episodes are viral in origin.

- **ECG** is often normal. In advanced pulmonary hypotension, the P wave is tall (P pulmonale) and there may be right bundle branch block and evidence of right ventricular hypertrophy (see p. 1030).

- **Echocardiogram** is useful to assess cardiac function where there is disproportionate dyspnoea.

- **α₁-Antitrypsin** levels and genotype are worth measuring in premature disease or lifelong non-smokers.

**Management**

See **Figure 24.22** for management strategies.
Smoking cessation
The single most useful measure is to persuade the patient to stop smoking. Even in advanced disease, this may slow down the rate of deterioration and prolong the time before disability and death occur (see Fig. 24.22). Smoke from burning biomass fuels in poorly ventilated homes should also be reduced.

Drug therapy
This is used both for the short-term management of exacerbations and for the long-term relief of symptoms. Many of the drugs used are similar to those employed in asthma (see pp. 1097–1099).

Bronchodilators
- **β-Adrenoceptor agonists.** Many patients with mild COPD feel less breathless after inhaling a β-adrenergic agonist such as salbutamol (200 µg every 4–6 h). In more severe airway limitation (moderate and severe COPD), a long-acting β_{2} agonist should be used, e.g. formoterol 12 µg powder inhaled twice daily, salmeterol 50 µg twice daily or indacaterol.
150–300 µg once daily.

- **Antimuscarinic drugs.** More prolonged and greater bronchodilatation is achieved with antimuscarinic agents; the long-acting agents tiotropium (18 µg daily) and aclidinium (375 µg daily) are preferred to ipratropium or oxtropium. Tiotropium improves function and quality of life but does not affect the decline in FEV$_1$. If patients find inhalers difficult to use, spacer devices improve delivery. Objective evidence of improvement in peak flow rate or FEV$_1$ may be small, and decisions to continue or stop therapy are based mainly on the patient's reported symptoms.

- **Theophyllines.** Long-acting preparations of theophylline are of little benefit in COPD.

**Phosphodiesterase type 4 inhibitors**

Roflumilast is a phosphodiesterase inhibitor with anti-inflammatory properties. It is used as an adjunct to bronchodilators for the maintenance treatment of COPD patients.

**Corticosteroids**

In symptomatic patients with moderate/severe COPD, a trial of corticosteroids is always indicated, since a proportion of individuals have an unsuspected reversible element to their disease and airway function may improve considerably. Prednisolone 30 mg daily should be given for 2 weeks, with measurements of lung function before and after the treatment period. If there is objective evidence of a substantial degree of improvement in airflow limitation (FEV$_1$ increase of >15%), prednisolone should be discontinued and replaced by inhaled corticosteroids (beclometasone 40 µg twice daily in the first instance, adjusted according to response). The value of long-term regular inhaled corticosteroids in all patients with COPD has not been proven.

Combinations of corticosteroids with long-acting β$_2$ agonists may protect against lung function decline but do not improve overall mortality. High-dose inhaled steroids are not advised, as their use is linked to increased rates of pneumonia.

**Antibiotics**

Prompt antibiotic treatment shortens exacerbations and should always be given in acute episodes, as it may prevent hospital admission and further lung damage. Patients can be given antibiotics to keep at home, starting them as soon as their sputum turns yellow or green. Although amoxicillin-resistant *H. influenzae* is increasing worldwide (occurring in about 20% of isolates from sputum), it is not a serious clinical problem. Resistance to cefaclor (500 mg 8-hourly) or cefixime (400 mg once daily) is significantly less frequent; co-amoxiclav is a useful alternative.

Long-term treatment with antibiotics remains controversial. They were once thought to be of no value, but eradication of infection and maintenance of the lower respiratory tract free of bacteria may help to prevent deterioration in lung function.
**Antimucolytic agents**
These reduce sputum viscosity and can reduce the number of acute exacerbations. A 4-week trial of carbocisteine 2.25 g daily can be tried.

**Diuretic therapy**
Diuretic therapy (see p. 156) is necessary for all oedematous patients. Daily weights should be recorded during acute inpatient episodes.

**Oxygen therapy**
Two controlled trials (chiefly in males) have shown improved survival with the continuous administration of oxygen at 2 L/min via nasal prongs to achieve an oxygen saturation of >90% for large proportions of the day and night. Survival curves from these two studies are shown in Figure 24.23. Only 30% of those not receiving long-term oxygen therapy survived for more than 5 years. A fall in pulmonary artery pressure was achieved if oxygen was given for 15 hours daily, but substantial improvement in mortality was achieved only by the administration of oxygen for 19 hours daily. These results suggest that long-term continuous domiciliary oxygen therapy will benefit patients who have:
- $P_aO_2$ of $<7.3$ kPa (55 mmHg) when breathing air. Measurements should be taken on two occasions at least 3 weeks apart after appropriate bronchodilator therapy (*Box 24.14*).
- $P_aO_2$ 7.3–8 kPa with secondary polycythaemia, nocturnal hypoxaemia, peripheral oedema or evidence of pulmonary hypertension.
- Carboxyhaemoglobin of $<3\%$ (i.e. patients who have stopped smoking).

![Figure 24.23](image) Cumulative survival curves for patients receiving oxygen. Oxygen doses are in hours per day.
Box 24.14

Guidelines for domiciliary oxygen (Royal College of Physicians, 1999)

• Chronic obstructive pulmonary disease with $P_aO_2 < 7.3$ kPa when breathing air during a period of clinical stability
• Chronic obstructive pulmonary disease with $P_aO_2$ 7.3–8 kPa in the presence of secondary polycythaemia, nocturnal hypoxaemia, peripheral oedema or evidence of pulmonary hypertension
• Severe chronic asthma with a $P_aCO_2 < 7.3$ kPa or persistent disabling breathlessness
• Diffuse lung disease with $P_aO_2 < 8$ kPa and in patients with $P_aO_2 > 8$ kPa with disabling dyspnoea
• Cystic fibrosis when $P_aO_2 < 7.3$ kPa or if $P_aO_2$ 7.3–8 kPa in the presence of secondary polycythaemia, nocturnal hypoxaemia, pulmonary hypertension or peripheral oedema
• Pulmonary hypertension without parenchymal lung involvement when $P_aO_2 < 8$ kPa
• Neuromuscular or skeletal disorders, after specialist assessment
• Obstructive sleep apnoea despite continuous positive airways pressure therapy, after specialist assessment
• Pulmonary malignancy or other terminal disease with disabling dyspnoea
• Heart failure with daytime $P_aO_2 < 7.3$ kPa (on air) or with nocturnal hypoxaemia

Domiciliary oxygen is best provided by using an oxygen concentrator, which is considerably cheaper than using oxygen cylinders.

Nocturnal hypoxia

COPD patients with severe arterial hypoxaemia may experience profound nocturnal hypoxaemia, which may cause the $P_aO_2$ to drop as low as 2.5 kPa (19 mmHg), particularly during the rapid eye movement (REM) phase of sleep.

Because patients with COPD are already hypoxic, the fall in $P_aO_2$ produces a much larger fall in oxygen saturation (owing to the shape of the oxygen–haemoglobin dissociation curve) and desaturation of up to 50% occurs. The mechanism is alveolar hypoventilation due to:

• inhibition of intercostal and accessory muscles in REM sleep
• shallow breathing in REM sleep, which reduces ventilation, particularly in severe COPD
• an increase in upper airway resistance because of a reduction in muscle tone.

These nocturnal hypoxaemic episodes are associated with a further rise in pulmonary arterial pressure owing to vasoconstriction. Most deaths in patients with COPD occur at night, possibly from cardiac arrhythmias due to hypoxaemia. Secondary polycythaemia may be
exacerbated by the severe nocturnal hypoxaemia.

Each episode of desaturation is usually terminated by arousal from sleep, so the amount of normal sleep is reduced and patients suffer from daytime sleepiness.

**Management** is with nocturnal administration of oxygen and ventilatory support. Patients with arterial hypoxaemia should not be given sleeping tablets, as these will further depress respiratory drive.

Non-invasive positive-pressure ventilation can be administered with a tightly fitting nasal mask and bilevel positive airway pressure (BiPAP) – inspiratory to provide inspiratory assistance and expiratory to prevent alveolar closure, each adjusted independently. This improves ventilation during sleep and allows respiratory muscles to rest at night. BiPAP helps prevent hypoxaemic damage at night in COPD but it does not improve daytime respiratory function, respiratory muscle strength, exercise tolerance or breathlessness.

**Pulmonary rehabilitation**

Exercise training can modestly increase exercise capacity, with a diminished sense of breathlessness and improved general wellbeing. Regular training periods can be instituted at home; climbing stairs or walking fixed distances can be combined with regular clinic visits for encouragement. Breathing exercises are probably of less value. Quality of life can be improved by a multidisciplinary approach involving physiotherapy, exercise and education, although this does not alter life expectancy or the rate of decline in lung function; stopping smoking is still the most useful thing patients can do to help themselves. Nutritional advice and psychological, social and behavioural interventions are also helpful.

**Additional measures**

- **Vaccines.** Patients with COPD should receive a single dose of the polyvalent pneumococcal polysaccharide vaccine and yearly influenza vaccinations.

- **α₁-Antitrypsin replacement.** Weekly or monthly infusions of α₁-antitrypsin have been recommended for patients with serum levels <310 mg/L and abnormal lung function. Whether this modifies the long-term progression of the disease remains to be determined.

- **Heart failure.** This should be treated (see pp. 948–988).

- **Secondary polycythaemia.** This requires venesection if the PCV is >55%.

- **Pulmonary hypertension.** This can be partially relieved by the use of oral β-adrenergic agonists, such as salbutamol (4 mg three times daily), but the long-term value is unknown.

- **Sensation of breathlessness.** This can be reduced by either promethazine 125 mg daily or dihydrocodeine 1 mg/kg by mouth. Although opiates are the most effective treatment for intractable breathlessness, they depress ventilation and carry the risk of increasing respiratory failure.

- **Leukotriene receptor antagonists.** Although these have been tried, they are rarely effective (see p. 1099).

- **Air travel.** Commercial aircraft are pressurized to the equivalent of 2000–2400 m altitude. In
healthy people, this causes $P_{a}O_{2}$ to fall from 13.5 to 10 kPa, leading to a trivial 3% drop in oxygen saturation, but patients with moderate COPD may desaturate significantly. The desaturation associated with air travel can be simulated by breathing 15% oxygen at sea level. Patients whose saturation drops below 85% within 15 minutes should be advised to contact their airline to request supplemental oxygen during their flight.

• **Surgery.** Some patients have large emphysematous bullae that reduce lung capacity. Surgical bullectomy can enable adjacent areas of collapsed lung to re-expand and start functioning again. In addition, carefully selected patients with severe COPD (FEV1 <1 L) have been treated with lung volume reduction surgery. This increases elastic recoil, which reduces the expiratory collapse of the airway and decreases expiratory airflow limitation. It also enables the diaphragm to work at a mechanical advantage. Initial studies suggested that ventilation was improved and patients felt less breathless, although mortality was unchanged. However, a controlled trial in severe emphysema found increased mortality and no improvement in the patients' condition. *Single lung transplantation* (see p. 1090) is used for end-stage emphysema, with 3-year survival rates of 75%. The principal benefit is improved quality of life but it does not extend survival.

**Acute respiratory failure in COPD**

• **Oxygen therapy.** COPD is by far the most common cause of respiratory failure. In managing respiratory failure, the main goal is to improve the $P_{a}O_{2}$ by continuous oxygen therapy *(Fig. 24.24)*. In type II respiratory failure, the $P_{a}CO_{2}$ is elevated and the patient is dependent on hypoxic drive. In this setting, giving additional oxygen will nearly always cause a further rise in $P_{a}CO_{2}$. Small increases in $P_{a}CO_{2}$ can be tolerated but the pH should not be allowed to fall below 7.25; if it does, non-invasive ventilation is required. In COPD exacerbations, a fixed-percentage mask (Venturi mask; *Fig. 24.25*) is used to deliver controlled concentrations of oxygen. Initially, 24% oxygen is given, and the concentration of inspired oxygen can be gradually increased, provided the $P_{a}CO_{2}$ does not rise unacceptably.
**FIGURE 24.24** Algorithm for the treatment of respiratory failure in COPD. BiPAP, bilevel positive airway pressure; CPAP, continuous positive airway pressure; CXR, chest X-ray.
‘Fixed-performance’ device for administration of oxygen to spontaneously breathing patients (Venturi mask). Oxygen is delivered through the injector of the Venturi mask at a given flow rate. A proportionate amount of air is entrained and the inspired oxygen can be predicted accurately. Masks are available to deliver 24%, 28% and 35% oxygen.

**Removal of retained secretions.** Patients should be encouraged to cough up secretions. Physiotherapy is helpful. If this fails, secretions can be aspirated by bronchoscopy or via an endotracheal tube.

**Respiratory support** (see pp. 1163–1167). Non-invasive ventilatory techniques can be very helpful in avoiding the need for endotracheal intubation. The best current technique uses tight-fitting facial masks to deliver BiPAP. Assisted ventilation with an endotracheal tube is occasionally used for patients with COPD who have severe respiratory failure but only when there is a clear precipitating factor and the overall prognosis is reasonable. Assessing the likelihood of reversibility in an acute setting can present a difficult ethical problem.

**Respiratory stimulants.** Respiratory stimulants such as doxapram were used, but are now rarely chosen due to improvements in non-invasive ventilation.

**Corticosteroids, antibiotics and bronchodilators.** These should be administered in the acute phase of respiratory failure but decisions on long-term use should wait until the patient has recovered (see above).

---

### Prognosis of COPD

Predictors of a poor prognosis are increasing age and worsening airflow limitation: that is, decreasing FEV₁. A predictive index (BODE: body mass index (BMI), degree of airflow obstruction, dyspnoea and exercise capacity) is shown in **Box 24.15**. A patient with a BODE index of 0–2 has a 4-year mortality rate of 10%, compared with an 80% rate in someone with a BODE index of 7–10.

---

### Obstructive sleep apnoea

Obstructive sleep apnoea (OSA) affects 1–2% of the population and occurs most often in overweight, middle-aged men. It can occur in children, particularly those with enlarged tonsils. The major symptoms and their frequency are listed in **Box 24.16**. During sleep, activity of the respiratory muscles is reduced, especially during REM sleep when the diaphragm is virtually the only active muscle. Apnoeas occur when the airway at the back of the throat is sucked closed when breathing in during sleep. When awake, this tendency is overcome by the action of opening muscles of the upper airway, the genioglossus and palatal muscles, but these become hypotonic during sleep ([Fig. 24.26](#)). Partial narrowing results in snoring, complete occlusion causes apnoea and critical narrowing causes hypopnoeas. Apnoea leads to hypoxia and increasingly strenuous respiratory efforts until the patient overcomes the resistance. The combination of the central hypoxic stimulation and the effort to overcome obstruction wakes the patient from sleep. These awakenings are so brief that patients remain unaware of them but may be woken hundreds of times per night, leading to sleep deprivation, especially a reduction in REM sleep, with consequent daytime sleepiness and impaired intellectual performance. Contributory factors are obesity, narrow pharyngeal opening and coexistent COPD.

---

### Box 24.16

**Symptoms (%) of obstructive sleep apnoea**
Correctable factors occur in about one-third of cases and include:

- **encroachment on pharynx** – obesity, acromegaly, enlarged tonsils
- **nasal obstruction** – nasal deformities, rhinitis, polyps, adenoids
- **respiratory depressant drugs** – alcohol, sedatives, strong analgesics.

**Diagnosis**

Relatives often provide a good history of the snore–silence–snore cycle. The Epworth Sleepiness Scale *(Box 24.17)* helps discriminate OSA from simple snoring. The diagnosis is supported by overnight pulse oximetry performed at home. Characteristically, oxygen saturation falls in a cyclical manner, giving a sawtooth appearance to the tracing. If oximetry is negative or equivocal, inpatient assessment with oximetry and video-recording is indicated, preferably in a room specifically adapted for sleep studies. Full polysomnographic studies are rarely needed for clinical diagnosis but are useful in research laboratories. These involve oximetry, direct measurements of thoracic and abdominal movement to assess breathing, and electroencephalography to record patterns of sleep and arousal.
Epworth sleepiness scale

How likely are you to doze off or fall asleep in the following situations, in contrast to just feeling tired? This refers to your usual way of life in recent times. Even if you have not done some of these things recently, try to work out how they would have affected you. Use the following scale to choose the most appropriate number for each situation.

0 = would never doze
1 = slight chance of dozing
2 = moderate chance of dozing
3 = high chance of dozing

</tbody>
</table>

Normal 5 ± 4
Severe obstructive sleep apnoea 16 (± 4)
Narcolepsy 17

The diagnosis of sleep apnoea/hypopnoea is confirmed if there are more than 10–15 apnoeas or hypopnoeas in any 1 hour of sleep. There is, however, overlap with central sleep apnoea (see p. 939).

Management

Management consists of correction of treatable factors (see above) with, if necessary, nasal continuous positive airway pressure (CPAP) delivered by a nasal mask during sleep. Such systems raise the pressure in the pharynx by about 1 kPa, keeping the walls apart. Nasal CPAP improves symptoms, quality of life, daytime alertness and survival. However, up to 50% of OSA patients cannot tolerate CPAP. Modafinil (a central nervous system (CNS) stimulant) is a useful short-term alternative.

Bronchiectasis
Bronchiectasis describes abnormal and permanently dilated airways. The disease is characterized by a vicious circle of neutrophilic inflammation, recurrent infection and damage to the airway. This further impairs mucociliary clearance, and persistent inflammation leads to impairment of immunity.

Bronchiectasis is associated with a number of diseases but a cause will only be found in around 50% of cases. Little is known about the epidemiology of bronchiectasis and there is a wide variation in reported incidence. Bronchiectasis related to cystic fibrosis (see p. 1088) is generally considered a separate entity.

**Aetiology**

The causes of bronchiectasis are listed in Box 24.18. Globally, tuberculosis is the leading cause. Bronchiectasis associated with other lung diseases – in particular, COPD – is becoming increasingly recognized.

---

**Box 24.18**

**Causes of bronchiectasis**

**Congenital**

- Deficiency of bronchial wall elements
- Pulmonary sequestration

**Mechanical bronchial obstruction**

**Intrinsic**

- Foreign body
- Inspissated mucus
- Post-tuberculous stenosis
- Tumour

**Extrinsic**

- Lymph node
- Tumour

**Postinfective bronchial damage**

- Bacterial and viral pneumonia, including pertussis, measles and aspiration pneumonia

**Granuloma**

- Tuberculosis, sarcoidosis

**Diffuse diseases of the lung parenchyma**
• e.g. Idiopathic pulmonary fibrosis

**Immunological over-response**

• Allergic bronchopulmonary aspergillosis
• Post-lung transplant

**Immune deficiency**

**Primary**

• Panhypogammaglobulinaemia
• Selective immunoglobulin deficiencies (IgA and IgG₂)

**Secondary**

• Human immunodeficiency virus (HIV) and malignancy

**Mucociliary clearance defects**

**Genetic**

• Primary ciliary dyskinesia (Kartagener syndrome with dextrocardia and situs inversus)
• Cystic fibrosis

**Acquired**

• Young syndrome – azoospermia, sinusitis

---

**Clinical features**

See *Box 24.19*.

---

**Box 24.19**

**Symptoms and signs in bronchiectasis**

• Cough, usually persistent
• Sputum production, large amounts and purulent
• Breathlessness occurs as disease progresses
• Haemoptysis is usually a sign of infection; streaking is common but massive haemoptysis is a rare medical emergency
• Infection, usually characterized by increased sputum volume and increased purulence
• Pleuritic chest pain can be a feature of infection, as well as fever and systemic upset
• Coarse crackles heard on auscultation but examination can be normal
• Clubbing can occur, especially in cystic fibrosis
Investigations

The aims of investigation are to confirm the diagnosis, rule out an underlying cause, look for reversible factors and exclude complications.

- **HRCT scanning** is the investigation of choice. Characteristically, non-tapering ‘tram track’ airways and an increased bronchoarterial ratio ‘signet ring’ sign can be seen (Fig. 24.27).

![CT scan showing bronchiectasis. Note the dilated bronchi with thickened wall, which are larger than adjacent arteries, giving a signet ring appearance.](image)

- **Chest X-ray** may often be normal but tram track airways, ring shadows and cysts may be seen.

- **Sputum examination** is useful for a focused antibiotic treatment plan, as well as the exclusion of non-tuberculous mycobacterial disease.

- **Immune assessment** would include immunoglobulins and responses to Hib, tetanus and pneumococcal vaccines as baseline tests. Second-line immunological investigation by an immunologist may be necessary.

- **Sweat test (pp. 1089) and cystic fibrosis genetic assessment (pp. 1088)** should be carried out for all patients under 40, but also for patients at any age where there is a high index of suspicion.

- **Nasal nitric oxide** is a useful test for screening for primary ciliary dyskinesia (PCD). It is very low in PCD. Further ciliary investigation in a specialist centre may be required.

- **Total IgE and Aspergillus-specific IgE or Aspergillus skin-prick testing** should be done to exclude allergic bronchopulmonary aspergillosis.
Management

There is a distinct lack of trials in bronchiectasis to guide therapies, and therapeutic options often have been extrapolated from trials in cystic fibrosis and COPD. Therapy can broadly be divided into airway clearance, anti-inflammatories, and treatment of infection and complications.

Airway clearance

Daily airway clearance therapies are advised. The activated cycle of breathing technique, autogenic (self-)drainage and postural drainage are popular modalities. A number of devices are available to assist this, such as the ‘Flutter’ or ‘Acapella’, which provide positive expiratory pressure with or without airway oscillation.

Nebulized hypertonic saline is also approved for use in bronchiectasis; it works as a mucoactive agent.

Anti-inflammatories

Long-term azithromycin has an immunomodulatory effect and has been demonstrated to reduce exacerbation frequency. Inhaled corticosteroids are beneficial to some patients.

Treatment of infection

Treatment of exacerbations usually lasts 2 weeks and is based on previously obtained microbiological information. When *Pseudomonas aeruginosa* is being treated, dual therapy is often used where there are multi-resistant pathogens and where multiple antibiotic courses would be expected. High-dose ciprofloxacin (750 mg twice daily) is a useful oral drug for treatment of *Pseudomonas*. *Haemophilus influenzae* infection is common in bronchiectasis and usually responds to oral antibiotics such as amoxicillin, co-amoxiclav or doxycycline. Some multi-resistant species need intravenous cephalosporin treatment.

Experience in cystic fibrosis has promoted the use of aggressive antibiotic strategies in bronchiectasis, with eradication therapy and chronic suppressive nebulized therapy with colistimethate or an aminoglycoside for *Pseudomonas aeruginosa* (see p. 1089).

Rotating oral antibiotic regimes are no longer recommended routinely. Long-term quinolones should be avoided.

Treatment of complications

- Pulmonary rehabilitation should be offered to patients with a reduced exercise capacity and breathlessness.
- Massive haemoptysis is a life-threatening medical emergency; treatment is resuscitation with airway protection until a bronchial artery embolization can be performed to control the bleeding. If this is not successful, surgery may be required.
- Treatment of *Aspergillus* lung disease and non-tuberculous mycobacteria is covered on pages 1113 and 1122–1123.
• Respiratory failure should be treated with oxygen and non-invasive ventilation. Suitable patients should be referred to a transplant centre.
• Surgery is used for localized disease.

Prognosis
Prognosis is undefined and obviously quite variable, depending on disease severity. A lower FEV₁ and infection with *Pseudomonas aeruginosa* are associated with a poorer outcome.

Cystic fibrosis
Cystic fibrosis (CF) is an autosomal recessive condition. In the UK, the birth prevalence is 1 in 2415 and the carrier rate is 1 in 25. Prevalence is a little lower in North America, rates being much lower in the non-Caucasian population. CF is no longer a disease that causes most patients to die in childhood: survival is improving dramatically. The current expected median survival is now around 36 years. CF is a multisystem disease, although respiratory problems are usually the most prominent. A vicious circle of mucus stasis, inflammation and infection leads to respiratory failure and death in the majority of patients. Most individuals with CF also have pancreatic insufficiency.

Pathogenesis
The CF gene is located on the long arm of chromosome 7 at position 31.2 (see pp. 117–118). Mutations lead to abnormalities in the production of the cystic fibrosis transmembrane conductance regulator (CFTR) protein. This protein is expressed in the apical membrane of epithelial cells and acts as a chloride channel. Over 1000 mutations have been identified, most of them rare. The F508del mutation is the most common, accounting for around 70% of cases. Mutations have been divided into different classes, depending on their effect on CFTR (*Box 24.20*). This classification is used therapeutically, with new CF treatments aimed at improving CFTR function. Ivacaftor is the first drug available for CF that improves CFTR function. Previous therapeutic strategies have been based on managing downstream complications only. Ivacaftor is available for patients with the G551D mutation (class III gating defect).

In the lungs, CFTR dysfunction leads to dehydrated airway surface liquid, mucus stasis, airway inflammation and recurrent infection. This process originates in the small airways, leading to progressive airway obstruction and bronchiectasis (Fig. 24.28).

**FIGURE 24.28**  Cystic fibrosis: pathogenesis of lung disease.

### Clinical features and complications

CF is a multisystem disease but in 90% of cases the eventual cause of death is related to respiratory disease. Pancreatic insufficiency occurs in the majority of patients and CF-related diabetes is becoming increasingly common as survival improves, occurring in up to 40–50% of older adults with CF. Liver disease occurs in around 20% of the CF population and can lead to cirrhosis in around 2%. Clinical manifestations and complications are summarized in **Box 24.21**.

### Box 24.21

**Clinical features and complications of cystic fibrosis (CF)**

**Respiratory**

- Recurrent respiratory infection
- Chronic daily cough and sputum production
• Breathlessness
• Nasal polyps
• Haemoptysis (sometimes massive)
• Pneumothorax
• Respiratory failure and cor pulmonale
• Recurrent sinusitis

**Gastrointestinal**
• Failure to thrive in infancy and low body mass index in adults
• Meconium ileus in infancy
• Distal intestinal obstruction syndrome
• Steatorrhoea secondary to pancreatic insufficiency
• CF-related liver disease and cirrhosis
• Increased risk of gastrointestinal malignancy

**Other**
• CF-related diabetes
• Male infertility
• Osteoporosis
• Arthropathy

---

**Diagnosis**

Most new CF diagnoses are currently made at newborn screening. The test involves measuring immunoreactive trypsinogen at the time of the neonatal heel prick test. If the concentration is raised, formal testing is performed.

Aside from neonatal screening, diagnosis for children and adults is based on a combination of:

• Common clinical features (Box 24.21).

• CFTR functional testing. The **sweat test (pilocarpine iontophoresis)** measures chloride concentration and is the test routinely performed. The normal range is <30 mmol/L, with borderline cases at 30–60 mmol/L. These cases often represent patients with a milder ‘atypical’ phenotype. In difficult cases, nasal potential difference can be measured.

• Confirmatory genetic testing.

---

**Management**

Patients with CF should be managed in a specialist centre by a multidisciplinary group of experienced healthcare professionals. Patients should be seen at least every 3 months and have
an annual review. Lung function (FEV$_1$) and BMI should be recorded at every appointment, as they have prognostic importance.

**Pulmonary disease**

The aim of chronic pulmonary therapies is to reduce FEV$_1$ decline, daily symptoms and exacerbation frequency.

- **Airway clearance techniques** are a vital part of CF treatment regimens. There is no consensus on the best type and patient choice is the main factor.

- **Nebulized therapy**:
  - Recombinant human DNase (rhDNase) is advised for routine treatment from early childhood (regardless of disease status). There is clear evidence of improvement in lung disease and therapy may influence survival.
  - Hypertonic saline works as an osmotic agent to draw water to the cell surface.
  - Inhaled mannitol also increases mucociliary clearance.

- **Anti-inflammatory treatment** with long-term azithromycin is widely used in CF and has an immunomodulatory effect.

**Respiratory infection**

Spread of respiratory infection is a great threat to CF patients. Clinics are microbiologically cohorted, patients are managed in single rooms and no patient social events are organized.

*Pseudomonas aeruginosa* infection is common in patients with CF and is associated with accelerated lung function decline. Eradication is the treatment aim. A combination of nebulized colistimethate and oral ciprofloxacin, or inhaled tobramycin, can be given. Long-term nebulized suppression therapy with these medications is also used to improve respiratory health.

Other organisms, such as *Burkholderia cepacia*, meticillin-resistant *Staph. aureus* (MRSA) and *Stenotrophomonas maltophilia*, have been associated with worsening respiratory outcomes, so eradication regimes for these bacteria are being used. Non-tuberculous mycobacterial disease, in particular *Mycobacterium abscessus*, can be associated with a rapid decline and active infection may preclude transplantation.

In exacerbations, intravenous antibiotic therapy is based on previous infection history. For *Pseudomonas*, a combination of a β-lactam antibiotic such as ceftazidime with an aminoglycoside such as tobramycin would be the first-line choice. *In vitro* sensitivities are less useful in CF. Many CF patients have a permanently implanted venous access device for delivery of intravenous therapy.

**Advanced disease**

Respiratory failure should be treated with oxygen and non-invasive ventilation. Patients should be referred for consideration of lung transplantation when FEV$_1$ falls to around 30% predicted. In end-stage disease, palliative care is an essential part of management. This can be
challenging when patients are on an active waiting list for a lung transplant.

**Non-respiratory complications**

Pancreatic enzymes and vitamin supplements are used to treat those patients with pancreatic insufficiency. Close attention is paid to diet and calorie supplementation. Overnight gastric feeding may be required to maintain BMI in some patients.

CF-related diabetes will often require treatment with insulin and is screened for at annual review. It is distinct from type 1 and type 2 diabetes. Osteoporosis is screened for and treated. Fertility treatment is available for men with CF who are infertile.

**The future**

CFTR modulation has proved to be a major therapeutic advance. Chemical libraries have been screened and a number of compounds have been developed. Studies for therapies for the F508Del mutation are ongoing. Recently, lumacaftor (a CFTR corrector) in combination with ivacaftor has been shown to be beneficial in patients with p.Phe508del CFTR mutation. Other trials continue.

### Chronic cough

Pathological coughing (see p. 1066) results from two mechanisms:

- stimulation of sensory nerves in the epithelium (by secretions, foreign bodies, cigarette smoke and tumours)
- sensitization of the cough reflex with abnormal increase in the sensitivity of the cough receptors.

Sensitization of the cough reflex can be demonstrated by inhalation of capsaicin or saline solution; it presents clinically as a persistent tickling sensation in the throat with paroxysms of coughing induced by changes in air temperature, aerosol sprays, perfumes and cigarette smoke. It is found in association with viral infections, oesophageal reflux, postnasal drip, cough-variant asthma, and in 15% of patients taking angiotensin-converting enzyme (ACE) inhibitors. The association with ACE inhibitors implicates neuropeptides, prostaglandins E₂ and F₂, and bradykinin as causes of cough. In some patients, no cause can be found (idiopathic cough). In the absence of chest X-ray abnormalities, possible investigations include:

- ENT examination (see p. 1318) and sinus CT for postnasal drip
- lung function tests and bronchial provocation testing (see p. 1092) for cough-variant asthma
- ambulatory oesophageal pH monitoring and manometry for oesophageal reflux
- fibreoptic bronchoscopy for inhaled foreign body or tumour
- ECG, echocardiography and exercise testing and impedance for cardiac causes
- hyperventilation testing
- psychiatric appraisal.
Symptomatic management of unexplained cough can be difficult. Morphine depresses the sensitized cough reflex but its unwanted effects limit its long-term use. Dihydrocodeine linctus may help some patients. Demulcent preparations and cough sweets provide only temporary relief. Patients who cough while taking ACE inhibitors should switch to an angiotensin II receptor antagonist, such as losartan (see pp. 985–987), which does not block Bradykinin breakdown.

### Lung and heart–lung transplantation

#### Indications and donor selection

The main diseases treated by transplantation are:

- pulmonary fibrosis
- primary pulmonary hypertension
- cystic fibrosis
- bronchiectasis
- emphysema – particularly α1-antitrypsin inhibitor deficiency
- Eisenmenger syndrome.

Patients selected for transplantation are usually under 60 years with a life expectancy of less than 18 months, no underlying cancer and no serious systemic disease.

Organs are taken from donors under 40 years, with good cardiac and lung function, and chest measurements slightly smaller than those of the recipient. Matching for ABO blood group is essential, but rhesus blood group compatibility is not essential. Since donor material is limited, single-lung transplantation is preferred to double-lung or heart–lung transplantation; this can be successfully undertaken in pulmonary fibrosis, pulmonary hypertension and emphysema. Bilateral lung transplantation is required in infective conditions to prevent spillover of bacteria from the diseased lung to a single transplanted lung. Eisenmenger syndrome requires heart–lung transplant.

#### Complications and their treatment

- **Early post-transplant pulmonary oedema** requires diuretics and ventilatory support.
- **Infections**, particularly within the first 3 months, are treated as follows:
  - bacterial pneumonia – antibiotics
  - cytomegalovirus – ganciclovir
  - herpes simplex – aciclovir.
  - *Pneumocystis jiroveci* – prophylactic co-trimoxazole.
- **Immunosuppression** is with ciclosporin (inhaled formulation has shown benefit) or tacrolimus, azathioprine or mycophenolate mofetil and prednisolone.
• **Rejection:**
  
  – Early (first few weeks) – high-dose intravenous corticosteroids
  – Late (after 3 months) – high-dose intravenous corticosteroids are sometimes effective in obliterative bronchiolitis. Post-transplant lymphoproliferative disease may respond to rituximab, an anti-B-cell monoclonal antibody.

**Prognosis**

Several studies show a major improvement in overall quality of life. One-year survival rates have improved, with a yearly mortality rate of about 10%. Death is due mainly to bronchiolitis. Overall survival varies with the original diagnosis but the median survival is approximately 4 years.

**Further reading**

**Asthma**

Asthma is a common chronic condition whose cause is incompletely understood. Symptoms include wheeze, chest tightness, cough and shortness of breath, often worse at night. Asthma commonly starts in childhood between the ages of 3 and 5 years and may either worsen or improve during adolescence. Classically, asthma has three characteristics:

- **airflow limitation**, which is usually reversible spontaneously or with treatment
- **airway hyper-responsiveness** to a wide range of stimuli (see below)
- **bronchial inflammation** with T lymphocytes, mast cells, eosinophils with associated plasma exudation, oedema, smooth muscle hypertrophy, matrix deposition, mucus plugging and
epithelial damage.

In chronic asthma, inflammation may be accompanied by irreversible airflow limitation as a result of airway wall remodelling that may involve large and small airways and mucus impaction.

**Prevalence**

In many countries, the prevalence of asthma has increased over the past 30 years. This increase is particularly marked in children and young adults, with up to 15% of the population being affected. Asthma is more common in more developed countries, with some of the highest rates in the UK, New Zealand and Australia, and much lower rates in Far Eastern countries such as China and Malaysia, Africa, and Central and Eastern Europe. Long-term follow-up in developing countries suggests that asthma may become more frequent as individuals adopt a more ‘Westernized’ lifestyle, but the environmental factors accounting for this remain unknown. Studies of occupational asthma suggest that a large proportion of the workforce (15–20%) may become asthmatic if exposed to potent sensitizers. Worldwide, approximately 300 million people have asthma and this is expected to rise to 400 million by 2025.

**Classification**

Asthma is a complex disorder. Current thinking is that the symptoms can be caused by several different processes. Asthma can be classified according to its trigger factors, by age of onset, by inflammatory subtypes or by response to therapy. There is considerable overlap between populations separated along these different dimensions, and it is now fashionable to describe clinical subtypes (or endotypes).

Many childhood-onset asthmatics have wheezing illness with inhalant allergic triggers. Some 90% of children and 70% of adults with persistent asthma have positive skin-prick tests to common inhalant allergens such as dust mite, animal danders, pollens and fungi. Childhood-onset asthma is often accompanied by eczema (atopic dermatitis; see pp. 1349–1351). Sensitization to chemicals or biological products in the workplace is a frequently overlooked cause of late-onset asthma in adults.

In some people with asthma, inhaled allergens are not relevant. This illness often starts in middle age and attacks are usually triggered by respiratory infections. Nevertheless, many patients with adult-onset asthma show positive allergen skin tests and, on close questioning, some of these will give a history of childhood respiratory symptoms suggesting they have extrinsic asthma.

Non-atopic individuals may develop asthma in middle age from extrinsic causes such as sensitization to occupational agents like toluene diisocyanate, intolerance to NSAIDs such as aspirin, or prescription of β-adrenoceptor-blocking agents that block the protective effect of endogenous catecholamines. Extrinsic causes must be considered in all cases of asthma and, where possible, avoided.

**Other clinical phenotypes**
Based on the clinical picture, several subtypes or endotypes of asthma are recognized, including ‘brittle asthma’ and steroid-resistant asthma. While eosinophilic airway inflammation is often present in asthma, there are also patients with eosinophilic bronchitis, who have sputum eosinophilia without wheeze. It remains unclear whether this is a pre-asthmatic state or whether anti-eosinophil treatment is helpful.

**Aetiology**

The major factors involved in the development of asthma and stimuli that can precipitate attacks are shown in *Figure 24.29*.

---

**Atopy and allergy**

The term ‘atopy’ was coined in the early 1900s to describe a group of disorders, including asthma and hayfever, which appeared to:

- run in families
- have characteristic wealing skin reactions to common allergens in the environment
• have circulating allergen-specific antibodies (later shown to be IgE).

Allergen-specific IgE is present in 30–40% of the UK population, and elevated serum IgE levels are linked to airway hyper-responsiveness and the prevalence of asthma. Serum total IgE levels are affected by several genetic and environmental factors.

**Genetic factors**

There is no single gene for asthma, but several genes, in combination with environmental factors, appear to influence the development of asthma.

• Genes controlling the production of the cytokines IL-3, IL-4, IL-5, IL-9, IL-13 and granulocyte–macrophage colony stimulating factor (GM-CSF) are present in a cluster on chromosome 5q31-33 (the IL-4 gene cluster). These cytokines affect the development and survival of mast cells and eosinophils, as well as IgE production.

• Polymorphic variation in proteins along the IL-4/13 signalling pathway is strongly associated with allergy and asthma.

• Novel asthma genes identified by positional cloning from whole-genome scans are the PHF11 locus on chromosome 2 (which includes genes SETDB2 and RCBTB1) and transcription factors, which are implicated in IgE synthesis and associated more with atopy than asthma.

• ADAM33 (a disintegrin and metalloproteinase) on chromosome 20p13 is associated with airway hyper-responsiveness and tissue remodelling.

• Other genes associated with asthma are those that encode neuropeptide S receptor (GPRA or GPR154) on chromosome 7p15, HLA-G on chromosome 6p21, dipeptidyl peptidase 10 on chromosome 2q14 and ORMDL3, a member of a gene family that encodes transmembrane proteins anchored in the endoplasmic reticulum, on chromosome 17q21.

Recent evidence from genome-wide association studies has shown that the epithelial–ILC2 cell axis is involved in the pathogenesis of asthma. ILC2 cells are also known as natural type 2 helper cells or nuocytes. IL33 and its receptor, IL1RL1(ST2), thymic stromal lymphopoietin (TSLP), the transcription factor RORalpha and IL13 have been identified as the major asthma susceptibility genes.

**Environmental factors**

Early childhood exposure to allergens and maternal smoking has a major influence on IgE production. Much interest focuses on the role of intestinal bacteria and childhood infections in shaping the immune system in early life. It has been suggested that growing up in a relatively ‘clean’ environment may predispose towards an IgE response to allergens (the ‘hygiene hypothesis’). Conversely, growing up in a ‘dirtier’ environment may allow the immune system to avoid developing allergic responses. Components of bacteria (e.g. lipopolysaccharide endotoxin, immunostimulatory CpG DNA sequences, flagellin), viruses (e.g. SS- and DS-RNA) and fungi (e.g. chiton, a cell-wall component) stimulate various toll-like receptors (TLRs) expressed on immune and epithelial cells to direct the immune and inflammatory response away from the allergic (Th2) towards protective (Th1 and Treg) pathways. Th1
immunity is associated with antimicrobial protective immunity, whereas regulatory T cells are strongly implicated in tolerance to allergens. Thus early life exposure to inhaled and ingested products of microorganisms, as occurs in livestock farming communities and developing countries, may reduce the subsequent risk of a child becoming allergic and/or developing asthma.

The allergens involved in allergic asthma are similar to those implicated in rhinitis, although pollens are relatively less implicated in asthma. Most allergic asthmatics are sensitized to house-dust mite allergens. Cockroach allergy has been implicated in asthma in US inner-city children, while allergens from furry pets (especially cats) are increasingly common causes. The fungal spores from Aspergillus fumigatus cause a range of lung disorders, including asthma (see pp. 1122–1123). Many allergens, including those from Aspergillus, have intrinsic biological properties: for example, enzymes with a proteolytic function that may increase their sensitizing capacity.

Increased responsiveness of the airways of the lung (airway hyper-responsiveness)

Airway hyper-responsiveness (AHR) is a characteristic feature of asthma and can be demonstrated by asking patients to inhale gradually increasing concentrations of histamine or methacholine (bronchial provocation tests). This induces transient airflow limitation in susceptible individuals (approximately 20% of the population); the severity of AHR can be graded according to the provocation dose (PD) or concentration (PC) of the agonist that produces a 20% fall in FEV₁ (PD₂₀ FEV₁ or PC₂₀ FEV₁). Patients with clinical symptoms of asthma respond to very low doses of methacholine: that is, they have a low PD₂₀ FEV₁. AHR can also be assessed by exercise testing or inhalation of cold, dry air, mannitol or hypertonic saline. These are indirect tests that release endogenous mediators such as histamine, prostaglandins and leukotrienes, which then cause bronchoconstriction. Indirect measures of AHR correlate more closely with symptoms and diurnal PEFR variation than PC₂₀ histamine or methacholine; both are useful in diagnosing asthma if there is doubt, and in guiding treatment.

Some patients also react to methacholine but at higher doses, including those with:

• attacks of asthma only on extreme exertion
• wheezing or prolonged periods of coughing following a viral infection
• seasonal wheeze during the pollen season
• allergic rhinitis, but not complaining of lower respiratory symptoms until specifically questioned
• some subjects with no respiratory symptoms.

Although the degree of AHR can be influenced by allergic mechanisms (see p. 1094 and Fig. 24.32), its pathogenesis and mode of inheritance involve a combination of airway inflammation and tissue remodelling.

Precipitating factors
**Occupational sensitizers**

Over 250 materials encountered at the workplace can cause occupational asthma, which accounts for up to 15% of all asthma cases *(Box 24.22)*. These are recognized occupational diseases in the UK, and patients in insurable employment are eligible for statutory compensation, provided they apply within 10 years of leaving the occupation in which the asthma developed.

Asthma can be due to:

- low-molecular-weight compounds, e.g. reactive chemicals such as isocyanates and acid anhydrides that bond chemically to epithelial cells to activate them, as well as provide haptens recognized by T cells
- high-molecular-weight compounds, e.g. flour, organic dusts and other large protein molecules involving specific IgE antibodies.

Smoking increases the risk of developing some forms of occupational asthma. The proportion of employees developing occupational asthma depends primarily upon the level of exposure. Proper enclosure of industrial processes or appropriate ventilation greatly reduces
the risk. Atopic individuals develop occupational asthma more rapidly when exposed to agents causing the development of specific IgE antibody. Non-atopic individuals can also develop asthma when exposed to such agents, but after a longer period of exposure.

**Non-specific factors**

Due to their AHR, patients with asthma will respond to a wide variety of non-specific direct and indirect stimuli, as well as reacting to specific allergens.

**Cold air and exercise**

Most asthmatics wheeze after prolonged exercise or inhalation of cold, dry air. Typically, the attack does not occur while exercising but afterwards. Exercise-induced wheeze is driven by release of histamine, prostaglandins (PGs) and leukotrienes (LTs) from mast cells, as well as stimulation of neural reflexes when the epithelial lining fluid of the bronchi becomes hyperosmolar owing to drying and cooling during exercise. The phenomenon can be shown by exercise, cold air and hypertonic provocation tests with saline or mannitol.

**Atmospheric pollution and irritant dusts, vapours and fumes**

Many patients with asthma experience worsening of symptoms on exposure to tobacco smoke, car exhaust fumes, solvents, strong perfumes or high concentrations of airborne dust. Major epidemics have been recorded when large amounts of allergens are released into the air: for example, soybean dust in Barcelona. Asthma exacerbations increase during summer and winter air pollution episodes associated with climatic temperature inversions. Epidemics of asthma have occurred in the presence of high concentrations of ozone, particulates and NO₂ in the summer and particulates, NO₂ and SO₂ in the winter.

**Diet**

Increased intake of fresh fruit and vegetables has been shown to be protective, possibly owing to the increased intake of antioxidants or other protective molecules such as flavonoids. Genetic variation in antioxidant enzymes is associated with more severe asthma.

**Emotion**

Emotional factors influence asthma both acutely and chronically, but there is no evidence that patients with the disease are any more psychologically disturbed than their non-asthmatic peers. An asthma attack is a frightening experience, especially when its onset is sudden or unexpected. Patients at high risk of life-threatening attacks are understandably anxious.

**Drugs**

**NSAIDs.** NSAIDs, particularly aspirin and propionic acid derivatives, such as indometacin and ibuprofen, are implicated in triggering asthma in approximately 5% of patients. NSAID intolerance is especially prevalent in those with both nasal polyps and asthma, and is often associated with rhinitis and flushing on drug exposure. NSAIDs inhibit arachidonic acid
metabolism via the cyclo-oxygenase (COX) pathway, preventing the synthesis of certain prostaglandins. In aspirin-intolerant asthma, there is reduced production of PGE$_2$, which, in a sub-proportion of genetically susceptible subjects, induces the overproduction of cysteinyl leukotrienes by eosinophils, mast cells and macrophages. Genetic polymorphisms involving the enzymes and receptors of the leukotriene-generating pathway are seen (Fig. 24.30). COX-2 inhibitors do not trigger attacks, indicating that blockade of the COX-1 isoenzyme is the underlying trigger.

**Beta-blockers.** The airways have a direct parasympathetic innervation that tends to produce bronchoconstriction. There is no direct sympathetic innervation of bronchial smooth muscle, so antagonism of parasympathetically induced bronchoconstriction is critically dependent upon circulating adrenaline (epinephrine) acting through β$_2$-receptors on the surface of smooth muscle cells. Inhibition of this effect by β-adrenoceptor-blocking drugs, such as propranolol, leads to bronchoconstriction and airflow limitation, but only in asthmatic subjects. Selective β$_1$-adrenergic-blocking drugs, such as atenolol, may also induce attacks of asthma.

**Allergen-induced asthma**

The experimental inhalation of allergen by atopic asthmatic individuals leads to the
development of different types of reaction, as illustrated in *Figure 24.31*. 

**Immediate asthmatic reaction.** Airflow limitation begins within minutes of contact with the allergen, reaches its maximum in 15–20 minutes and subsides by 1 hour.

**Dual and late-phase reactions.** Following an immediate reaction, many asthmatics develop a more prolonged and sustained attack of airflow limitation that responds less well to inhalation of bronchodilator drugs such as salbutamol. Isolated late-phase reactions with no preceding immediate response can occur after the inhalation of some occupational sensitizers such as isocyanates. AHR increases during and for several weeks after late-phase reactions, which may explain why symptoms persist after allergen exposure.

### Pathogenesis

The pathogenesis of asthma is complex and not fully understood. The role of different cells has been extensively studied to try to find new targets for therapy. Allergen-driven models have dominated this field but some caution is needed in extrapolating to the real disease. Schematically, asthma involves several cells and mediators that can be activated by various different mechanisms, including exposure to allergens (*Fig. 24.32*). The varying clinical
severity and chronicity of asthma are dependent on an interplay between airway inflammation and airway wall remodelling. The inflammatory component is driven by Th2-type T lymphocytes (Fig. 24.32). However, as the disease becomes more severe and chronic, and loses its sensitivity to corticosteroids, there is greater evidence of a Th1 response with release of mediators such as TNF-α and associated tissue damage, mucous metaplasia and aberrant epithelial and mesenchymal repair.

**FIGURE 24.32** Inflammatory and remodelling responses in asthma with activation of the epithelial mesenchymal trophic unit. Epithelial damage alters the set point for communication between bronchial epithelium and underlying mesenchymal cells, leading to myofibroblast activation, an increase in mesenchymal volume, and induction of structural changes throughout the airway wall. GM-CSF, granulocyte–macrophage colony stimulating factor; Ig, immunoglobulin; IL, interleukin; TNF-α, tumour necrosis factor alpha. (Adapted from Holgate ST, Polosa R. The mechanisms, diagnosis, and management of severe asthma in adults. Lancet 2006; 368:780–793, with permission from Elsevier.)

**Inflammation**

**Mast cells**

Mast cells (see also pp. 125–126) are increased in the epithelium, smooth muscle and mucous glands in asthma, and release mediators, such as histamine, tryptase, PGD₂ and cysteinyl
leukotrienes, which act on smooth muscle, small blood vessels, mucus-secreting cells and sensory nerves, causing the immediate asthmatic reaction. Mast cells also release an array of cytokines, chemokines and growth factors that contribute to the late asthmatic response and more chronic aspects of asthma.

**Eosinophils**

These are found in large numbers in the bronchial wall and secretions of asthmatics. They are attracted to the airways by the cytokines IL-3, IL-5 and GM-CSF, as well as by chemokines that act on type 3 C-C chemokine receptors (CCR-3) (i.e. eotaxin, RANTES, MCP-1, MCP-3 and MCP-4). These mediators also prime eosinophils for enhanced mediator secretion. When activated, eosinophils release LTC4, and basic proteins that are toxic to epithelial cells. Both the number and activation of eosinophils are rapidly decreased by corticosteroids. Sputum eosinophilia is diagnostically useful and provides a biomarker of response to therapy.

**Dendritic cells and lymphocytes**

Asthmatic airways show a Th2 pattern of cytokine expression. T-helper lymphocytes (CD4+) in the airways show evidence of activation *(Fig. 24.32)*; their cytokines aid the migration and activation of mast cells (IL-3, IL-4, IL-9 and IL-13) and eosinophils (IL-3, IL-5, GM-CSF). In mild/moderate asthma, there is selective upregulation of Th2 T cells with reduced evidence of the Th1 phenotype (producing interferon-gamma (IFN-γ), TNF-α and IL-2), although Th1 cells are more prominent in more severe disease. The activity of macrophages and lymphocytes is influenced by corticosteroids but not by β2-adrenoceptor agonists.

**Remodelling**

A characteristic feature of chronic asthma is alteration of the structure and functions of the formed elements of the airways. Together, these structural changes interact with inflammatory cells and mediators to alter airways physiology and hence trigger symptoms. Deposition of matrix proteins, swelling and cellular infiltration expand the submucosa beneath the epithelium so that, for a given degree of smooth muscle shortening, there is excess airway narrowing. Swelling outside the smooth muscle layer reduces the retractile forces exerted by the surrounding alveoli so that the airways close more easily. Several factors contribute to these changes.

**The epithelium**

In asthma, the epithelium of the conducting airways is stressed and damaged with loss of ciliated columnar cells. The epithelium is a major source of mediators, cytokines and growth factors that enhance inflammation and promote tissue remodelling *(Fig. 24.32)*. Damage and activation of the epithelium make it more vulnerable to infection by common respiratory viruses (e.g. rhinovirus, coronavirus) and to the effects of air pollutants. Increased production of nitric oxide (NO), due to the increased expression of inducible NO synthase, is a feature of epithelial damage and activation. Measurement of exhaled NO is a useful non-invasive test of
continuing inflammation (see p. 1096).

The epithelial basement membrane
A pathognomonic feature of asthma is the deposition of repair collagens (types I, III and V) and proteoglycans in the lamina reticularis beneath the basement membrane. This, along with the deposition of other matrix proteins such as laminin, tenascin and fibronectin, causes the appearance of a thickened basement membrane observed by light microscopy in asthma. This collagen deposition reflects activation of an underlying sheath of fibroblasts that transform into contractile myofibroblasts, which also have an increased capacity to secrete matrix. Aberrant signalling between the epithelium and underlying myofibroblasts is thought to be the principal cause of airway wall remodelling, since the cells are prolific producers of a range of tissue growth factors such as epidermal growth factor (EGF), transforming growth factor (TGF)-α and β, connective tissue-derived growth factor (CTGF), platelet-derived growth factor (PDGF), endothelin (ET), insulin-like growth factors (IGF), nerve growth factors and vascular endothelial growth factors (Fig. 24.32).

Smooth muscle
Another prominent feature of asthma is hyperplasia of the helical bands of airway smooth muscle. In addition to increasing in amount, the smooth muscle alters in function so it contracts more easily and stays contracted because of a change in actin–myosin cross-link cycling. These changes allow asthmatic airways to contract too much and too easily at the least provocation. Asthmatic smooth muscle also secretes a wide range of cytokines, chemokines and growth factors that help sustain the chronic inflammatory response.
Nerves
Central and peripheral neural reflexes contribute to the irritability of asthmatic airways. Central reflexes involve stimulation of nerve endings in the epithelium and submucosa with transmission of impulses via the spinal cord and brain back down to the airways, where release of acetylcholine from nerve endings stimulates M₃ receptors on smooth muscle, causing contraction. Local neural reflexes involve antidromic neurotransmission and the release of a variety of neuropeptides, which constrict smooth muscle (substance P, neurokinin A), and affect small blood vessels. Bradykinin generated by tissue and serum proteolytic enzymes (including mast cell tryptase and tissue kallikrein) is also a potent stimulus of local neural reflexes involving (non-myelinated) nerve fibres.

Clinical features
The principal symptoms of asthma are wheezing attacks and episodic shortness of breath. Symptoms are usually worst during the night, especially in uncontrolled disease. Cough is a frequent symptom that sometimes predominates, especially in children, in whom nocturnal cough can be a presenting feature. Attacks vary greatly in frequency and duration. Some patients only have one or two attacks a year that last for a few hours, while others have attacks lasting for weeks. Some patients have chronic persistent symptoms, on top of which there are fluctuations. Attacks may be precipitated by a wide range of triggers (see Fig. 24.29). Asthma is a major cause of impaired quality of life and has an impact on work and recreation, affecting both physical activities and emotions.

Investigations
There is no single satisfactory diagnostic test for all patients with asthma.

Lung function tests
*Peak expiratory flow rate (PEFR)* measurements on waking, prior to taking a bronchodilator, and before bed, after a bronchodilator, are particularly useful in demonstrating the variable airflow limitation that characterizes the disease (see Fig. 24.14). The diurnal variation in PEFR is a good measure of asthma activity and is of help in the longer-term assessment of the patient's disease and its response to treatment.

*Spirometry* is useful, especially in assessing reversibility. Asthma can be diagnosed by demonstrating a greater than 15% improvement in FEV₁ or PEFR following the inhalation of a bronchodilator. However, there may be less reversibility when asthma is in remission or in severe chronic asthma, when little reversibility can be demonstrated, or if the patient is already being treated with long-acting bronchodilators.

The carbon monoxide (CO) transfer test is normal in asthma.

Exercise tests
These have been widely used in the diagnosis of asthma in children. Ideally, the child should run for 6 minutes on a treadmill at a workload sufficient to increase the heart rate above 160 b.p.m. Alternative methods use cold air challenge, isocapnic hyperventilation (forced overbreathing with artificially maintained $P_A\text{CO}_2$) or aerosol challenge with hypertonic solutions. A negative test does not automatically rule out asthma.

**Histamine or methacholine bronchial provocation test**

This test (see p. 1092) indicates the presence of AHR, a feature found in most asthmatics, and can be particularly useful in investigating those patients whose main symptom is cough. The test should not be performed on individuals who have poor lung function ($\text{FEV}_1 < 1.5 \ L$) or a history of ‘brittle’ asthma. In children, it is often easier to carry out controlled exercise testing as a measure of bronchial hyper-responsiveness.

**Trial of corticosteroids**

All patients who present with severe airflow limitation should undergo a formal trial of corticosteroids. Prednisolone 30 mg orally should be given daily for 2 weeks, with lung function measured before and immediately after the course. A substantial improvement in $\text{FEV}_1 (>15\%)$ confirms the presence of a reversible element and indicates that the administration of inhaled steroids will prove beneficial to the patient. If the trial is for $\leq 2$ weeks, the oral corticosteroid can be withdrawn without tailing off the dose, and should be replaced by inhaled corticosteroids in those who have responded.

**Exhaled nitric oxide**

This test is a measure of airway inflammation and an index of corticosteroid response; it used to assess the efficacy of corticosteroids.

**Blood and sputum tests**

Patients with asthma sometimes have increased numbers of eosinophils in peripheral blood ($>0.4 \times 10^9/L$) but sputum eosinophilia is a more specific diagnostic finding.

**Chest X-ray**

There are no diagnostic features of asthma on the chest X-ray, although overinflation is characteristic during an acute episode or in chronic severe disease. A chest X-ray may be helpful in excluding a pneumothorax, which can occur as a complication, or in detecting the pulmonary infiltrates associated with allergic bronchopulmonary aspergillosis.

**Skin tests**

Skin-prick tests should be performed in all cases of asthma to help identify allergic trigger factors. Allergen-specific IgE can be measured in serum if skin-prick test facilities are not available, if the patient is taking antihistamines, or if no suitable allergen extracts are
available.

**Allergen provocation tests**

Allergen inhalation challenge is a useful research tool, and is required when investigating patients with suspected occupational asthma, but not in ordinary asthma.

### Management

The **aims of treatment** are to:

- abolish symptoms
- restore normal or best possible lung function
- reduce the risk of severe attacks
- enable normal growth to occur in children
- minimize absence from school or employment.

This involves:

- patient and family education about asthma
- patient and family participation in treatment
- avoidance of identified causes where possible
- use of the lowest effective doses of convenient medications to minimize short-term and long-term side-effects.

Many asthmatics join self-help groups in order to improve their understanding of the disease and to foster self-confidence and fitness.

### Control of extrinsic factors

Where specific allergen triggers are identified, these should be avoided if possible. Unfortunately, there is little evidence that bedding covers or changes to living accommodation improve asthma outcomes. Sublingual allergen immunotherapy (SLIT) with house dust mites has shown a reduction in the number of asthma attacks in early studies. Active and passive smoking should be avoided, as should beta-blockers in either tablet or eye drop form. Individuals intolerant to aspirin should avoid NSAIDs, although they may tolerate COX-2 inhibitors. About one-third of individuals sensitized to occupational agents may be cured if they are kept permanently away from exposure. The remaining two-thirds will continue to have symptoms, and in half of these the symptoms may be as severe as when exposed to materials at work, especially if they were symptomatic for a long time before the diagnosis was made.

This emphasizes that:

- The rapid identification of extrinsic causes of asthma and their removal are necessary wherever possible (e.g. occupational agents, family pets).
- Once extrinsic asthma is initiated, it may become self-perpetuating, possibly by non-immune mechanisms.
Drug treatment

The mainstay of asthma therapy is the use of therapeutic agents delivered as aerosols or powders directly into the lungs (Box 24.23). The advantages of this method of administration are that drugs are delivered direct to the airways and first-pass metabolism in the liver is avoided; thus lower doses are necessary and systemic unwanted effects are minimized.

Box 24.23

Inhaled therapy for asthma

Patients should be taught how to use inhalers and their technique should be checked regularly.

Use of a metered-dose inhaler

1. The canister is shaken.
2. The patient exhales to functional residual capacity (not residual volume), i.e. normal expiration.
3. The aerosol nozzle is placed to the open mouth.
4. The patient simultaneously inhales rapidly and activates the aerosol.
5. Inhalation is completed.
6. The breath is held for 10 seconds if possible. Even with good technique, only 15% of the contents is inhaled and 85% is deposited on the wall of the pharynx and ultimately swallowed.

Spacers

These are plastic cones or spheres inserted between the patient's mouth and the inhaler. Some inhalers have a built-in spacer extension. These are designed to reduce particle velocity so that less drug is deposited in the mouth. Spacers also diminish the need for coordination between aerosol activation and inhalation. They are useful in children and in the elderly, and reduce the risk of candidiasis.

Several national and international guidelines have been published on the stepwise treatment of asthma (Box 24.24), based on three principles:

• Asthma self-management with regular asthma monitoring using PEF meters and individual treatment plans that are discussed with each patient and written down.
• The appreciation that asthma is an inflammatory disease and that anti-inflammatory (controller) therapy should be started, even in mild cases.
• Use of short-acting inhaled bronchodilators (e.g. salbutamol and terbutaline) only to relieve breakthrough symptoms. Increased use of bronchodilator treatment to relieve increasing symptoms is an indication of deteriorating disease.
## The stepwise management of asthma

Short-acting bronchodilator treatment taken at any step on an as-required basis.

A list of drugs used in asthma is shown in **Box 24.25**. These are given in a stepwise fashion, as indicated in **Box 24.24**.

## Box 24.25

**Drugs used in asthma**

### Short-acting relievers
- Inhaled β₂ agonists (e.g. salbutamol (albuterol in USA), terbutaline)

### Long-acting relievers/disease controllers
• Inhaled long-acting β₂ agonists (e.g. salmeterol, formoterol)
• Inhaled corticosteroids (e.g. beclometasone, budesonide, fluticasone)
• Compound inhaled salmeterol and fluticasone
• Sodium cromoglicate
• Leukotriene modifiers (e.g. montelukast, zafirlukast, zileuton)

Other agents with bronchodilator activity
• Inhaled antimuscarinic agents (e.g. ipratropium, oxitropium, aclidinium)
• Theophylline preparations
• Oral corticosteroids (e.g. prednisolone 40 mg daily)

Steroid-sparing agents
• Methotrexate
• Ciclosporin
• Intravenous immunoglobulin
• Anti-IgE monoclonal antibody – omalizumab
• Etanercept (see p. 680), infliximab, lebrikizumab

Once asthma is brought under control, for at least 2–3 months, the drug regimen should be reassessed in order to reduce the dosage of inhaled steroids.

Beta₂-adrenoceptor agonists
Beta₂-adrenoceptor agonists are selective for the respiratory tract and do not stimulate the β₁ adrenoceptors of the myocardium. These drugs relax the bronchial smooth muscle and are very effective in relieving symptoms, but do not affect underlying airways inflammation.

• **Short-acting β agonists (SABAs)**, such as salbutamol 100 µg (called albuterol in the USA) or terbutaline 250 µg, can be taken at any step, as and when required, from step 1 to step 5 (see above), and should be prescribed as ‘two puffs as required’.

• **Mildest asthmatics with intermittent attacks**. Only these people should rely on bronchodilator treatment alone. Any patients using β₂-adrenoceptor agonists on a daily basis should be started on inhaled corticosteroids. Excessive use of SABAs was linked to two epidemics of asthma mortality in the 1960s and 1980s.

• **Poorly controlled asthmatics** on standard doses of inhaled steroids. These patients require long-acting β₂-adrenoceptor agonists (LABAs) such as salmeterol or formoterol, which are highly selective and potent. LABAs are effective by inhalation for up to 12 hours, and given once or twice daily. LABAs improve symptoms and lung function, and reduce exacerbation rates in patients. They should never be used alone but always in combination with an inhaled corticosteroid. Nowadays, LABAs are usually administered as fixed-dose combinations with
corticosteroids (e.g. salmeterol/fluticasone and formoterol/budesonide) in the same inhaler.

To help those who cannot coordinate activation of the aerosol and inhalation, several breath-activated or dry powder devices have been developed. Devices like the Accuhaler and Turbuhaler require a slower steady inhalation to deliver the drug (compared to pressurized metered-dose inhalers). Patients vary in their ability to use such devices; care should be taken to select an appropriate device and train the individual to use it properly.

**Antimuscarinic bronchodilators**

Muscarinic receptors are found in the respiratory tract; large airways contain mainly $M_3$ receptors, whereas the peripheral lung tissue contains $M_3$ and $M_1$ receptors (see pp. 1060–1061). Non-selective muscarinic antagonists – ipratropium bromide (20–40 µg three or four times daily) or oxitropium bromide (200 µg twice daily) – by aerosol inhalation can be useful during asthma exacerbations, but they are less helpful in stable asthma. Longer-acting antimuscarinics (tiotropium, aclidinium) can be tried in more severe cases.

**Anti-inflammatory drugs**

Sodium cromoglicate and nedocromil sodium prevent activation of many inflammatory cells, particularly mast cells, eosinophils and epithelial cells, but not lymphocytes, by blocking a specific chloride channel, which in turn prevents calcium influx. These drugs are effective in patients with *milder asthma (step 2)* but are used much less often than in the past.

**Inhaled corticosteroids**

All patients who have regular persistent symptoms (even mild symptoms) need regular treatment with inhaled corticosteroids delivered in a stepwise fashion (*from step 2 upwards*) or as a high dose followed by a reduction to maintenance levels. Beclometasone dipropionate (BDP) is the most widely used inhaled steroid and is available in doses of 50, 100, 200 and 250 µg per puff. Other inhaled steroids include budesonide, fluticasone propionate, fluticasone furoate, mometasone furoate and triamcinolone.

Much of the inhaled dose does not reach the lung but is either swallowed or exhaled. Deposition in the lung varies between 10% and 25%, depending on inhaler technique and the technical characteristics of the aerosol device. Drug that is deposited in the airways reaches the systemic circulation directly, through the bronchial circulation, while any drug that is swallowed has to pass through the liver before it can reach the systemic circulation. Gram for gram, fluticasone and mometasone are more potent than beclometasone with considerably less systemic bioavailability, owing to their greater sensitivity to hepatic metabolism. Absorption of beclometasone and budesonide does not seem to present a risk at doses up to 800 µg/day, but fluticasone or mometasone may be preferred because of their lower bioavailability when high-dose inhaled steroids are needed. The dose–response curve for inhaled corticosteroids is flat beyond 800 µg beclometasone or equivalent, and in patients with moderate asthma who are taking this daily, addition of a LABA is more effective than doubling the dose of inhaled corticosteroid.
**Unwanted effects** of inhaled corticosteroids include oral candidiasis (5% of patients) and hoarseness. Sub-capsular cataract formation is rare but can occur in the elderly. Osteoporosis is less likely than with oral steroids but can occur with high-dose inhaled corticosteroids (beclometasone or budesonide >800 µg daily). In children, inhaled corticosteroids at doses >400 µg daily have been shown to retard short-term growth, but final heights are not affected. Inhaled corticosteroid use should be stepped down once asthma comes under control (see p. 1097). Candidiasis and gastrointestinal absorption can be reduced by using spacers, mouth washing and teeth cleaning after use. Systemic effects may also be reduced by choosing corticosteroids that are esterified in the lung (e.g. ciclesonide 80 µg daily).

Asthmatic patients who smoke are less responsive to inhaled corticosteroids due to induction of a range of genes and proteins in their respiratory epithelium. Assistance with smoking cessation should be offered, and additional therapy – for example, with leukotriene receptor antagonists or theophylline – is required.

Patients with anything more than mild/moderate asthma often benefit from combination LABA/corticosteroid therapy and there is some evidence that the two drugs interact therapeutically.

**Oral corticosteroids and steroid-sparing agents**

Oral corticosteroids are needed for individuals not controlled on inhaled corticosteroids (step 5). The dose should be kept as low as possible to minimize side-effects. The effect of short-term treatment with prednisolone 30 mg daily is shown in Figure 24.14. Some patients require continuing treatment with oral corticosteroids. Several studies suggest that treatment with low doses of methotrexate (15 mg weekly) can significantly reduce the dose of prednisolone needed to control the disease in some patients, and ciclosporin also improves lung function in some steroid-dependent asthmatics. Several other steroid-sparing strategies have also been tried, with varying success.

**Leukotriene receptor antagonists**

This class of anti-asthma therapy targets the cysteinyl LT₁ receptor. A second receptor (cystLT₂) has been identified on inflammatory cells. Montelukast, pranlukast (only available in South-east Asia) and zafirlukast are given orally and are effective in a sub-population of asthma patients. However, it is not possible to predict which individuals will benefit; a 4-week trial of leukotriene receptor antagonist (LTRA) therapy is recommended before a decision is made to continue or stop. LTRAs should be tried in any patient who is not controlled on low to medium doses of inhaled steroids (step 2; see Box 24.24). Their action is additive to that of LABAs. LTRAs are particularly useful in patients with aspirin-intolerant asthma, in those patients requiring high-dose inhaled or oral corticosteroids, and in asthmatic smokers. Because these drugs are orally active they are helpful in asthma combined with rhinitis and in young children with asthma and/or virus-associated wheezing.

**Monoclonal antibodies**
Omalizumab, a recombinant humanized monoclonal antibody directed against IgE, chelates free IgE and downregulates the number and activity of mast cells and basophils. It is given subcutaneously every 2–4 weeks, depending on total serum IgE level and body weight. Although expensive, it is cost-effective in patients with frequent exacerbations requiring hospital admission. Proof-of-concept trials have shown that anti-TNF therapy (infliximab or etanercept) may be helpful in severe corticosteroid-refractory asthma. There is still a need to examine other biological agents as potential new controller therapies for the 5–10% of patients with severe disease, who account for a high proportion of the health costs of asthma.

Lebrikizumab, a monoclonal antibody to IL-13, showed improvement in lung function in one study. Mepolizumab and reslizumab, monoclonal antibodies to IL-5, are being introduced in steroid-refractory asthma.

**Antibiotics**

Although wheezing frequently occurs in infective exacerbations of COPD, there is little evidence that antibiotics are helpful in managing patients with asthma. During acute exacerbations, yellow or green sputum containing eosinophils and bronchial epithelial cells may be coughed up. This is usually due to viral rather than bacterial infection and antibiotics are not required. Occasionally, Mycoplasma and Chlamydia infections can cause chronic relapsing asthma, and macrolide antimicrobials may be helpful if a bacterial diagnosis has been established by culture or serology.

**Bronchial thermoplasty**

Bronchial thermoplasty is a novel approach for moderate to severe persistent asthma. This bronchoscopic procedure reduces the mass of airway smooth muscle, decreasing bronchoconstriction, and is currently being evaluated.

**Asthma attacks**

Although these may occur spontaneously, asthma exacerbations are most commonly caused by lack of treatment adherence, respiratory virus infections associated with the common cold, and exposure to allergen or triggering drug, e.g. an NSAID. Whenever possible, patients should have a written personalized plan that they can implement in anticipation of or at the start of an exacerbation that includes the early use of a short course of oral corticosteroids. If the PEFR is >150 L/min, patients may improve dramatically on nebulized therapy and may not require hospital admission. Their regular treatment should be increased, to include treatment for 2 weeks with 30–60 mg of prednisolone, followed by substitution by an inhaled corticosteroid preparation. Short courses of oral prednisolone can be stopped abruptly without tailing down the dose.

**Acute severe asthma**

The term acute severe asthma is used to mean an exacerbation of asthma that has not been controlled by the use of standard medication.
Patients with acute severe asthma typically have:

- **inability to complete a sentence** in one breath
- a **respiratory rate** of ≥25 breaths/min
- **tachycardia** of ≥110 b.p.m. (pulsus paradoxus is not useful, as it is only present in 45% of cases)
- **PEFR <50%** of predicted normal or best.

**Features of life-threatening attacks are:**

- a **silent chest**, cyanosis or feeble respiratory effort
- **exhaustion**, confusion or coma
- **bradycardia** or **hypotension**
- **PEFR <30%** of predicted normal or best (approximately 150 L/min in adults).

**Arterial blood gases** should always be measured in asthmatic patients requiring admission to hospital, with particular attention paid to the $P_{a}CO_2$. **Pulse oximetry** is useful in monitoring oxygen saturation during the admission and can reduce the need for repeated arterial puncture.

**Features suggesting very severe life-threatening attacks are:**

- a high $P_{a}CO_2 > 6$ kPa
- severe hypoxaemia $P_{a}O_2 < 8$ kPa despite treatment with oxygen
- a low and/or falling arterial pH.

**Management (Box 24.26)** consists of nebulized short-acting bronchodilators; nebulized antimuscarinics (e.g. ipratropium bromide) are also helpful. A chest X-ray is helpful to exclude pneumothorax and other causes of dyspnoea. Intravenous hydrocortisone is useful, and in very severe cases, $\beta_2$-adrenoceptor agonists and/or magnesium sulphate are also given intravenously. Prednisolone (40–60 mg daily) should be given orally. Ventilation is required for patients who deteriorate despite this initial regimen.

---

**Box 24.26**

**Treatment of acute severe asthma**

**At home**

1. The patient is assessed. Tachycardia, a high respiratory rate and inability to speak in sentences indicate a severe attack.
2. If the PEFR is <150 L/min (in adults), an ambulance should be called. (All doctors should carry peak flow meters.)
3. Nebulized salbutamol 5 mg or terbutaline 10 mg is administered.
4. Hydrocortisone sodium succinate 200 mg i.v. is given.
5. Oxygen 40–60% is given if available.
6. Prednisolone 60 mg is given orally.

**At the hospital**

1. The patient is reassessed.
2. Oxygen 40–60% is given.
3. The PEFR is measured using a low-reading peak flow meter, as an ordinary meter measures only from 60 L/min upwards. O₂ saturation is measured with a pulse oximeter.
4. Nebulized salbutamol 5 mg or terbutaline 10 mg is repeated and administered 4-hourly.
5. Add nebulized ipratropium bromide 0.5 mg to nebulized salbutamol/terbutaline.
6. Hydrocortisone 200 mg i.v. is given 4-hourly for 24 h.
7. Prednisolone is continued at 60 mg orally daily for 2 weeks.
8. Arterial blood gases are measured; if the $P_{a}CO_2$ is >7 kPa, ventilation may be required.
9. A chest X-ray is performed to exclude pneumothorax.
10. One of the following intravenous infusions is given if no improvement is seen:
    - Salbutamol 3–20 µg/min, or
    - Terbutaline 1.5–5.0 µg/min, or
    - Magnesium sulphate 1.2–2 g over 20 min.
11. If there is still no improvement, urgent transfer to the intensive treatment unit is arranged.

Depending on progress, patients may go home after receiving nebulized therapy. More severe cases should be kept in hospital for 2–5 days with regular monitoring of oxygen saturation and peak flow rates. Downstream assessment of patients admitted with asthma should address trigger factors and aim to reduce the risk of re-admission.

**Management of catastrophic sudden severe asthma (brittle asthma)**

A small minority of patients with asthma suffer sudden life-threatening attacks despite being well controlled between episodes. These attacks may occur within hours or even minutes, and can cause sudden death. Such patients require a carefully worked-out management plan agreed by patient, primary care physician, hospital emergency services and the respiratory physician, which may include:

- **optimization of standard therapy**
- **emergency supplies of medications** at home, in the car and at work
- **oxygen and resuscitation equipment** at home and at work
- **nebulized β₂-adrenoceptor agonists** at home and at work
- **self-injectable adrenaline (epinephrine):** two autoinjectors of 0.3 mg adrenaline at home, at work and to be carried by the patient at all times
- **prednisolone tablets 60 mg**
• **MedicAlert bracelet.**

On developing wheeze, the patient should attend the nearest hospital immediately. Direct admission to intensive care may be required.

---

**Prognosis of asthma**

Although asthma often improves in children as they reach their teens, the disease frequently returns in the second, third and fourth decades. In the past, the data indicating a natural decrease in asthma through the teenage years have led to childhood asthma being treated as an episodic disorder. However, airway inflammation is present continuously from an early age and usually persists, even if the symptoms resolve. Moreover, airways remodelling accelerates the process of decline in lung function over time. This has led to a reappraisal of the treatment strategy for asthma, mandating the early use of controller drugs and environmental measures from the time that asthma is first diagnosed.

---

**Pneumonia**

Pneumonia is defined as inflammation of the substance of the lungs. It is usually caused by bacteria but can also be caused by viruses and fungi. Clinically, it usually presents as an acute illness with cough, purulent sputum, breathlessness and fever, together with physical signs or radiological changes compatible with consolidation of the lung (Fig. 24.33). However, it can present with more subtle symptoms, particularly in the elderly.
Pneumonia is usually classified by the setting in which the person has contracted their infection, for example:

- **in the community setting** – community-acquired pneumonia in a person with no underlying immunosuppression or malignancy
- **in a hospital** or other institution such as a nursing home – hospital-acquired pneumonia
- in a patient whose **immune system is compromised**, through either a genetic defect, immunosuppressive medication or acquired immunodeficiency such as human immunodeficiency virus (HIV) infection.

**Community-acquired pneumonia**

Community-acquired pneumonia (CAP) occurs across all ages but is more common at the extremes of age. There has been an increase in rates of hospital admission due to CAP over the last 10 years, reflecting changes in clinical practice and an ageing population, rather than a true increase in incidence.

Pneumonia can be classified either according to the organism responsible for infection or according to the site of disease. *Pneumococcus* is the most common cause overall; however, in 30–50% of cases, no organism is identifiable, while in about 20% of cases more than one organism is present. Infection can be localized, when the whole of one or more lobes is affected (‘lobar pneumonia’), or diffuse, when the lobules of the lung are mainly affected, often due to infection centred on the bronchi and bronchioles (‘bronchopneumonia’).
Pathophysiology

Several different microorganisms commonly cause CAP. Infection is spread by respiratory droplets. Both the clinical presentation and the range of causative organisms vary with age and with the effectiveness of the host's immune response and innate defence mechanisms. Factors that increase the risk of developing CAP are shown in Box 24.27.

Box 24.27

Risk factors for community-acquired pneumonia

• **Age:** <16 or >65 years
• **Co-morbidities:** HIV infection, diabetes mellitus, chronic kidney disease, malnutrition, recent viral respiratory infection
• **Other respiratory conditions:** cystic fibrosis, bronchiectasis, chronic obstructive pulmonary disease, obstructing lesion (endoluminal cancer, inhaled foreign body)
• **Lifestyle:** cigarette smoking, excess alcohol, intravenous drug use
• **Iatrogenic:** immunosuppressant therapy (including prolonged corticosteroids)

Other causes of pneumonitis are:

• **chemical insult**, such as in the aspiration of vomit (see p. 1106)
• **radiotherapy** (see p. 1124)
• **allergic mechanisms** (see pp. 1115–1117).

Clinical features

The clinical presentation varies according to the immune state of the patient and the infecting agent.

• **Cough:** this may be dry or productive; haemoptysis can occur. In pneumococcal pneumonia, sputum is characteristically rust-coloured.

• **Breathlessness:** the alveoli become filled with pus and debris, impairing gas exchange. Coarse crackles are often heard on auscultation, due to consolidation of the lung parenchyma. Bronchial breath sounds may be heard over areas of consolidated lung.

• **Fever:** this can be as high as 39.5–40°C. If swinging fevers are present, this often indicates empyema (see p. 1104).

• **Chest pain:** this is commonly pleuritic in nature and is due to inflammation of the pleura. A pleural rub may be heard early on in the illness.

• **Extrapulmonary features (Box 24.28):** these are more common in certain infections and are not universal. Sometimes the presence of these symptoms gives a clinical clue as to the
aetiology.

– Haemolysis due to cold agglutinins occurs in approximately 50% cases of *Mycoplasma* pneumonia. Thrombocytopenia is relatively common.

**Box 24.28**

**Extrapulmonary features of community-acquired pneumonia**

- **Myalgia, arthralgia and malaise** are common, particularly in infections caused by *Legionella* and *Mycoplasma*.
- **Myocarditis and pericarditis** are cardiac manifestations of infection, most commonly in *Mycoplasma* pneumonia.
- **Headache** is common in *Legionella* pneumonia. Meningoencephalitis and other neurological abnormalities also occur but are much less common.
- **Abdominal pain, diarrhoea and vomiting** are common. Hepatitis can be a feature of *Legionella* pneumonia.
- **Labial herpes simplex** reactivation is relatively common in pneumococcal pneumonia.
- **Other skin rashes**, such as erythema multiforme and erythema nodosum, are found in *Mycoplasma* pneumonia. Stevens–Johnson syndrome (see pp. 1383–1384) is a rare and potentially life-threatening complication of pneumonia.

**Other features**: in the elderly, CAP can present with confusion or non-specific symptoms such as recurrent falls. CAP should always be considered in the differential diagnosis of sick elderly patients, given their frequently atypical presentation.

Where symptoms have been present for several weeks or have failed to respond to standard antibiotics, *tuberculosis* should be excluded.

**Investigations and management**

The clinical presentation varies between different causative organisms, but there is considerable overlap. *Streptococcus pneumoniae* (pneumococcus) is the most common single cause, and all treatment and investigation strategies need to cover this. The most likely causative pathogens must be treated while considering alternative, less common infectious causes (such as tuberculosis) or an alternative pathology (such as lung cancer). The treatment plan can always be refined and focused later. Pneumonia caused by endobronchial obstruction due to lung cancer is the main concern.

**Initial assessment**

The type and extent of investigation depend on the severity of the illness, which also guides where the patient should be managed and predicts their outcome. Diagnostic microbiological
tests are not needed in mild infection, which should be treated at home with standard antibiotics (amoxicillin, or clarithromycin for those with a history of penicillin allergy). Where patients have mild disease, chest X-ray is not routinely recommended unless they fail to improve after 48–72 hours. Antibiotics can be administered orally.

Severity is commonly assessed by the CURB-65 or the CRB-65 score (Box 24.29). These give a guide to the likely risk of fatal outcome but antibiotic choice must always be tempered by clinical assessment and judgement, taking into account other factors associated with increased rates of mortality (Box 24.30). The CRB-65 score is used in the community where the serum urea level is not usually available (Fig. 24.34). Other severity scores are available to predict mortality and where a patient should be cared for, such as the Pneumonia Severity Index (PSI), which is used more widely in the USA. Figure 24.34 shows a diagnostic and treatment algorithm for CAP, which incorporates treatment recommendations from the British Thoracic Society guidance for the management of CAP (2009) and the Infectious Diseases Society of America/American Thoracic Society guidance (2007).

### Box 24.29

**CURB-65 score**

<table>
<thead>
<tr>
<th>C: confusion present (abbreviated mental test score &lt;8/10)</th>
</tr>
</thead>
<tbody>
<tr>
<td>U: (plasma) urea level &gt;7 mmol/L</td>
</tr>
<tr>
<td>R: respiratory rate &gt;30 breaths/min</td>
</tr>
<tr>
<td>B: systolic blood pressure &lt;90 mmHg; diastolic &lt;60 mmHg</td>
</tr>
<tr>
<td>65: age &gt;65</td>
</tr>
</tbody>
</table>

1 point for each of the above:

- **Score 0–1:** Treat as outpatient
- **Score 2:** Admit to hospital
- **Score 3+:** Often require care in the intensive treatment unit

Mortality rates increase with increasing score.

### Box 24.30

**Other markers of severe community-acquired pneumonia**

- **Chest X-ray** – more than one lobe involved
- **\( P_a O_2 \)** – <8 kPa
- **Low albumin** – <35 g/L
- **White cell count** – <4 \( \times \) 10^9/L or >20 \( \times \) 10^9/L
- **Blood culture** – positive
- **Other co-morbidities**
Absence of fever in the elderly

**FIGURE 24.34** Algorithm for the assessment and treatment of community-acquired pneumonia. CRB, confusion, respiratory rate, blood pressure; CURB, includes urea; PCR, polymerase chain reaction.

**Investigations**

All patients admitted to hospital with suspected CAP should have a chest X-ray, blood tests and microbiological tests.

**Chest X-ray**

Radiological abnormalities can lag behind clinical signs. A normal chest X-ray on presentation should be repeated after 2–3 days if CAP is suspected clinically. The chest X-ray must be repeated 6 weeks later to rule out an underlying bronchial malignancy causing pneumonia due
to bronchial obstruction. Chest X-ray appearances are not diagnostic of any organism, but in *Mycoplasma* and *Chlamydophila* infection the shadowing is often more extensive than would be expected from the clinical picture.

**Blood tests**

Full blood count, urea and electrolytes, biochemistry and C-reactive protein (CRP) are helpful.

- **Strep. pneumoniae.** White cell count is usually >$15 \times 10^9$/L (90% polymorphonuclear leucocytosis); inflammatory markers are significantly elevated: erythrocyte sedimentation rate (ESR) >100 mm/h; CRP >100 mg/L.

- **Mycoplasma.** White cell count is usually normal. In the presence of anaemia, haemolysis should be ruled out (direct Coombs' test and measurement of cold agglutinins).

- **Legionella.** There is lymphopenia without marked leucocytosis, hyponatraemia, hypoalbuminaemia and high serum levels of liver aminotransferases.

**Other tests**

The causative organism must be identified if possible:

- **Sputum culture and Gram stain** are required for all patients:
  - *Strep. pneumoniae*: there are Gram-positive diplococci.
  - *Staph. aureus*: Gram-positive organisms commonly appear in clusters like a bunch of grapes
  - Also diagnostic in infections caused by *Staph. aureus, H. influenzae, M. catarrhalis* and Gram-negative organisms.

- **Blood culture** should be done for all patients who have moderate to severe CAP, ideally before antibiotics are administered. In *Strep. pneumoniae* infection, positive blood cultures indicate more severe disease with greater mortality.

  **Box 24.31** highlights more specific diagnostic tests used to identify the causative organism in patients with moderate to severe CAP.

---

**Box 24.31**

**Specific diagnostic tests in patients with moderate to severe community-acquired pneumonia**
<table>
<thead>
<tr>
<th>Organism</th>
<th>Diagnostic confirmatory test</th>
</tr>
</thead>
</table>
| Streptococcus pneumoniae                | CIE of sputum, urine and serum is 3–4 times more sensitive than sputum or blood cultures  
   Urinary antigen test detects C-polysaccharide. This is rapid and unaffected by antibiotics; sensitivity is 65–80% and specificity about 80%  
   Pneumococcal PCR (not routinely recommended, as inferior to blood cultures and low sensitivity)                                                                 |
| Mycoplasma pneumoniae                   | PCR of respiratory tract samples (throat swab/sputum/BAL fluid) – higher detection rates than serological assays  
   PCR on serum under assessment and likely to become more available  
   CFT (though sensitivity and specificity low) – measure paired samples 10–14 days apart and look for rising titres or single level approximately 7 days after onset of illness |
| Legionella spp. (also termed legionnaire’s disease) | Urinary antigen test detects only serogroup 1, which accounts for most of these infections. Sensitivity (~80%) and specificity are high (almost 99%)  
   DIF staining of organism in the pleural fluid, sputum or bronchial washings  
   Serum antibodies are less reliable. Paired serum antibody titres 10–14 days apart (or single level 7 days after onset of illness)  
   Culture on special media is possible but takes up to 3 weeks. This gives valuable information on antibiotic sensitivity and should be performed if urinary antigen positive  
   *Legionella* is not visible on Gram staining |
| Chlamydia pneumoniae                    | Paired serum antibody titres 10–14 days apart  
   Antigen detection (DIF) on throat swabs/respiratory samples  
   CFT usually only weakly positive and less reliable than in *C. psittaci* |
| Chlamydia psittaci                      | Paired serum antibody titres 10–14 days apart  
   CFT relatively sensitive and specific  
   Antigen detection (DIF) not available for *C. psittaci* |
| Coxiella burnetti (Q fever)             | Paired serum antibody titres 10–14 days apart |
| All respiratory viruses                 | PCR of respiratory tract samples (throat swab/sputum, bronchial aspirate, BAL fluid) |

BAL, bronchoalveolar lavage; CFT, complement fixation test; CIE, counter-immunoelectrophoresis; DIF, direct immunofluorescence; PCR, polymerase chain reaction.

**Pulse oximetry** and **arterial blood gas analysis** are necessary if oxygen saturation is <94%.

Since pneumonia is a common initial presenting illness in patients with previously undiagnosed HIV infection, an **HIV test** should be offered to all patients with pneumonia, unless the patient is unable to give consent or comfort measures alone are implemented due to poor prognosis.

**General management**

- **Oxygen**. Supplemental oxygen should be administered to maintain saturations between 94% and 98% (provided the patient is not at risk of carbon dioxide retention, due to loss of hypoxic drive in COPD). In patients with known COPD, oxygen saturations should be maintained between 88% and 92%, normally with controlled oxygen via fixed-percentage delivery mask (see **Fig. 24.25**).
• **Intravenous fluids.** These are required in hypotensive patients showing any evidence of volume depletion.

• **Antibiotics.** The first dose of antibiotic should be administered *within 4 h of presentation in hospital* and treatment should not be delayed while investigations are awaited.
  
  – Parenteral antibiotics should be switched to oral once the temperature has settled for a period of 24 h, provided there is no contraindication to oral therapy.
  
  – If patients fail to respond to initial treatment, microbiological advice should be sought and alternative diagnoses considered (e.g. *Staph. aureus* pneumonia, which requires addition of flucloxacillin, and possibly cover for MRSA infection). Causes of failure are shown in **Box 24.32**.

### Box 24.32

**Causes of slow-resolving pneumonia**

**Incorrect or incomplete antimicrobial treatment**

- Underlying antibiotic resistance
- Inadequate dose/duration
- Non-adherence
- Malabsorption

**Complication of community-acquired pneumonia**

- Parapneumonic pleural effusion (exudative)
- Empyema
- Lung abscess

**Underlying neoplastic lesion or other lung disease**

- Obstructing lesion
- Bronchoalveolar cell carcinoma
- Bronchiectasis
- Tuberculosis

**Alternative diagnosis**

- Pulmonary thromboembolic disease
- Cryptogenic organizing pneumonia
- Eosinophilic pneumonia
- Pulmonary haemorrhage

  – The antibiotic regimen should be adjusted specifically once culture and sensitivity results
are available. There is an increased incidence of *Clostridium difficile*-associated diarrhoea (CDAD) linked with some antibiotics, such as cephalosporins, which should be avoided if possible. The risk of MRSA increases with antibiotic overuse.

- Antibiotic resistance is an increasing international problem. In some countries, including the USA, rates of resistance of *Strep. pneumoniae* to macrolides are >25% and there is concern over the development of resistance to fluoroquinolones due to their overuse. If tuberculosis is suspected as a differential diagnosis, fluoroquinolones should never be used as a single agent due to the risk of potentiating monoresistance.

- In patients with significant co-morbidities, such as COPD, or those who have received recent antibiotics in the last 90 days, there is an increased risk of drug-resistant pathogens. Antibiotic resistance is a cause of patients failing to improve.

- **Thromboprophylaxis.** If admitted for >12 h, subcutaneous low-molecular-weight heparin should be prescribed, unless contraindications exist, and thromboembolus deterrent (TED) stockings should be fitted.

- **Physiotherapy.** Chest physiotherapy is not needed unless sputum retention is an issue.

- **Nutritional supplementation.** Need is assessed by a dietician, particularly in severe disease.

- **Analgesia.** Simple analgesia, such as paracetamol or NSAID, helps treat pleuritic pain, thereby reducing the risk of further complications due to restricted breathing because of pain (e.g. sputum retention, atelectasis or secondary infection).

### Complications

Complications of pneumonia must be excluded, especially if the patient does not respond quickly to initial treatment (see *Box 24.34*).

### Prevention

Cigarette smoking is an independent risk factor for CAP; if the patient still smokes, cessation advice and support should be given.

Vaccination against influenza is recommended for at-risk groups. All patients over the age of 65 who have not previously been vaccinated and are admitted with CAP should have the pneumococcal vaccine before discharge from hospital.

### Types of pneumonia

The clinical presentation of pneumonia varies according to the causative organism but there is considerable overlap (*Box 24.33*). Pneumococcal disease is typically acute in onset, with prominent respiratory symptoms and a high fever. Pneumonia due to the so-called atypical pathogens (*Mycoplasma pneumoniae, Chlamydia pneumoniae, Legionella pneumophila*) tends to have a slower onset, often with more prominent extrapulmonary symptoms and
complications. The radiographic appearances are indistinguishable from those of CAP caused by pneumococcal pneumonia. The other atypical feature is that these organisms do not respond to penicillin because they lack a cell wall. Macrolides (e.g. clarithromycin) and doxycycline are usually effective.

### Box 24.33

**Types of pneumonia and their clinical features**

<table>
<thead>
<tr>
<th>Organism</th>
<th>Features</th>
</tr>
</thead>
</table>
| *Streptococcus pneumoniae*       | Acute onset, often preceded by influenza-like symptoms. Cough with rust-coloured sputum  
High fevers and pleuritic chest pain common  
Bacteraemia more common in females, excess alcohol, dry cough and COPD, diabetes or HIV infection                                                                                                                                                                     |
| *Mycoplasma pneumoniae*          | Usually mild disease in young patient; occurs in cycles every 3–4 years  
Usually prominent extrapulmonary symptoms (headache, malaise, myalgia); complications common: haemolytic anaemia, erythema multiforme, hepatitis, meningoencephalitis                                                                                                                                 |
| *Legionella* spp. (legionnaire's disease) | Usually *Legionella pneumophila* but other species implicated in around 10% of cases  
Causes more severe disease with need for early intensive care  
Usually acquired by inhaling water mist containing bacteria  
Neurological symptoms frequently seen, along with gastrointestinal involvement and deranged liver enzymes, elevated creatine kinase  
More common in smokers, in males and in young people with no co-morbidities |
| *Staphylococcus aureus*           | Evidence of recent influenza found in up to around 40–50% of patients (increasing frequency with greater-severity disease)  
Usually MSSA but increasing incidence of MRSA, which can produce PVL (see pp. 269–270) and result in necrotizing cavitating pneumonia and bilateral infiltrates                                                                                                                                 |
| *Chlamyphila pneumoniae*         | Unclear whether this is a causative or associated organism  
Generally causes mild disease but with prolonged prodrome                                                                                                                                                                                                                     |
| *Haemophilus influenza,* Moraxella catarrhalis | More common in pre-existing structural lung disease (cystic fibrosis, bronchiectasis, COPD) and in the elderly                                                                                                                                                                                                 |
| *Chlamyphila psittaci*           | Acquired from birds (only 20% have positive history)  
Can be person-to-person spread; usually mild illness                                                                                                                                                                                                                         |
| *Coxiella burnetti* (Q fever)    | Tends to occur more commonly in young men. History of dry cough and high fever  
Recognized cause of endocarditis                                                                                                                                                                                                                                          |
| **Gram-negative organisms**      |                                                                                                                                                                                                                                                                                                                                 |
| *Klebsiella pneumoniae*          | More common in men and those with history of excess alcohol (bacteraemia more likely), poor dental hygiene, diabetes and other co-morbidities; often presents with low platelet and white cell count. Systemic upset is usual; high mortality                                                                                      |
| *Pseudomonas aeruginosa*         | Cavitation and abscess formation seen  
Infection is associated with underlying lung disease (cystic fibrosis, bronchiectasis, COPD) or immune suppression                                                                                                                                                     |
| **All respiratory**              | Infection more likely in elderly with subsequent staphylococcal pneumonia                                                                                                                                                                                                                                                               |
Complications of pneumonia

See **Box 24.34**.

### Box 24.34

**Complications of pneumonia**

#### General

- Respiratory failure
- Sepsis – multisystem failure

#### Local

- Pleural effusion
- Empyema
- Lung abscess
- Organizing pneumonia

### Parapneumonic effusion and empyema

Pleural effusions are common with pneumonia and complicate around one-third to one-half of cases of CAP. The majority of these are simple exudative effusions but empyema may also develop (purulent fluid in the pleural space). Early indications of empyema are ongoing fever, and rising or persistently elevated inflammatory markers, despite appropriate antibiotic therapy.

Thoracocentesis should be performed to make a diagnosis. Fluid should be aspirated under
ultrasound guidance and sent for Gram stain, culture, fluid protein, glucose and lactate dehydrogenase (LDH) (with comparison to serum levels). Light's criteria (see p. 1134) can be applied to assess whether an effusion is transudative or exudative. An exudative effusion with pleural fluid pH < 7.2 is strongly suggestive of empyema. Pathogens are often detectable; sensitivity analysis will help guide antimicrobial therapy.

If an empyema develops, the fluid should be urgently drained to prevent further complications, such as development of a thick pleural rind or prolonged hospital admission. The presence of empyema further increases mortality risk. The duration of antibiotic administration will usually need to be extended. Whenever possible, the choice of antimicrobial should be guided by the results of cultures. Thoracic surgical intervention is necessary in severe cases.

### Lung abscess

This term is used to describe severe localized suppuration within the lung associated with cavity formation visible on the chest X-ray or CT scan, often with a fluid level (which always indicates an air–liquid interface).

There are several causes of lung abscess *(Box 24.35)*:

- **Aspiration pneumonia**: rarely, abscesses develop as a complication of aspiration pneumonia. A history of excessive alcohol consumption or impaired swallowing in a patient with pneumonia suggests aspiration.
- **Tuberculosis**: see pages 1106–1113.
- **Pneumonia caused by certain species**, particularly *Staph. aureus* or *Klebsiella pneumoniae*, may lead to abscess development.
- **Septic emboli usually containing staphylococci**: these can cause multiple lung abscesses. The presence of multiple lung abscesses in an injecting drug user should prompt investigation for infective endocarditis of the tricuspid (or rarely, pulmonary) valves. Infarcted areas of lung (due to pulmonary emboli) occasionally cavitate and become infected.
- **Inadequately treated CAP**.
- **Spread from an amoebic liver abscess**: amoebic lung abscesses occasionally develop in the right lower lobe following transdiaphragmatic spread.
- **Bronchial obstruction by an endoluminal cancer**.
- **Foreign body inhalation**.

#### Box 24.35

**Common causative organisms in lung abscess**

- *Klebsiella pneumoniae*
- *Staphylococcus aureus*
- Gram-negative enteric bacilli
- *Mycobacterium tuberculosis*
- *Streptococcus milleri*
- Anaerobic bacteria (post aspiration)
- *Haemophilus influenzae*

CT scanning is essential and bronchoscopy is often used to obtain samples or remove foreign bodies.

### Clinical features

The clinical features are usually persisting or worsening pneumonia associated with the production of large quantities of sputum, which is often foul-smelling owing to the growth of anaerobic organisms. There is usually a swinging fever; malaise and weight loss frequently occur. On examination, there may be little to find in the chest. Clubbing occurs in chronic suppuration. Patients have a normocytic anaemia and/or raised inflammatory markers (ESR/CRP).

### Management

Treatment should be guided by available culture results or clinical judgement and is often prolonged (4–6 weeks). Surgical drainage is sometimes necessary.

### Pneumonia in other settings

#### Hospital-acquired pneumonia

Hospital-acquired pneumonia (HAP) is defined as new onset of cough with purulent sputum, along with a compatible X-ray demonstrating consolidation, in patients who are beyond 2 days of their initial admission to hospital or who have been in a healthcare setting within the last 3 months (including nursing/residential homes, as well as acute care facilities such as hospitals). HAP is the second most common form of hospital-acquired infection after urinary tract infections and carries a significant mortality risk, particularly in the elderly or those with co-morbidities such as stroke, respiratory disease or diabetes. In HAP, the causative organisms differ from those causing CAP ([Box 24.36](#)). Viral or fungal pathogens only affect immunocompromised hosts. Aerobic Gram-negative bacilli are commonly involved (e.g. *P. aeruginosa*, *Escherichia coli*, *K. pneumoniae* and *Acinetobacter* species). *Staph. aureus* is increasingly recognized in HAP, particularly MRSA, in both Europe and the USA. HAP due to *Staph. aureus* is more common in patients with diabetes mellitus or head trauma, and in those on intensive care units. Empirical antimicrobial therapy should be tailored accordingly. Other conditions should be excluded, including aspiration of gastric contents due to impaired
swallowing or bulbar weakness.

Box 24.36
Organisms implicated in hospital-acquired pneumonia

- Gram-negative bacteria (*Pseudomonas* spp., *Escherichia* spp., *Klebsiella* spp.)
- Anaerobic bacteria (*Enterobacter* spp.)
- *Staphylococcus aureus* (including meticillin-resistant *Staphylococcus aureus*)
- *Acinetobacter* spp.

Elderly residents of long-term care facilities who develop pneumonia have a similar range of pathogens to those found in HAP. In the USA, *Staph. aureus*, Gram-negative rods, pneumococcus and *Pseudomonas* species are the most common causes of pneumonia acquired in nursing homes. Pneumonia associated with ventilation has the same range of organisms as other forms of HAP (see p. 1165). Piperacillin–tazobactam is commonly used in severe HAP.

Aspiration pneumonia

Acute aspiration of gastric contents into the lungs can produce an extremely severe and sometimes fatal illness owing to the intense destructiveness of gastric acid. This can complicate anaesthesia, particularly during pregnancy (Mendelson syndrome). Because of the bronchial anatomy, the most usual sites for aspirated material to end up are the right middle lobe and apical or posterior segments of the right lower lobe. The persistent pneumonia is often due to anaerobes and progresses to lung abscess or even bronchiectasis if protracted. It is vital to identify any underlying problem, since without appropriate corrective measures aspiration will recur.

Treatment should be directed specifically against positive cultures if available. If not, then co-amoxiclav is used for mild to moderate disease, and covers Gram-negative and anaerobic bacteria. Treatment needs to be escalated where there is a lack of response or in severe cases.

Rare causes of pneumonia

Pneumonia can occur as a minor feature during infection by *Bordetella pertussis*, typhoid and paratyphoid bacillus, brucellosis, leptospirosis and a number of viral infections including measles, chickenpox and glandular fever. Details of these infections are provided in Chapter 11.

Pneumonia in immunocompromised patients

Patients who are immunosuppressed (either iatrogenically or due to a defect in host defences)
are at risk not only from all the usual organisms that can cause pneumonia but also from opportunistic pathogens that would not be expected to cause disease. These opportunistic pathogens can be commonly occurring microorganisms (i.e. ubiquitous in the environment) or bacteria, viruses and fungi that are found less often (see Box 12.21). The symptom pattern may resemble CAP or be more non-specific. A high degree of clinical suspicion is therefore necessary when assessing an ill patient who is immunocompromised.

**Pneumocystis jiroveci pneumonia**

*Pneumocystis* pneumonia is one of the most common opportunistic infections encountered in clinical practice. It affects patients on immunosuppressant therapy, such as long-term corticosteroids, monoclonal antibody therapy or methotrexate for autoimmune disease; those on anti-rejection medication post solid organ transplantation or stem cell transplantation; and those infected with HIV. Individuals with CD4 counts of <200/mm$^3$ are at particular risk. *Pneumocystis jiroveci* is found in the air, and pneumonia arises from re-infection rather than reactivation of persisting organisms acquired in childhood.

Clinically, the pneumonia is associated with a high fever, breathlessness and dry cough. A characteristic feature on examination is rapid desaturation on exercise or exertion. The typical radiographic appearance is one of diffuse bilateral alveolar and interstitial shadowing beginning in the perihilar regions and spreading out in a butterfly pattern. Other chest X-ray appearances include localized infiltration, nodules, cavitation or a pneumothorax. Empirical treatment is justified in very sick high-risk patients; wherever possible, however, the diagnosis should be confirmed by indirect immunofluorescence on induced sputum or bronchoalveolar lavage fluid. First-line treatment of *Pneumocystis* pneumonia is with high-dose co-trimoxazole (see p. 349).

**Further reading**

**Tuberculosis**

**Epidemiology**
It is estimated that one-third of the world's population are infected with tuberculosis (TB; see also p. 290). The World Health Organization (WHO) declared TB a world emergency in 1993. There were almost 9 million new and relapsed cases of TB worldwide in 2010. Its incidence had been increasing by around 1% per year to a peak in 2005, but since then the global incidence per capita has started to decline slowly. The majority of cases (around 65%) are seen in Africa and Asia (India and China). Co-infection with HIV remains a problem, not only because this is a huge health burden on resource-poor nations, but also because of the growing incidence of multi- and extremely drug-resistant strains and the high mortality of the two coexistent diseases. TB was responsible for 1.4 million deaths in 2010 and a quarter of these were in HIV co-infected individuals. There are a number of factors affecting the prevalence and risk of developing TB (Box 24.37).

### Box 24.37

**Factors affecting prevalence and risk of developing tuberculosis in the developed world**

- **Contact with high-risk groups:**
  - Origination from a high-incidence country (defined as >40/100 000)
  - Frequent travel to high-incidence areas
- **Immune deficiency:**
  - HIV infection
  - Corticosteroids or immunosuppressant therapy
  - Chemotherapeutic drugs
  - Nutritional deficiency (vitamin D)
  - Diabetes mellitus
  - Chronic kidney disease
  - Malnutrition/body weight >10% below ideal body weight
- **Lifestyle factors:**
  - Drug/alcohol misuse
  - Homelessness/hostels/overcrowding
  - Prison inmates
- **Genetic susceptibility** (twin studies of gene polymorphisms)

### Pathophysiology

TB is caused by four main mycobacterial species, collectively termed *Mycobacterium tuberculosis complex* (MTb):

- *Mycobacterium tuberculosis*
- *Mycobacterium bovis*
• *Mycobacterium africanum*
• *Mycobacterium microti.*

These are obligate aerobes and facultative intracellular pathogens, usually infecting mononuclear phagocytes. They are slow-growing with a generation time of 12–18 hours. Due to their high lipid content in the cell wall, they are relatively impermeable and stain only weakly with Gram stain. When stained with dye combined with phenol and washed with acidic organic solvents, they resist decolorization and therefore are termed ‘acid-fast bacilli’.

### Pathogenesis

TB is an airborne infection spread via respiratory droplets. Only a small number of bacteria need to be inhaled for infection to develop but not all those who are infected develop active disease. The outcome of exposure is dictated by a number of factors, including the host's immune response (*Fig. 24.35*).
Primary tuberculosis

‘Primary TB’ describes the first infection with MTb. Once inhaled into the lung, alveolar macrophages ingest the bacteria; the bacilli then proliferate inside the macrophages and cause the release of neutrophil chemoattractants and cytokines, resulting in an inflammatory cell infiltrate reaching the lung and draining hilar lymph nodes. Macrophages present the antigen to the T lymphocytes with the development of a cellular immune response. A delayed hypersensitivity-type reaction occurs, resulting in tissue necrosis and formation of a granuloma.

Granulomatous lesions consist of a central area of necrotic material called caseation, surrounded by epithelioid cells and Langhans giant cells with multiple nuclei, both cells being derived from the macrophage. Lymphocytes are present and there is a varying degree of fibrosis. Subsequently, the caseated areas heal completely and many become calcified. Some of these calcified nodules contain bacteria, which are contained by the immune system (and the
hypoxic acidic environment created within the granuloma) and are capable of lying dormant for many years. The initial focus of disease is termed the ‘Ghon focus’.

On a chest X-ray, the Ghon focus is evident as a small, calcified nodule, often within the upper parts of the lower lobes or the lower parts of the upper lobes, seen in the mid-zone. A focus can also develop within the regional draining lymph node (primary complex of Ranke).

Upon initial contact with infection, <5% of patients develop active disease. This percentage increases to 10% within the first year of exposure.

**Latent tuberculosis**

In the majority of people who are infected by *Mycobacterium* spp., the immune system contains the infection and the patient develops cell-mediated immune memory to the bacteria. This is termed ‘latent TB’.

**Reactivation tuberculosis**

The majority of TB cases are due to reactivation of latent infection. The initial contact usually occurred many years or decades earlier. In patients with HIV infection, newly acquired TB infection is also common. There are several factors implicated in the development of active disease (*Box 24.38*). The clinical features of latent and reactivation TB are contrasted in *Box 24.39*.

---

**Box 24.38**

**Factors implicated in the reactivation of latent tuberculosis**

- HIV co-infection
- Immunosuppressant therapy (chemotherapy/monoclonal antibody treatment), including corticosteroids
- Diabetes mellitus
- End-stage chronic kidney disease
- Malnutrition
- Ageing

---

**Box 24.39**

**Some features contrasting latent infection with active tuberculous disease**
Latent infection | Active disease
---|---
Bacilli present in Ghon focus | Bacilli present in tissues or secretions
Sputum smear- and culture-negative | Sputum commonly smear- and culture-positive in pulmonary disease
MTb can usually be cultured from infected tissue
Tuberculin skin test usually positive | Tuberculin skin test usually positive (and can ulcerate)
Chest X-ray normal (small calcified Ghon focus frequently visible) | Chest X-ray shows signs of consolidation/cavitation/effusion in pulmonary disease
Asymptomatic | Symptomatic – night sweats, fevers, weight loss and cough common
Not infectious to others | Infectious to others if bacilli detectable in sputum

MTb, *Mycobacterium tuberculosis* complex.

### Clinical features and diagnosis

Any of the manifestations of disease shown in **Box 24.40** can occur in primary or reactivation disease, but extrapulmonary involvement is far less common in primary disease and is usually seen only in regions of high endemicity.

---

**Box 24.40**

*Common sites of tuberculosis infection with relevant radiological findings and appropriate diagnostic investigations*
| Pulmonary, pleural and laryngeal TB | Smear and culture of:  
Sputum (≥2 samples increase diagnostic yield)  
Induced sputum (inhaled hypertonic saline, which induces coughing): diagnostic yield comparable to bronchoscopic samples  
Bronchoalveolar lavage fluid if cough unproductive and induced sputum not possible  
Aspiration of pleural fluid and pleural biopsy  
Gastric aspirates – can be useful in paediatric disease  
Nasoendoscopic or bronchoscopic examination/biopsy of vocal cords with biopsy for smear/culture and histology in laryngeal disease |
|-----------------------------------|---------------------------------------------------------------|
| Miliary TB | Blood cultures  
Bronchoalveolar lavage fluid (usually smear-negative but culture-positive)  
Lumbar puncture should be performed in all cases, unless contraindicated, to assess for CNS involvement (affects treatment duration) – see below  
Sampling of other involved organs often necessary |
| Central nervous system TB | Lumbar puncture if no contraindication. Characteristics of lumbar puncture:  
CSF protein may be very high (usually >2–3 g/L)  
CSF glucose < ½ blood glucose  
CSF lymphocytosis |
| Lymph node TB | All samples should be sent for histocytopathological examination as well as culture and smear:  
Fine needle aspiration or biopsy of an involved lymph node, usually under radiological guidance  
Mediastinal nodal sampling (endobronchial ultrasound transbronchial needle aspiration, mediastinoscopy/mediastinotomy) |

CNS, central nervous system; CSF, cerebrospinal fluid.

In all cases of suspected TB, strong efforts should be made to obtain tissue or fluid for microscopy, smear and culture to obtain information on sensitivities. Tissue samples should also be sent for histopathological examination. Where pulmonary TB is suspected, serial sputum samples should be collected on at least three occasions (ideally, immediately upon waking); where the patient is unable to produce sputum, it is necessary to obtain induced sputum or perform bronchoscopy and lavage to obtain respiratory secretions, not only to make the diagnosis but also to ascertain infectivity of the index case.
Patients are frequently symptomatic with a productive cough and, occasionally, haemoptysis, along with systemic symptoms of weight loss, fevers and sweats (commonly at the end of the day and through the night). Where there is laryngeal involvement, a hoarse voice and a severe cough are found. If disease involves the pleura, then pleuritic pain is a frequent presenting complaint.

The chest X-ray (Fig. 24.36) demonstrates several findings: consolidation with or without cavitation, pleural effusion or thickening or widening of the mediastinum caused by hilar or paratracheal adenopathy.

![Figure 24.36](image)

**FIGURE 24.36** Chest X-ray showing tuberculosis of the left upper lobe with cavitation (arrowed).

**Lymph node TB**

The next most common site for infection is lymph node TB. Extrathoracic nodes are more commonly involved than intrathoracic or mediastinal. Usually, this presents as a firm, nontender enlargement of a cervical or supraclavicular node. The node becomes necrotic centrally and can liquefy and be fluctuant if peripheral. The overlying skin is frequently indurated or there can be sinus tract formation with purulent discharge, but characteristically there is no erythema (cold abscess formation). Nodes typically can be enlarged for several months prior to diagnosis. On CT imaging, the central area appears necrotic (see Box 24.40).
Other forms of TB

**Gastrointestinal TB**
See page 401.

**TB of bone and spine**
See pages 718 and 691.

**Miliary TB**
Miliary disease occurs through haematogenous spread of the bacilli to multiple sites, including the CNS in 20% of cases.

Systemic upset is the rule, with respiratory symptoms in the majority. Other findings are liver and splenic microabscesses with deranged liver enzymes or cholestasis and gastrointestinal symptoms.

The chest X-ray demonstrates multiple nodules, which appear like millet seeds: hence the term ‘miliary’.

**Central nervous system TB**
See page 865.

**Pericardial TB**
See page 1043.

**Skin**
See page 1343.

**Microbiological diagnosis**
Rapid identification of the presence of bacteria by immediate stains is essential and should be performed within 24 hours; culture of the sample allows determination of the antibiotic sensitivity of the infecting strain.

**Stains**
Auramine–rhodamine staining is more sensitive (though less specific) than Ziehl–Neelsen; as a result, it is more widely used. It requires fluorescence microscopy and highlights bacilli as yellow–orange on a green background.

**Culture**
The majority of the developed world uses liquid/broth culture of mycobacteria in addition to solid media (Lowenstein–Jensen slopes or Middlebrook agar), as time to culture is shorter than for solid culture (1–3 weeks compared with 3–8 weeks). Using liquid culture in the
presence of anti-mycobacterial drugs (usually first-line therapy initially) establishes the drug sensitivity for that strain and usually takes approximately 3 weeks.

The use of the microscopic-observation drug-sensitivity (MODS) assay allows rapid detection of bacteria and susceptibility by comparing growth in multiple wells with anti-mycobacterial drugs within liquid media. This technique has the advantage of being relatively inexpensive (although is labour-intensive and operator-dependent) and is therefore more widely used in resource-poor areas.

**Nucleic acid amplification**

Nucleic acid amplification (NAA) is increasingly used for rapid identification of MTb complex and is useful in differentiating between MTb and non-tuberculosis mycobacteria, as well as identifying TB in smear-negative sputum specimens. Culture and staining are still necessary and should not be replaced by PCR. PCR is only useful at the initial stage of diagnosis, as it frequently remains positive despite treatment, due to the detection of dead organisms. This test has a high specificity and moderate sensitivity on cerebrospinal fluid and should be routinely looked for in suspected CNS TB.

The identification of mycobacterial DNA is useful in facilitating rapid commencement of treatment and also rapid identification of drug resistance. Genetic mutations in bacterial DNA conferring rifampicin resistance are highly predictive of multidrug resistance. The development of a highly specific probe designed to detect this mutation thereby allows rapid identification of resistant disease and commencement of appropriate therapy sooner than waiting for cultures to complete (may take up to 8 weeks).

Molecular testing for drug resistance has also become possible using PCR to detect genetic mutations associated with rifampicin resistance. This is performed where resistance is suspected due to specific risk factors in the patient, such as HIV co-infection, previous treatment for TB, location in an area with high rates of resistance or known contact with drug-resistant disease.

**Management**

Patients with fully sensitive TB require 6 months of treatment; the exception is TB of the CNS, for which the recommended duration is at least 12 months. Shorter-duration courses are being studied, aiming at reducing the duration of treatment and increasing the armamentarium against resistant strains. In CNS and pericardial disease, corticosteroids are used as an adjunct at treatment initiation to reduce long-term complications. **Box 24.41** summarizes the standard recommended regimens.

**Box 24.41**

**Usual treatment and duration in fully sensitive tuberculosis**

- **CNS**, central nervous system; E, ethambutol; H, isoniazid; R, rifampicin; Z, pyrazinamide. ²For pulmonary TB, 2HRZE + 4(HR)³, i.e. 3 times weekly for 4HR, is acceptable. ³2HRZE + 4HR, 2 months of HRZE + 4 months of HR.

**Directly observed therapy (DOT)** is widely recommended and employed with an aim to achieve treatment-completion rates of over 85%. DOT is defined as treatment supervised by a healthcare professional or family member, where the person is observed swallowing their medication. WHO advocates universal DOT as one of their strategies to reduce the incidence of TB worldwide, partly because the majority of relapsed disease or treatment failure is due to lack of adherence, interrupted therapy or incorrect treatment (**Box 24.42**). Where DOT is used, the dosing frequency may be reduced to three times per week to make treatment more convenient. Success rates for this regimen and standard daily unsupervised therapy are comparable.

---

**Box 24.42**

**Criteria for implementation of directly observed therapy (DOT) for tuberculosis**

- Patients thought unlikely to comply
  - History of serious mental illness
  - History of non-adherence to TB therapy in past or during current treatment course
- Street- or shelter-dwelling homelessness
- Multidrug-resistant TB

**Unwanted effects of drug treatment**

**Rifampicin** induces liver enzymes, which may be transiently elevated in the serum of many patients. The drug should be stopped only if the serum bilirubin becomes elevated or if transferases are more than three times elevated, which is uncommon. Induction of liver enzymes means that concomitant drug treatment may be made less effective (see p. 24). Thrombocytopenia has been reported. Rifampicin stains body secretions pink and the patients
should be warned of the change in colour of their urine, tears (affects contact lenses) and sweat. Oral contraception will not be effective, so alternative birth-control methods should be used. Rifabutin, a rifamycin, is similar and is used for prophylaxis against *M. avium-intracellularare* complex infection in HIV patients with CD4 counts <200 mm$^3$.

**Isoniazid** has very few unwanted effects. At high doses, it may produce a polyneuropathy due to a $B_6$ deficiency, as isoniazid interacts with pyridoxal phosphate. This is extremely rare when the normal dose of 200–300 mg is given daily. Nevertheless, it is customary to prescribe pyridoxine 10 mg daily to prevent this. Occasionally, isoniazid gives rise to allergic reactions, such as a skin rash and fever. Hepatitis occurs in less than 1% of cases but may be fatal if the drug is continued.

**Pyrazinamide** may cause hepatic toxicity, though this is much rarer with present dosage schedules. Pyrazinamide reduces the renal excretion of urate and may precipitate hyperuricaemic gout.

**Ethambutol** can cause a dose-related optic retrobulbar neuritis that presents with colour blindness for green, reduction in visual acuity and a central scotoma (more common at doses of 25 mg/kg). This usually reverses, provided the drug is stopped when symptoms develop; patients should therefore be warned of its effects. All patients prescribed the drug should be seen by an ophthalmologist prior to treatment and doses of 15 mg/kg should be used.

**Streptomycin** can cause irreversible damage to the vestibular nerve. This is more likely to occur in the elderly and in those with renal impairment. Allergic reactions to streptomycin are more common than those to rifampicin, isoniazid or pyrazinamide. This drug is used only if patients are very ill, have multidrug-resistant TB, or are not responding adequately to therapy.

**Drug resistance**

Worldwide, drug resistance is an increasing problem, with an estimated incidence of 444 000 cases in 2008, responsible for around 150 000 deaths (*Fig. 24.37* and *Box 24.43*). It arises due to incomplete or incorrect drug treatment and can be spread from person to person. Monoresistance is reasonably common: for example, the incidence is approximately 10% in the UK. A risk assessment for drug resistance should be routinely performed. The incidence of multidrug resistance (resistance to both rifampicin and isoniazid, termed MDR-TB) is relatively low in developed countries (around 1%) and only a handful of extensively drug-resistant (XDR-TB) cases have been seen, though most countries have reported at least one case. XDR-TB is defined as high-level resistance to rifampicin, isoniazid, fluoroquinolones and at least one injectable agent such as amikacin, capreomycin or kanamycin. A few cases of total drug resistance (TDR) have been reported from Italy, Iran and Mumbai (India).
Box 24.43

Factors associated with an increased risk of drug-resistant tuberculosis

- History of prior drug treatment of TB (particularly if unsupervised, self-administered treatment)
- Co-infection with advanced HIV and previous TB treatment
- Infection acquired in a region with high rates of drug resistance
- Contact with a known case of resistant TB
- Failure to respond to empirical TB therapy despite documented adherence
- Exposure to multiple courses of fluoroquinolone antibiotics for presumed community-acquired pneumonia
- Healthcare workers exposed to cases of resistant TB

TB in special situations

*Mycobacterium bovis* infection occurs in humans who have consumed unpasteurized milk sometime in their life, in farmers working with infected cows for over 3 years and abattoir workers. TB due to *M. bovis* does not differ from ordinary TB in the chest, but extrapulmonary sites of infection are more common. Immunosuppression is also a risk factor. Diagnosis is with
acid-fast staining and culture of tissues and sputum. The tuberculin text is positive. Treatment is with isoniazid, rifampicin and ethambutol; pyrazinamide resistance is common.

**HIV co-infection**

The increase in TB seen over recent decades has occurred to a considerable extent in association with the incidence of HIV infection, with high levels seen in Africa (particularly sub-Saharan Africa), the Indian subcontinent and parts of Eastern Europe and Russia. The incidence of HIV infection in TB worldwide is around 15% and TB is responsible for around one-quarter of acquired immunodeficiency syndrome (AIDS)-related deaths.

Alongside the increased morbidity and mortality of co-infection, there are specific issues relating to the treatment of TB in HIV: namely, the incidence of drug interactions and intolerability, the increased risk of treatment toxicity and the higher incidence of drug resistance. TB/HIV infection should be managed by experts in TB (respiratory or infectious disease physicians) alongside HIV specialists.

**Chronic kidney disease**

Chronic kidney disease (CKD) is a risk factor for reactivation of latent TB infection (LTBI) due to relative immune paresis. Patients due to undergo renal transplantation may need to be screened for LTBI and given complete chemoprophylaxis if necessary before undergoing their procedure. The presence of CKD also complicates the treatment regimen, as there is an increased risk of toxicity due to altered pharmacokinetics, which necessitates dosage adjustments and therapeutic drug level monitoring. Management should be undertaken by TB specialists in conjunction with renal physicians.

**Latent TB infection (LTBI)**

LTBI is diagnosed by demonstrating immune memory to mycobacterial proteins. Two tests are available.

**Tuberculin skin test**

A positive result is indicated by a delayed hypersensitivity reaction evident 48–72 hours after the intradermal injection of purified protein derivative (PPD) resulting in:

- a raised, indurated lesion >6 mm diameter in non-vaccinated adults
- a raised, indurated lesion >15 mm in bacille Calmette–Guérin (BCG)-vaccinated adults.

False-negative (anergic) tuberculin skin tests (TSTs) are common in immunosuppression due to HIV infection (CD4+ <200/mm³), sarcoidosis, or drugs (chemotherapy, anti-TNF therapy, steroids), at the extremes of age and in active disease. False-positives occur due to cross-reactivity with non-tuberculous mycobacteria and BCG vaccination.

**Interferon-gamma release assays**

Interferon-gamma release assays (IGRAs) detect T-cell secretion of IFN-γ following exposure
to *M. tuberculosis*-specific antigens (ESAT-6, CFP-10). Where a person has been infected (previously or currently) with TB, activated T cells within their extracted whole blood secrete quantifiable levels of IFN-γ in response to re-exposure to TB-specific antigens. The test does not differentiate between active and latent infection. However, it is highly specific compared with the TST and has a similar or better sensitivity and only requires a single visit.

**Global TB strategy**

Part of the global TB strategy is to increase the identification and treatment of LTBI, thereby reducing the risk of conversion to active disease and transmission to others. In certain groups with LTBI, chemoprophylaxis is offered to reduce the risk of active infection (*Box 24.44*).

---

**Box 24.44**

**People who should be treated for latent tuberculosis infection (after excluding active TB)**

- People aged ≤35 years with positive TST or IGRA
- Healthcare workers with positive TST or IGRA
- Patients commencing anti-TNF therapy with positive IGRA
- HIV-positive people with positive IGRA
- People with evidence of previous TB on chest X-ray and inadequate treatment

IGRA, interferon-gamma release assay; TNF, tumour necrosis factor; TST, tuberculin skin test.

---

Active case-finding forms part of a number of programmes:

- **Contact tracing**: carried out after diagnosis of a new case of TB; involves identifying close contacts who are at risk of infection or who may have active infection and have not yet sought medical attention.

- **Screening of healthcare workers**: as part of an occupational health programme, with BCG vaccination of those with no evidence of previous TB exposure.

- **Screening of new entrants**: for those arriving from a country of high incidence of TB, who should be offered screening for latent or active infection and vaccination if not infected and previously unvaccinated.

- **Street-homeless or hostel dwellers**: at increased risk of active TB and should be offered opportunistic screening for active infection.

- **Immunocompromised people**:
  - Patients due to commence monoclonal antibody therapy for autoimmune conditions – should be screened for active or latent infection and given appropriate treatment before commencing immunosuppressive therapy, as they are at a particularly high risk for
reactivation of LTBI.
– People with HIV infection (see above).
– People with underlying haematological malignancies or solid-organ transplants or undergoing chemotherapy – require screening.

BCG vaccination

BCG is a live attenuated vaccine derived from *M. bovis* that has lost its virulence. It has variable efficacy but is still recommended in certain situations in developed countries (but not the USA), though no longer offered routinely to all due to the lack of cost-efficacy. It has been shown to reduce the risk of disseminated and CNS TB in babies and children and is therefore used worldwide. There are safety concerns in babies with HIV. Its efficacy in adults is very variable.

Non-tuberculous mycobacterial infection

Non-tuberculous mycobacterial (NTM) infections occur in soil and water and are not usually pathogenic due to their lack of virulence. However, where there is a breach of the normal host defence mechanisms, certain strains have the potential to become pathogenic *(Box 24.45)*. Factors associated with increased risk of pulmonary NTM infection are shown in *(Box 24.46)*. Treatment is suggested if there is a compatible clinical picture and (a) the organism is isolated from an invasive sample or (b) an NTM is isolated from more than one sputum sample obtained at different times.

**Diffuse Parenchymal Lung Diseases**

These are also referred to as **interstitial lung diseases (ILDs)**. They are a heterogeneous group of conditions accounting for about 15% of respiratory clinical practice. They are characterized by varying degrees of inflammation and fibrosis, initially affecting the interstitium of the lung, which typically present with exertional dyspnoea, with or without cough. A classification of ILDs is shown in **Figure 24.38**.

![Classification of the interstitial lung diseases. RA, rheumatoid arthritis; SLE, systemic lupus erythematosus.](image)
Idiopathic interstitial pneumonias

The terminology used to describe the idiopathic interstitial pneumonias can be confusing but it is necessary to distinguish between subgroups, as there are significant differences in terms of prognosis and treatment options. Clinical patterns usually link to particular histological subtypes; their classification is shown in Box 24.47.

Idiopathic pulmonary fibrosis

Idiopathic pulmonary fibrosis (IPF) is the most common of the idiopathic interstitial pneumonias. It is a progressive and ultimately fatal disease of unknown cause. There is significant worldwide variation in reported prevalence but the incidence appears to be increasing (6.8–8.8/100 000 in the USA). Mean onset is in the sixties and presentation is very uncommon under the age of 50. Males are twice as likely to be affected.

Pathology

Usual interstitial pneumonia (UIP) is the histological finding in IPF. The key feature is a heterogenous appearance with areas of normal lung punctuated by areas of marked fibrosis, honeycombing mainly in subpleural areas and fibroblastic foci (dense proliferations of fibroblasts and myofibroblasts). The terms IPF and UIP are often used interchangeably but they are *not* synonymous, as UIP is also the primary histological finding in several other diffuse parenchymal lung diseases (e.g. pulmonary autoimmune rheumatic disease).
Pathogenesis

It is thought that repetitive injury to the alveolar epithelium, caused by currently unidentified environmental stimuli, leads to the activation of several pathways responsible for repair of the damaged tissue. However, in IPF, the wound healing mechanisms become uncontrolled, leading to over-production of fibroblasts and deposition of increased extracellular matrix in the interstitium with little inflammation. The structural integrity of the lung parenchyma is therefore disrupted: there is loss of elasticity and the ability to perform gas exchange is impaired, leading to progressive respiratory failure. Factors implicated in triggering the aberrant wound healing include inhalational insults (cigarette smoke, occupational dust exposure), viruses (e.g. Epstein–Barr), drugs (e.g. methotrexate, nitrofurantoin) and chronic gastro-oesophageal reflux disease (GORD); none of these has been substantiated. There may be a genetic predisposition in a small (2–20%) of patients. Polymorphisms in the MUC5B gene and mutations in genes encoding telomerase and surfactant have been reported.

Clinical features

Patients typically present with insidious onset of progressive dyspnoea that may be accompanied by cough, with or without sputum production. It is not uncommon for patients to be mistakenly treated for heart failure or recurrent chest infections before the diagnosis of IPF is made. The onset is usually in the patient's sixties and is rare below the age of 50. There is a 2 : 1 male : female ratio. Finger clubbing is seen in 25–50% of cases. Examination of the chest shows bi-basal end-inspiratory crackles.

Progressive respiratory failure may be complicated by pulmonary hypertension. Stepwise deterioration can occur due to pneumothorax, pulmonary embolism or intercurrent infection, but acute exacerbations with no identifiable cause are well recognized and are associated with increased mortality. An acute form (also known as Hamman–Rich syndrome) occasionally occurs and has a particularly poor prognosis.

Investigations

The aims of investigation in IPF are to confirm the presence of pulmonary fibrosis and exclude identifiable (and potentially reversible) causes. A combination of typical clinical features and characteristic radiological abnormalities may be sufficient for diagnosis. However, further tests are necessary where the diagnosis is in doubt.

- **Respiratory function tests** usually show a restrictive pattern (FEV₁/FVC ratio >70%) with reduced lung volumes and gas transfer. However, spirometry may be normal in early disease and lung volumes can be preserved in the presence of coexisting emphysema.

- **Blood tests**, including antinuclear antibodies (ANA) and rheumatoid factor (RF), are performed to exclude autoimmune rheumatic disease but there is no specific serological test for IPF.
• **Chest X-ray** shows small-volume lungs with increased reticular shadowing at the bases but may be normal in early disease.

• **HRCT** is the imaging modality of choice. A confident diagnosis of IPF may be made in patients with typical clinical features and absence of an identifiable cause if the following HRCT abnormalities are present:
  
  – **Basal distribution**: abnormalities are more pronounced at the bases.
  – **Subpleural reticulation**: reticulation is most evident in the lung peripheries.
  – **Traction bronchiectasis**: the fibrotic process distorts the normal lung architecture, pulling the airways open and causing bronchiectasis.
  – **Honeycombing**: there are basal layers of small, cystic airspaces with irregularly thickened walls composed of fibrous tissue *(Fig. 24.39)*.

![CT scan showing idiopathic pulmonary fibrosis. There is reticular shadowing and honeycombing predominantly in the basal and subpleural areas.](image)

• **Bronchoalveolar lavage** is only necessary if an infective or malignant cause is suspected. A differential cell count may lend support to an alternative diagnosis: a lymphocytosis is suggestive of *hypersensitivity pneumonitis* whereas a neutrophilic pattern (neutrophils >3%) is commonly seen in IPF.

• **Histological confirmation** is necessary in some patients. Surgical lung biopsy, usually via video-assisted thoracoscopic surgery (VATS), is the most reliable method for obtaining diagnostic histological samples. Parenchymal tissue can also be obtained bronchoscopically via transbronchial biopsy. This avoids the need for general anaesthetic but the samples obtained are frequently too small for accurate analysis, although may be sufficient to confirm alternative diagnoses such as sarcoidosis.
**Differential diagnosis**

The main differential diagnosis for IPF is an alternative interstitial lung disease. Other differentials for the chest X-ray appearances include interstitial pulmonary oedema, infection and lymphangitis carcinomatosa.

**Prognosis and management**

The median survival time for patients with IPF is 2–5 years, although mortality is higher in the more acute forms. The disease course is highly variable and unpredictable; living with this uncertainty is one of the most difficult aspects of this disease. Serial lung function testing is used to monitor disease progression and a 10% decline in FVC or 15% decline in gas transfer (TLCO) in the first 6–12 months confers a worse prognosis. Periods of stability may be interspersed with periods of more accelerated decline, but failure to recover back to baseline following these episodes is common. Mortality is increased following acute exacerbations.

Previous treatment strategies included a combination of prednisolone, azathioprine and N-acetylcysteine. Intravenous methylprednisolone may still be used in acute presentations with life-threatening disease.

Treatment now targets the aberrant fibroblastic proliferation and tissue remodelling implicated in the pathogenesis. **Pirfenidone**, an antifibrotic agent, has been shown to slow the rate of FVC decline in a number of large randomized controlled trials and has been approved for use in several countries. It is generally well tolerated, with the most common side-effects being a reversible photosensitive rash and gastrointestinal disturbance. Other treatments include **nintedanib**, an intracellular inhibitor of tyrosine kinases, believed to activate the cell-signalling pathways responsible for the uncontrolled fibroproliferative process.

GORD should be treated, as this is thought to contribute to repetitive alveolar epithelial damage. Even with treatment, IPF is a life-limiting disease and transplant assessment should be undertaken in accordance with local guidelines. All patients should have their need for supportive care assessed with respect to oxygen therapy, pulmonary rehabilitation and palliative care input.

**Other idiopathic interstitial pneumonias**

These are described in Box 24.48.

One of the most common causes worldwide is farmer's lung, which can affect up to 9% of farmers in humid climates. Interestingly, cigarette smokers have a lower risk of developing HP due to decreased antibody reaction to the antigen, but once established, smoking may lead to a more chronic or severe disease course.

Pathogenesis

Histological features include:

- a chronic inflammatory infiltrate
- poorly defined interstitial granulomas
- interstitial fibrosis and honeycomb change in chronic disease (may be indistinguishable from other causes of pulmonary fibrosis).

The allergic response to the inhaled antigen involves both cellular immunity and the deposition of immune complexes, causing foci of inflammation through the activation of complement via the classical pathway. Some of the inhalant materials may also lead to inflammation by directly activating the alternate complement pathway. These mechanisms attract and activate alveolar and interstitial macrophages so that continued antigenic exposure results in the progressive development of pulmonary fibrosis.
**Clinical features**

HP can be categorized according to the chronicity of symptoms, as determined by duration and intensity of exposure. Symptoms include malaise, dyspnoea and cough. Weight loss is a prominent feature of subacute and chronic HP. Auscultation reveals inspiratory squeaks due to bronchiolitis, and bilateral fine crackles. Wheeze is uncommon.

- **Acute**: symptom onset 4–6 h following exposure. Fever is common and patients may be mistakenly diagnosed with a chest infection. Resolution occurs 24–48 h following removal from the inciting antigen.

- **Subacute**: usually occurs with intermittent or lower-level exposure. Improvement is seen in weeks to months following removal from exposure.

- **Chronic**: usually no history of preceding acute symptoms. Insidious onset of respiratory and constitutional symptoms is typical. Finger clubbing may be present. Progression to irreversible fibrosis is associated with increased mortality.

**Investigations**

A diagnosis can often be made by maintaining a high index of suspicion and taking a detailed exposure history. Identification of a culprit antigen in the context of typical clinical and radiological findings often makes lung biopsy unnecessary.

- **Chest X-ray** is neither sensitive nor specific for HP and may be normal in acute and subacute disease. When present, abnormalities include diffuse small nodules and increased reticular shadowing.

- **HRCT** shows nodules with ground-glass opacity and evidence of air trapping. Increased reticulation and honeycomb change are seen in advanced disease. Abnormalities are most marked in the mid-/upper zones.

- **Lung function tests** are used to assess the degree of respiratory impairment but are not diagnostic. A restrictive ventilatory defect with decreased carbon monoxide gas transfer is seen in chronic disease.

- **Precipitating antibodies** are present in the serum. One-quarter of pigeon fanciers have precipitating IgG antibodies against pigeon protein and droppings in their serum, but only a small proportion have lung disease. Precipitating antibodies are therefore evidence of exposure, not disease.

- **Bronchoalveolar lavage** shows a lymphocytosis. A low CD4:CD8 ratio can help differentiate HP from sarcoidosis.

- **Lung biopsy** demonstrates a lymphocyte-rich infiltrate with varying degrees of fibrosis, depending on chronicity of disease.

**Differential diagnosis**
Although hypersensitivity pneumonitis due to inhalation of the spores of *Micropolyspora faeni* is common among farmers, it is probably more common for these individuals to suffer from asthma related to inhalation of antigens from a variety of mites that infest stored grain and other vegetable material, such as *Lepidoglyphus domesticus*, *L. destructor* and *Acarus siro*. Symptoms of asthma resulting from inhalation of these allergens are often mistaken for farmer's lung. Alternative differentials include one of the other interstitial lung diseases.

**Management**

The key to successful treatment is avoidance of exposure to the inciting antigen (if known) and this may be achieved by changes in work practice. Pigeon fancier's lung is more difficult to control since affected individuals remain strongly attached to their hobby. Prednisolone should be initiated in patients whose symptoms persist despite withdrawal from the causative antigen, and in severe disease. Established fibrosis will not resolve and, in some patients, the disease may progress inexorably to respiratory failure despite intensive therapy. Farmer's lung is a recognized occupational disease in the UK and sufferers are entitled to compensation, depending on their degree of disability.

**Humidifier fever**

Humidifier fever may present with the typical features of hypersensitivity pneumonitis without any radiographic changes, and is caused by humidifiers and air-conditioning units that emit a fine spray of antigenic microorganisms.

**Rare interstitial lung diseases**

**Langerhans cell histiocytosis**

This rare disease is characterized histologically by proliferation of Langerhans cells, identified by the presence of Birbeck granules on electron microscopy or the CD1a antigen on the surface of the cells. There is a wide variation in clinical presentation, from isolated lytic bone lesions to multisystem disease involving skin, lymph nodes and major organs (more commonly seen in young children). Pulmonary involvement occurs in 10% of Langerhans cell histiocytosis (LCH) cases and is strongly associated with cigarette smoking. Recurrent spontaneous pneumothorax is seen in up to 25% and is a common mode of presentation. HRCT shows characteristic interstitial thickening, nodules, cysts and honeycombing with mid- and upper zone predominance, and may be sufficient for diagnosis in a young smoker (typical age 20–40 years). Smoking cessation is essential. Various treatment strategies, including corticosteroids, chemotherapy agents and cladribine, have been used with variable success. Lung transplantation may be considered in advanced disease. Outcome varies from spontaneous remission to progressive end-stage fibrosis but overall 5-year survival is 75%.
**Pulmonary lymphangioleiomyomatosis**

Pulmonary lymphangioleiomyomatosis (LAM) is a rare disorder of premenopausal women, causing hamartomatous smooth muscle infiltration of the lungs. Gene mutations in the hamartin–tuberin complex are present; the gene products regulate the activity of rapamycin complex 1. Extrapulmonary involvement, especially with renal angiomyolipomas (hamartomas), is common. Some 15% of patients with pulmonary LAM have tuberous sclerosis. Presentation is with dyspnoea, chylous pleural effusions and pneumothorax. HRCT shows diffuse thin-walled cysts scattered throughout the lungs. Treatment with hormonal manipulation/oophorectomy has shown a variable response. Sirolimus (rapamycin) can be effective but lung transplantation may be necessary. Prognosis estimates range from 10 to 29 years.

**Pulmonary alveolar proteinosis**

This is a rare disease in which lipoproteinaceous material accumulates within the alveoli. It can be congenital but most cases are acquired and appear to have an autoimmune basis, with antibodies directed against the cytokine GM-CSF. The disease mostly affects men and presents with progressive exertional dyspnoea and cough. Inspiratory crackles are present in 50%. Diagnosis is made by bronchoalveolar lavage, which reveals a milky appearance and many large, foamy macrophages but few other inflammatory cells. Initial therapy is with whole-lung lavage.

**Granulomatous lung disease**

A granuloma is a mass or nodule composed of chronically inflamed tissue formed by the response of the mononuclear phagocyte system (macrophages/histiocytes) to an inciting antigen and characterized by the presence of epithelioid multinucleate giant cells. Granuloma formation acts to confine a pathogen and limit the extent of surrounding inflammation and tissue destruction. Granulomas are seen in TB and other infections, including fungal and helminthic ones, in sarcoidosis and in hypersensitivity pneumonitis. Granulomatous lung disease with pulmonary vasculitis is discussed on pages 1120–1121.

**Sarcoidosis**

Sarcoidosis is a multisystem granulomatous disorder, commonly affecting young adults and typically presenting with bilateral hilar lymphadenopathy, pulmonary infiltration and skin or eye lesions. Beryllium poisoning can produce a clinical and histological picture identical to sarcoidosis, though contact with this element is now strictly controlled.

**Epidemiology and aetiology**

Sarcoidosis is a common disease of unknown aetiology that is often detected on routine chest
X-ray. There is great geographical variation; sarcoidosis is most common in Northern Europe (annual incidence 5–40/100 000) but uncommon in Japan (incidence 1–2/100 000). In the USA, it is 3–4 times more prevalent in blacks than in Caucasians and they are more likely to develop extrapulmonary or chronic disease. There is a female preponderance with peak incidence in the third and fourth decades. There is no relation with any histocompatibility antigen, but first-degree relatives have an increased risk of developing sarcoidosis (particularly in Caucasians). Other proposed aetiological factors are an atypical mycobacterium or fungus, the Epstein–Barr virus, and occupational, genetic, social or other environmental factors (sarcoidosis is more common in rural than in urban populations and less common in smokers). None of these has been substantiated.

**Immunopathology**

- Typical sarcoid granulomas consist of focal accumulations of epithelioid cells, macrophages and lymphocytes, mainly T cells.
- There is depressed cell-mediated reactivity to tuberculin; the Mantoux test is usually negative. There is overall lymphopenia; circulating T lymphocytes are low but B cells are slightly increased.
- Bronchoalveolar lavage shows a great increase in the overall number of cells; a lymphocytosis (particularly CD4+ T-helper cells) is common.
- Transbronchial biopsies show infiltration of the alveolar walls and interstitial spaces with leucocytes, mainly T cells, prior to granuloma formation.

  It seems likely that the decrease in circulating T lymphocytes and changes in delayed hypersensitivity responses are the result of sequestration of lymphocytes within the lung. There is no evidence to suggest that patients with sarcoidosis suffer from an overall defect in immunity, since the frequency of fungal, viral and bacterial infections is not increased and there is no evidence of any increased risk of developing malignant neoplasms.

**Clinical features**

Sarcoidosis can affect any organ (*Box 24.50*) but has a predilection for the lungs (involvement in up to 90%). Presentation may be with respiratory symptoms but it is not unusual for the diagnosis to be made incidentally on chest X-ray. Common extrathoracic manifestations include eye, skin or lymph node involvement, and constitutional upset with fatigue is a frequent and often refractory symptom. The combination of bilateral hilar lymphadenopathy, erythema nodosum, arthralgia and fever is known as Löfgren syndrome and is a common presentation with a very favourable prognosis. In this case, the constellation of symptoms is usually sufficient to make a clinical diagnosis. In less classic presentations, HRCT may show features highly suggestive of sarcoidosis but the presence of non-caseating granulomas on tissue biopsy of an affected organ is often sought for definitive diagnosis. Skin biopsy is comparatively non-invasive and careful examination for infiltration of scars and tattoos amenable to sampling
should be undertaken, even in the absence of overt cutaneous involvement.

<table>

- Dyspnoea
- Wheeze

**Hepatic**
- Deranged liver function tests
- Hepatomegaly

**Ocular**
- Anterior uveitis
- Keratoconjunctivitis sicca

**Hypercalcaemia/hypercalciuria**
- Hypercalciuria
- Nephrocalcinosis – may cause kidney injury
- Calculi

**Cutaneous**
- Erythema nodosum
- Lupus pernio

**Neurological**
- Cognitive dysfunction
- Headache
- Cranial nerve palsies
- Mononeuritis multiplex
- Peripheral neuropathy
- Seizures

**Cardiac**
- Arrhythmias
- Heart block
- Cardiomyopathy
- Sudden death

**Pulmonary manifestations**
Although pulmonary involvement may be an incidental finding, cough, exertional breathlessness and vague chest discomfort are common presentations. Even in symptomatic individuals, the chest is often clear to auscultation, although wheeze may be evident if there is significant involvement of the airways with endobronchial disease. There are four radiological stages of lung involvement, which helps inform prognosis *(Box 24.51)*.

**Box 24.51**

**Radiological stages of pulmonary sarcoidosis**

</tr>
</tbody>
</table>

Patients may present with any stage of disease and do not necessarily progress through the stages sequentially. Moreover, the extent of disease on chest X-ray does not correlate with the
degree of impairment on pulmonary function testing.

**Bilateral hilar lymphadenopathy**

Symmetrical bilateral hilar lymphadenopathy (BHL) is a characteristic feature of sarcoidosis; it is usually asymptomatic and only detected on chest X-ray. Occasionally, BHL is associated with a dull ache in the chest, malaise and a mild fever. The differential diagnosis of BHL includes:

- **Lymphoma:** this rarely affects the hilar lymph nodes in isolation.
- **Pulmonary TB:** hilar lymph nodes are usually asymmetrically enlarged.
- **Carcinoma of the bronchus** with malignant spread to the hilar lymph nodes: again, this is rarely symmetrical.

**Pulmonary infiltration**

Although the lung fields may appear normal on plain chest X-ray, the lung parenchyma is frequently involved, as shown by CT scanning (*Fig. 24.40*), transbronchial biopsy and bronchoalveolar lavage. Symptoms may be minimal (or even absent), despite quite marked radiographic abnormalities. Progressive disease may lead to irreversible fibrosis in up to 20% of cases. The principal differential diagnoses are TB, pneumoconiosis, idiopathic pulmonary fibrosis and hypersensitivity pneumonitis.

**FIGURE 24.40** High-resolution CT scan in sarcoidosis. Note the bilateral hilar lymphadenopathy and reticular shadowing.

**Extrapulmonary manifestations**

Sarcoidosis can affect any organ. Cutaneous sarcoidosis and ocular sarcoidosis are the most common extrapulmonary presentations but cardiac and CNS involvement are the most important clinically.

*Skin lesions.* These occur in 10–30% of cases. Sarcoidosis is the most common cause of erythema nodosum (see p. 1363). Lupus pernio, presenting as indurated erythematous or
violaceous papules/plaques, may be seen over the nose, cheeks and ears.

**Eye lesions.** Anterior uveitis is common and presents with misting of vision and a painful, red eye, but posterior uveitis may present simply as progressive loss of vision. Although ocular sarcoidosis accounts for about 5% of uveitis presenting to ophthalmologists, asymptomatic uveitis may be found in up to 25% of patients with sarcoidosis and all patients with a new diagnosis of sarcoidosis should undergo ophthalmological assessment. Keratoconjunctivitis sicca and lacrimal gland enlargement also occur.

**Metabolic manifestations.** Hypercalcaemia and hypercalciuria can lead to the development of renal calculi, nephrocalcinosis and, ultimately, renal failure.

**Central nervous system.** CNS involvement is rare (2%) but can lead to severe neurological disease (see p. 862).

**Bone and joint involvement.** Arthralgia without erythema nodosum is seen in 5% of cases. Bone cysts with associated swelling, particularly affecting the digits, may be seen on X-ray.

**Hepatosplenomegaly.** Mild derangement of liver function tests is common and granulomas are seen in the majority of biopsy specimens, although these findings are rarely of clinical consequence. Progression to portal hypertension or liver failure is uncommon.

**Cardiac involvement.** Ventricular dysrhythmias, conduction defects and cardiomyopathy with congestive cardiac failure are rare (3%). Severity ranges from benign rhythm disturbance to sudden cardiac death. All patients with sarcoidosis should have an ECG at presentation.

### Investigations

- **Imaging.** Chest X-ray is the initial modality for staging (Box 24.51). HRCT is useful for assessment of parenchymal involvement and may show a range of abnormalities, including nodules of 1–10 mm diameter that form a characteristic ‘beading’ appearance along airways, vessels and fissures; aggregation of nodules into larger nodules or masses (up to 3 cm); increased reticulation due to septal thickening; and honeycombing.

- **Full blood count.** There may be a mild normochromic, normocytic anaemia with raised ESR.

- **Biochemistry.** Hypercalcaemia occurs in 10–20% and hypercalciuria in 30–50%. Activated macrophages in lung and lymph nodes are able to hydroxylate vitamin D directly (independent of parathyroid hormone levels), leading to increased intestinal absorption of dietary calcium. Twenty-four-hour urinary calcium excretion should be measured at presentation.

- **Serum angiotensin-converting enzyme (ACE) level.** This is elevated in over 75% of patients with untreated sarcoidosis. Raised (but lower) levels are also seen in patients with lymphoma, pulmonary TB, asbestosis and silicosis, limiting the diagnostic value of the test. The utility of serum ACE in monitoring disease activity and response to treatment is contentious.

- **Bronchoalveolar lavage.** This typically shows a lymphocytosis with raised CD4:CD8 ratio.

- **Transbronchial biopsy.** This is positive in up to 90% of cases of pulmonary sarcoidosis. Pulmonary non-caseating granulomas are found in approximately 50% of patients with
extrapulmonary sarcoidosis in whom the chest X-ray is normal.

- **Endobronchial biopsy.** When performed in addition to transbronchial biopsy, this may significantly increase the yield, even if the macroscopic appearances are normal.

- **Lung function tests.** These show a restrictive lung defect with reduced gas transfer in patients with parenchymal infiltration or fibrosis. However, an obstructive defect may be seen in endobronchial disease and a mixed pattern is also possible. Lung function is usually normal in patients with isolated hilar adenopathy or extrapulmonary disease.

### Prognosis and management

The natural history of sarcoidosis is unpredictable and varies from spontaneous remission to inexorable progression and death in a small number (1–5%). Even once remission has been achieved, relapses are common. Worse outcomes are seen in patients of Afro-Caribbean and Asian descent, and those presenting with extrathoracic disease. By contrast, patients presenting with *Löfgren syndrome* usually experience spontaneous resolution without the need for treatment. Systemic treatment is indicated for hypercalcaemia and extrathoracic major organ involvement, particularly neurological, cardiac or ocular disease resistant to topical therapy. **Treatment** of pulmonary sarcoidosis is less clear-cut, as spontaneous resolution is frequently seen, typically within the first 6 months. Moreover, although corticosteroids improve radiographic appearances, this is not consistently reflected in improved lung function tests. Treatment is therefore reserved for patients with troublesome symptoms, deteriorating lung function or radiological evidence of disease progression. Treatment for symptoms impacting on quality of life but not endangering major organs is a contentious issue and requires individual assessment. First-line treatment is with prednisolone (or equivalent) 0.5 mg/kg for 4–6 weeks, gradually tapering to a maintenance dose for at least 12 months. Alternative immunosuppressants, including methotrexate, azathioprine and hydroxychloroquine, have been used in place of, or in addition to, prednisolone. Relapses are common on withdrawal of therapy. Lung transplantation should be considered for suitable patients with stage IV disease and respiratory failure.

### Small-vessel vasculitides

There are several systems for classifying the vasculitides. The nomenclature has moved away from eponymous syndromes in favour of terms describing the underlying disease process. The vasculitides associated with **anti-neutrophil cytoplasmic antibody (ANCA)** may be differentiated from other systemic small-vessel vasculitides by the lack of immune deposition. ANCA-associated vasculitides include granulomatosis with polyangiitis, microscopic polyangiitis and eosinophilic granulomatosis with polyangiitis. Staining for ANCA shows either a diffuse pattern (c-ANCA) with antibodies directed against proteinase 3 (PR3), or a perinuclear pattern (p-ANCA) with antibodies to myeloperoxidase (MPO) (see also pp. 744–755). The respiratory tract and kidneys are frequently involved and the ESR is often markedly
elevated (>100).

**Granulomatosis with polyangiitis**

Granulomatosis with polyangiitis (GPA) typically affects older adults and is more common in Caucasians. The c-ANCA is usually positive with elevated PR3 antibodies. Constitutional symptoms are prominent and may precede the onset of organ-specific symptoms by many months. The ears and upper respiratory tract are frequently affected with bloody nasal discharge, crusting and destruction, sinusitis and otitis media. Evidence of glomerulonephritis should be sought on urinalysis (see p. 729). Respiratory symptoms include cough, dyspnoea and pleuritic chest pain. Diffuse alveolar haemorrhage occurs in up to 45% and haemoptysis can be life-threatening. Thoracic imaging characteristically shows multiple nodules that often cavitate, areas of consolidation and ground-glass opacification (which may be due to pulmonary haemorrhage). Diagnosis should be confirmed with biopsy of the active site but it is sometimes necessary to initiate empirical treatment in acutely unwell patients. Initial immunosuppressant therapy is with a combination of glucocorticoids and cyclophosphamide, rituximab or methotrexate.

**Microscopic polyangiitis**

Microscopic polyangiitis (MPA) is primarily associated with p-ANCA positivity. Presentation and treatment are similar to those of granulomatosis with polyangiitis. It is diagnosed on tissue biopsy, where the absence of granuloma formation differentiates it from GPA.

**Eosinophilic granulomatosis with polyangiitis**

Although ANCA is positive in up to 60% (usually p-ANCA), the presentation and prognosis of eosinophilic granulomatosis with polyangiitis (EGPA) differ from those of the other ANCA-associated vasculitides. The aetiology is uncertain. EGPA classically presents in early adulthood with allergic rhinitis, asthma that is often difficult to control, and peripheral blood eosinophilia (>10%). Systemic vasculitis subsequently develops, sometimes many years later. Involvement of skin (tender subcutaneous nodules, petechiae or purpuric lesions), peripheral nerves (mononeuritis multiplex), heart, kidneys and gastrointestinal tract may occur. The chest X-ray shows migratory patchy opacities that may be accompanied by nodules and pleural effusions. Bronchoalveolar lavage demonstrates an eosinophilia, and biopsy of affected tissues shows eosinophilic infiltration, vasculitis affecting the small arteries, veins and capillaries, and perivascular necrotizing granulomas. EGPA generally responds well to corticosteroids, although additional immunosuppressants are required for severe or refractory disease. Occasionally, EGPA is ‘unmasked’ when oral steroids are withdrawn in patients being treated for asthma.
**Anti-glomerular basement membrane disease (Goodpasture syndrome)**

Anti-glomerular basement membrane (anti-GBM) disease is characterized by the triad of pulmonary haemorrhage, glomerulonephritis, and the presence of circulating antibodies directed against an antigen intrinsic to the basement membrane of both kidney and lung. Respiratory symptoms may precede the onset of glomerulonephritis by weeks or months. The chest X-ray shows transient patchy shadows due to intrapulmonary haemorrhage, although haemoptysis can vary from negligible to life-threatening. The carbon monoxide gas transfer is increased due to the presence of haemoglobin in the alveoli. The extent of renal recovery depends on early detection and treatment. Treatment is with plasmapheresis to remove circulating antibodies and immunosuppression (prednisolone and cyclophosphamide) to prevent further antibody production.

**Diffuse alveolar haemorrhage**

Bleeding into the alveolar spaces occurs in association with certain drugs, infections, autoimmune rheumatic diseases and vasculitis but can also occur without an identifiable precipitating cause. Haemoptysis may be minimal (or even absent), despite significant blood loss into the lungs. It is one of the relatively few causes of raised carbon monoxide gas transfer. Gas exchange is impaired due to the presence of blood in the alveoli and patients may present with severe respiratory failure requiring intensive care support. Treatment is directed at the underlying cause, if known.

**Pulmonary manifestations of autoimmune rheumatic diseases**

**Rheumatoid disease**

The lungs can be affected by rheumatoid arthritis (RA) and also by some of the drugs used in its treatment ([Fig. 24.41](#)); see also pp. 677–678).

- **Pleural disease** may take the form of rheumatoid effusions, which are often unilateral and tend to be chronic. Low glucose content is typical but not specific. Several forms of parenchymal disease can occur in patients with RA. These include fibrosis, rheumatoid nodules, cryptogenic organizing pneumonia, lymphoid interstitial pneumonia and bronchiectasis; other pulmonary problems include pulmonary hypertension. Some patients will have modified presentations because they are already on disease-modifying drugs such as prednisolone or methotrexate for their arthritis.

- **Pulmonary fibrosis** occurring in RA has similar clinical features to the idiopathic form of the disease but often follows a more chronic course (see p. 1113). In patients taking methotrexate, it is often impossible to determine whether fibrosis is due to the drug or the underlying
disease; either way, methotrexate should be substituted for an alternative agent.

- **Rheumatoid nodules** appear on the chest X-ray as single or multiple nodules ranging in size from a few millimetres to a few centimetres. The nodules frequently cavitate. They usually produce no symptoms but can give rise to a pneumothorax or pleural effusion.

- **Obliterative bronchiolitis** causing concentric narrowing of the bronchioles is a rare disorder characterized by progressive breathlessness and irreversible airflow limitation. Response to immunosuppressive therapy is generally poor but macrolide antibiotics may have a role.

- **Cricoarytenoid joint involvement** in RA gives rise to dyspnoea, stridor and hoarseness. Occasionally, severe obstruction necessitates tracheostomy.

- **Caplan syndrome** is due to occupational dust inhalation in the context of the disturbed immunity seen in RA. It occurs particularly in coal worker's pneumoconiosis but can occur in individuals exposed to other dusts, such as silica and asbestos. Typically, the chest X-ray shows rounded nodules 0.5–5.0 cm in diameter but progressive fibrosis can sometimes occur. These lesions may precede the development of arthritis. Rheumatoid factor is positive in the majority of patients.

- **Drugs** used in the treatment of RA can cause pulmonary problems, e.g. pneumonitis with methotrexate, gold and NSAIDs; fibrosis with methotrexate; bronchospasm with NSAIDs; infections with corticosteroids and methotrexate; and reactivation of TB with anti-TNF therapy.

**FIGURE 24.41** Respiratory manifestations of rheumatoid disease. Many drugs affect the lungs; see page 681.
**Systemic lupus erythematosus**

The most common respiratory manifestation of this disease is pleurisy, occurring in up to two-thirds of cases, with or without an effusion (see also p. 693). Effusions are usually small and bilateral. Basal pneumonitis is often present, perhaps as a result of poor movement of the diaphragm, or restriction of chest movements due to pleuritic pain. Pneumonia also occurs because of either infection or the disease process itself. In contrast to RA, diffuse pulmonary fibrosis is uncommon.

**Systemic sclerosis**

Some degree of lung involvement is present in the majority of cases and pulmonary complications are the leading cause of death (see p. 696). Interstitial fibrosis and pulmonary arterial hypertension are the most common pathologies. Patients should be carefully monitored for their development, as damage may be irreversible by the time symptoms have developed. Serial lung function testing can aid early detection. Other complications include bronchiectasis and aspiration pneumonitis secondary to oesophageal dilatation.

**Pulmonary infiltration with eosinophilia**

The common types and characteristics of these diseases are shown in **Box 24.52**. They range from simple pulmonary eosinophilia to the often fatal hypereosinophilic syndrome.

**Simple and prolonged pulmonary eosinophilia**

Simple pulmonary eosinophilia is a relatively mild illness, with a slight fever and cough, and
usually lasts for less than 2 weeks. Occasionally, the disease becomes more prolonged, with a high fever lasting for over a month. There is usually an eosinophilia in the blood and the condition is then called prolonged pulmonary eosinophilia. In both conditions, the chest X-ray shows either localized or diffuse opacities. The simple form is probably due to a transient allergic reaction in the alveoli. Many allergens have been implicated, including *Ascaris lumbricoides*, *Ankylostoma*, *Trichuris*, *Trichinella*, *Taenia* and *Strongyloides*. Drugs such as aspirin, penicillin, nitrofurantoin and sulphonamides have also been implicated. However, often no allergen is identified. The disease is self-limiting and no treatment is required, apart from withdrawing culprit drugs and treating identified infective causes. In the more chronic form, all unnecessary treatment should be withdrawn and corticosteroid therapy is indicated, with resolution of the disease over the ensuing weeks.

**Asthmatic bronchopulmonary eosinophilia**

This is characterized by the presence of asthma, transient fleeting shadows on the chest X-ray, and blood or sputum eosinophilia. By far the most common cause worldwide is allergy to *Aspergillus fumigatus* (see below), although *Candida albicans* and other mycoses may be the inciting allergen in a small number of patients. In many, no allergen can be identified. Whether these cases are intrinsic or driven by an unidentified extrinsic factor is uncertain. Tropical pulmonary eosinophilia is the term reserved for an allergic reaction to microfilaria from *Wuchereria bancrofti*.

**Diseases caused by *Aspergillus fumigatus***

The various types of lung disease caused by *A. fumigatus* are illustrated in *Figure 24.42*.
The spores of *A. fumigatus* (diameter 5 mm) are readily inhaled and are present in the atmosphere throughout the year, though they are at their highest concentration in the late autumn. They can be grown from the sputum in up to 15% of patients with chronic lung disease in whom they do not produce disease. They are a cause of extrinsic asthma in atopic individuals.

Allergic bronchopulmonary aspergillosis (asthmatic pulmonary eosinophilia)
This rare disease is caused by a hypersensitivity reaction when the bronchi are colonized by *Aspergillus*. It can complicate asthma and cystic fibrosis. Proximal bronchiectasis occurs.

**Clinical features.** There are episodes of eosinophilic pneumonia throughout the year, particularly in late autumn and winter. The episodes present with a wheeze, cough, fever and malaise. They are associated with expectoration of firm sputum plugs containing the fungal mycelium, which results in clearing of the pulmonary infiltrates on the chest X-ray. Occasionally, large mucus plugs obliterate the bronchial lumen, causing collapse of the lung.

Left untreated, repeated episodes of eosinophilic pneumonia can result in progressive pulmonary fibrosis that usually affects the upper zones and can give rise to a chest X-ray appearance similar to that produced by TB.

**Investigations.** The peripheral blood eosinophil count is usually raised, and total levels of IgE are usually extremely high, at >1000 ng/mL (both that specific to *Aspergillus* and nonspecific). Skin-prick testing to protein allergens from *A. fumigatus* gives rise to positive immediate skin tests. Sputum may show eosinophils and mycelia. Precipitating antibodies are usually, but not always, found in the serum.

Lung function tests show a decrease in lung volumes and gas transfer in more chronic cases, but there is evidence of reversible airflow limitation in all cases.

**Treatment.** Therapy is with prednisolone 30 mg daily, which causes rapid clearing of the pulmonary infiltrates. Frequent episodes of the disease can be prevented by long-term treatment with prednisolone, but doses of 10–15 mg daily are usually required. Antifungal agents (itraconazole, voriconazole) should be used in patients on high doses of steroids; there is evidence that treatment with itraconazole improves pulmonary function. The asthma component responds to inhaled corticosteroids, although these do not influence the occurrence of pulmonary infiltrates. Omalizumab, a humanized monoclonal antibody against IgE, is being trialled.

**Aspergilloma and invasive aspergillosis**

Aspergilloma is the growth of *A. fumigatus* within previously damaged lung tissue, where it forms a ball of mycelium within lung cavities. Typically, the chest X-ray shows a round lesion with an air ‘halo’ above it. Continuing antigenic stimulation gives rise to large quantities of precipitating antibody in the serum. The aspergilloma itself causes little trouble, though occasionally massive haemoptysis may occur, requiring resection of the area of damaged lung containing the aspergilloma. The antifungal agent voriconazole is the drug of choice, although isavuconazole appears to have fewer adverse effects. Amphotericin is used if patients are intolerant of voriconazole. Invasive aspergillosis is a well-recognized complication of immunosuppression and requires aggressive antifungal therapy.

---

**The hypereosinophilic syndrome**

This disease is characterized by eosinophilic infiltration in various organs, sometimes associated with an eosinophilic arteritis. The heart muscle is particularly involved, but
pulmonary involvement in the form of a pleural effusion or interstitial lung disease occurs in about 40% of cases. Typical features are fever, weight loss, recurrent abdominal pain, persistent non-productive cough and congestive cardiac failure. Corticosteroid treatment may be of value in some cases.

**Drug and radiation-induced respiratory reactions**

Drugs affecting the respiratory system are shown in *Box 24.53*, together with the types of reaction they produce. The mechanisms are varied and include direct toxicity (e.g. bleomycin), immune complex formation with arteritis, hypersensitivity (involving both T-cell and IgE mechanisms) and autoimmunity. TB reactivation is seen with immunosuppressive drugs.

### Box 24.53

**Some drug-induced respiratory reactions**

**Bronchospasm**

- Penicillins, cephalosporins
- Sulphonamides
- Aspirin/NSAIDs
- Monoclonal antibodies, e.g. infliximab
- Iodine-containing contrast media
- β-Adrenoceptor-blocking drugs (e.g. propranolol)
- Non-depolarizing muscle relaxants
- Intravenous thiamine
- Adenosine

**Interstitial lung disease and/or fibrosis**

- Amiodarone
- Anakinra (IL-1 receptor antagonist)
- Nitrofurantoin
- Paraquat
- Continuous oxygen
- Cytotoxic agents (many, particularly busulfan, CCNU, bleomycin, methotrexate)

**Pulmonary eosinophilia**

- Antibiotics:
  - Penicillin
  - Tetracycline
- Sulphonamides, e.g. sulfasalazine
- NSAIDs
- Cytotoxic agents

**Acute lung injury**
- (Paraquat – a weedkiller)

**Pulmonary hypertension**
- Fenfluramine, dexfenfluramine, phentermine

**SLE-like syndrome including pulmonary infiltrates, effusions and fibrosis**
- Hydralazine
- Procainamide
- Isoniazid
- Phenytoin
- ACE inhibitors
- Monoclonal antibodies

**Reactivation of tuberculosis**
- Immunosuppressant drugs, e.g. steroids
- Biological agents, e.g. tumour necrosis factor blockers

ACE, angiotensin-converting enzyme; CCNU, chloroethyl-cyclohexyl-nitrosourea (lomustine); IL-1, interleukin 1; NSAIDs, non-steroidal anti-inflammatory drugs; SLE, systemic lupus erythematosus.

Pulmonary infiltrates with fibrosis may result from a number of cytotoxic drugs used in the treatment of cancer. The most common cause of these reactions is bleomycin. The pulmonary damage is dose-related, occurring when the total dosage is >450 mg, but will regress in some cases if the drug is stopped. The most sensitive test is a decrease in carbon monoxide gas transfer, and therefore gas transfer should be measured repeatedly during treatment with the drug. The use of corticosteroids may help resolution. Anaphylaxis with bronchospasm can occur with many drugs. The list is not exhaustive; for example, over 20 different drugs are known to produce a systemic lupus erythematosus-like syndrome, sometimes complicated by pulmonary infiltrates and fibrosis. Paraquat ingestion causes severe pulmonary oedema and death, and pulmonary fibrosis develops in many of the few who survive.

**Irradiation** of the lung during radiotherapy can cause a radiation pneumonitis. Patients complain of breathlessness and a dry cough. Radiation pneumonitis results in a restrictive lung defect. Corticosteroids should be given in the acute stage.

**Further reading**
Exposure to dusts, gases, vapours and fumes at work can cause several different types of lung disease:

- acute bronchitis and even pulmonary oedema from irritants such as sulphur dioxide, chlorine, ammonia or the oxides of nitrogen
- pulmonary fibrosis due to mineral dust
- occupational asthma (see Box 24.22) – now the most common industrial lung disease in the developed world
- hypersensitivity pneumonitis (see Box 24.49)
- bronchial carcinoma due to industrial agents (e.g. asbestos, polycyclic hydrocarbons, radon in mines).

The degree of fibrosis that follows inhalation of mineral dust varies. While iron (siderosis), barium (baritosis) and tin (stannosis) lead to dramatic, dense, nodular shadowing on the chest X-ray, their effect on lung function and symptoms is minimal. In contrast, exposure to silica or asbestos leads to extensive fibrosis and disability. Coal dust has an intermediate fibrogenic effect and used to account for 90% of all compensated industrial lung diseases in the UK. The term ‘pneumoconiosis’ means the accumulation of dust in the lungs and the reaction of the tissue to its presence. The term is not wide enough to encompass all occupational lung disease and is now generally used only in relation to coal dust and its effects on the lung.
Coal-worker's pneumoconiosis

The disease is caused by dust particles approximately 2–5 µm in diameter that are retained in the small airways and alveoli of the lung. The incidence of the disease is related to total dust exposure, which is highest at the coal face, particularly if ventilation and dust suppression are poor. Improved ventilation and working conditions have reduced the risk of this disease.

Two very different syndromes result from the inhalation of coal.

Simple pneumoconiosis

This simply reflects the deposition of coal dust in the lung. It produces fine micronodular shadowing on the chest X-ray and is by far the most common type of pneumoconiosis. It is graded on the chest X-ray appearance according to standard categories set by the International Labour Office (see below). Considerable dispute remains about the effects of simple pneumoconiosis on respiratory function and symptoms. In many cases, the symptoms are due to COPD related to cigarette smoking, but this is not always the case. Changes to UK workers' compensation legislation means that coal miners who develop COPD are compensated for their disability, regardless of their chest X-ray appearance.

*Categories of simple pneumoconiosis* are as follows:

1. Small round opacities definitely present but few in number.
2. Small round opacities numerous but normal lung markings still visible.
3. Small round opacities very numerous and normal lung markings partly or totally obscured.

Simple pneumoconiosis can progress to the development of progressive massive fibrosis (see below). The latter virtually never occurs on a background of category 1 simple pneumoconiosis but does arise in about 7% of those with category 2 and in 30% of those with category 3 disease. Miners with category 1 pneumoconiosis are unlikely to receive compensation unless they also have evidence of COPD. Those with more extensive radiographic changes are compensated solely on the basis of their X-ray appearances.

Progressive massive fibrosis

In progressive massive fibrosis (PMF), patients develop round fibrotic masses several centimetres in diameter, almost invariably situated in the upper lobes and sometimes having necrotic central cavities. The pathogenesis of PMF is still not understood, though it seems clear that some fibrogenic promoting factor is present in individuals developing the disease, leading to the formation of immune complexes, analogous to the development of large fibrotic nodules in coal miners with rheumatoid arthritis (Caplan syndrome). Rheumatoid factor and anti-nuclear antibodies are both often present in the serum of patients with PMF, and also in those suffering from asbestosis or silicosis. Pathologically, there is apical destruction and disruption of the lung, resulting in emphysema and airway damage. Lung function tests show a mixed restrictive and obstructive ventilatory defect with loss of lung volume, irreversible airflow limitation and reduced gas transfer.
The patient with PMF suffers considerable effort dyspnoea, usually with a cough. The sputum may be black. The disease can progress (or even develop) after exposure to coal dust has ceased and may lead to respiratory failure.

**Silicosis**

This disease is uncommon, though it may still be encountered in stonemasons, sand-blasters, pottery and ceramic workers, and foundry workers involved in fettling (removing sand from metal castings made in sand-filled moulds). Silicosis is caused by the inhalation of silica (silicon dioxide). This dust is highly fibrogenic. For example, a coal miner can remain healthy with 30 g of coal dust in his lungs but 3 g of silica is sufficient to kill. Silica seems particularly toxic to alveolar macrophages and readily initiates fibrogenesis. The chest X-ray appearances and clinical features of silicosis are similar to those of PMF, but distinctive thin streaks of calcification may be seen around the hilar lymph nodes (‘eggshell’ calcification).

**Diseases caused by asbestos**

Asbestos is a mixture of silicates of iron, magnesium, nickel, cadmium and aluminium, and has the unique property of occurring naturally as a fibre. It is remarkably resistant to heat, acid and alkali, and has been widely used for roofing, insulation and fireproofing. Asbestos has been mined in southern Africa, Canada, Australia and Eastern Europe. Several different types of asbestos are recognized: about 90% of asbestos is chrysotile, 6% crocidolite and 4% amosite.

- **Chrysotile (white asbestos)** is the softest asbestos fibre. Each fibre is often as long as 2 cm but only a few microns thick. It is less fibrogenic than crocidolite.

- **Crocidolite (blue asbestos)** is particularly resistant to chemical destruction and exists in straight fibres up to 50 mm in length and 1–2 µm in width. Crocidolite is the type of asbestos most likely to produce asbestosis and mesothelioma. This may be due to the fact that it is readily trapped in the lung. Its long, thin shape means that it can be inhaled, but subsequent rotation against the long axis of the smaller airways, particularly in turbulent airflow during expiration, causes the fibres to impact. Crocidolite is also particularly resistant to macrophage and neutrophil enzymatic destruction.

  Exposure to asbestos occurred particularly in shipbuilding yards and in power stations, but it was used so widely that low levels of exposure were very common. Up to 50% of city dwellers have asbestos bodies (asbestos fibres covered in protein secretions) in their lungs at postmortem. Regulations in the UK prohibit the use of crocidolite and severely restrict the use of chrysotile. Careful dust control measures are enforced, which should eventually abolish the problem. Workers continue to be exposed to blue asbestos in the course of demolition or in the replacement of insulation, and it should be remembered that there is a considerable time lag between exposure and development of disease, particularly mesothelioma (20–40 years).

  The risk of primary lung cancer (usually adenocarcinoma) is increased in people exposed to asbestos, even in non-smokers. This risk is about 5–7-fold greater in those who have
parenchymal asbestosis and about 1.5-fold in those with pleural plaques without parenchymal fibrosis. A synergistic relationship exists between asbestosis and cigarette smoking, with the risk of bronchial carcinoma multiplied about 5-fold above the risk attributable to smoking alone.

Diseases caused by asbestos are summarized in Box 24.54. Bilateral diffuse pleural thickening, asbestosis, mesothelioma and asbestos-related carcinoma of the bronchus are all eligible for industrial injuries benefit in the UK.

Asbestosis
Asbestosis is defined as fibrosis of the lungs caused by asbestos dust, which may or may not be associated with fibrosis of the parietal or visceral layers of the pleura. It is a progressive disease characterized by breathlessness and accompanied by finger clubbing and bilateral basal end-inspiratory crackles. Minor degrees of fibrosis that are not seen on chest X-ray are often revealed on HRCT scan. No treatment is known to alter the progress of the disease, though corticosteroids are often prescribed.

Mesothelioma

The number of cases of mesothelioma has increased progressively since the mid-1980s and has now reached 2100 deaths/year in the UK, which has the highest per capita death rate from this condition. Rates of mesothelioma in the UK are expected to peak around 2020 at about 2300/year. The most common presentation of mesothelioma is a pleural effusion, typically with persistent chest wall pain, which should raise the index of suspicion even if the initial pleural fluid or biopsy samples are non-diagnostic. Video-assisted thoracoscopic pleural biopsy is often needed to obtain sufficient tissue for diagnosis. Clinical trials of chemotherapy, sometimes combined with surgery, are under way but the outlook for most patients remains very limited.

Byssinosis

This disease occurs worldwide but is declining rapidly in areas where the number of people employed in cotton mills is falling. Typically, symptoms start on the first day back at work after a break (Monday sickness), with improvement as the week progresses. Tightness in the chest, cough and breathlessness occur within the first hour in dusty areas of the mill, particularly in the blowing and carding rooms where raw cotton is cleaned and the fibres are straightened.

The exact nature of the disease and its aetiology remain disputed. Pure cotton does not cause the disease, and cotton dust has some effect on airflow limitation in all those exposed. Individuals with asthma are particularly badly affected by exposure to cotton dust. The most likely aetiology is endotoxins from bacteria present in the raw cotton causing constriction of the airways of the lung. There are no changes on the chest X-ray and there is considerable dispute as to whether the progressive airflow limitation seen in some patients with the disease is due to cotton dust or to other factors such as cigarette smoking or coexistent asthma.

Berylliosis

Beryllium–copper alloy has a high tensile strength and is resistant to metal fatigue, high temperature and corrosion. It is used in the aerospace industry, atomic reactors and many electrical devices.

When beryllium is inhaled, it can cause a systemic illness with a clinical picture similar to sarcoidosis. Clinically, there is progressive dyspnoea with pulmonary fibrosis. However,
strict control of levels in the working atmosphere has made this disease a rarity.

Further reading

Lung Cysts
These can be congenital, bronchogenic or the result of a sequestrated pulmonary segment. Hydatid disease causes fluid-filled cysts. Lung abscesses are thin-walled cysts, which are found particularly in staphylococcal pneumonia, tuberculous cavities, septic pulmonary infarction, primary bronchogenic carcinoma, cavitating metastatic neoplasm, or paragonimiasis caused by the lung fluke Paragonimus westermani.

Tumours of the Respiratory Tract
Malignant tumours

Bronchial carcinoma
Bronchial carcinoma is the most common malignant tumour worldwide, with around 1.4 million deaths annually. It is the third most common cause of death in the UK after ischaemic heart disease and cerebrovascular disease, and is now the most common cause of cancer-related death in both men and women. Rates are declining in men but still increasing overall, reflecting the increasing incidence in women. The ratio in men to women is now 1.2 : 1.

Cigarette smoking (including passive smoke exposure) accounts for >90% of lung cancer. There remains a higher incidence of bronchial carcinoma in urban compared with rural areas, even when allowance is made for cigarette smoking. Other aetiological factors include:

• Environmental: radon exposure, asbestos, polycyclic aromatic hydrocarbons and ionizing radiation; occupational exposure to arsenic, chromium, nickel, petroleum products and oils.

• Host factors: pre-existing lung disease such as pulmonary fibrosis; HIV infection; genetic factors.

Legislative control over smoking in public places in many parts of the world has been introduced to reduce ill health related to cigarette smoke.

Pathophysiology
Historically, lung cancers have been broadly divided into small-cell carcinoma and non-small-cell carcinoma, based on the histological appearances of the cells seen within the tumour. This distinction is necessary with respect to the behaviour of the tumour, providing prognostic information and determining best treatment. Non-small-cell carcinoma is further divided into a
number of cell types (adenocarcinoma, squamous cell carcinoma, large-cell carcinoma, large-cell neuroendocrine (Box 24.55). A number of molecular characteristics have been described more recently (largely affecting adenocarcinoma non-small-cell types), which confer potential prognostic benefit and may result in the ability to deliver a more personalized therapy with targeted agents. The most common of these are activating mutations within epidermal growth factor receptor (EGFR), most commonly encountered in non-smokers, females and those of Asian origin, and the presence of anaplastic lymphoma kinase (ALK) fusion oncogene, again more commonly found in non-/ex-smokers and younger patients.

Clinical features

The presentation and clinical course vary between the different cell types (Box 24.55). Symptoms and signs may be different, depending on the extent and site of disease. Common presenting features can be divided into those caused by direct/local tumour effects,
metastatic spread and non-metastatic extrapulmonary features.

Local effects

- **Cough.** This is the most commonly encountered symptom in lung cancer. Because evidence suggests this symptom is neglected by both patients and healthcare professionals, campaigns in the UK have highlighted the ‘3-week cough’ as a symptom that merits a chest X-ray.

- **Breathlessness.** Central tumours occlude large airways, resulting in lung collapse and breathlessness on exertion. Many patients with lung cancer have coexistent COPD, which is also a cause of breathlessness.

- **Haemoptysis.** Fresh or old blood is coughed up due to the tumour bleeding into an airway.

- **Chest pain.** Peripheral tumours invade the chest wall or pleura (both well innervated), resulting in sharp pleuritic pain. Large-volume mediastinal nodal disease often results in a characteristic dull central chest ache.

- **Wheeze.** This is monophonic when due to partial obstruction of an airway by tumour.

- **Hoarse voice.** Mediastinal nodal or direct tumour invasion of the mediastinum results in compression of the left recurrent laryngeal nerve.

- **Nerve compression.** Pancoast tumours in the apex of the lung invade the brachial plexus, causing C8/T1 palsy with small muscle wasting in the hand and weakness, as well as pain, radiating down the arm. An associated Horner syndrome due to compression of the sympathetic chain, with classic features of miosis, ptosis and anhidrosis, also occurs.

- **Recurrent infections.** Tumour causing partial obstruction of an airway results in post-obstructive pneumonia.

- **Direct invasion of the phrenic nerve.** Bronchial carcinoma invading the phrenic nerve causes paralysis of the ipsilateral hemidiaphragm. It can involve the oesophagus, producing progressive dysphagia, and the pericardium, resulting in pericardial effusion and malignant dysrhythmias.

- **Superior vena caval obstruction.** See pages 605–606.

- **Tracheal tumours.** These present with progressive dyspnoea and stridor. Flow–volume curves show dramatic reductions in inspiratory flow (see *Fig. 24.7C*).

Metastatic spread

Bronchial carcinoma commonly spreads to mediastinal, cervical and even axillary or intra-abdominal nodes. In addition, the liver, adrenal glands, bones, brain and skin are frequent sites for metastases:

- **Liver.** Common symptoms are anorexia, nausea and weight loss. Right upper quadrant pain radiating across the abdomen is associated with liver capsular pain.

- **Bone.** Bony pain and pathological fractures occur as a result of tumour spread. If the spine is involved, there is a risk of spinal cord compression, which requires urgent treatment.
• **Adrenal glands.** Metastases to the adrenals do not usually result in adrenal insufficiency and are usually asymptomatic.

• **Brain.** Metastases present as space-occupying lesions with subsequent mass effect and signs of raised intracranial pressure. Less common presentations include carcinomatous meningitis with cranial nerve defects, headache and confusion.

• **Malignant pleural effusion.** This presents with breathlessness and is commonly associated with pleuritic pain.

Non-metastatic extrapulmonary manifestations of bronchial carcinoma

(Box 24.56.) Minor haematological extrapulmonary manifestations of lung cancer, such as normocytic anaemia and thrombocytosis, are reasonably common. Apart from finger clubbing and hypertrophic pulmonary osteoarthropathy (HPOA), most other non-metastatic complications are relatively rare. Approximately 10% of small-cell tumours produce ectopic hormones, giving rise to paraneoplastic syndromes (see Box 17.8).

**Investigations**

Investigations are necessary to:
• stage the extent of disease
• make a tissue diagnosis (differentiate small-cell from non-small-cell lung cancer (NSCLC), as well as to detail the cell type in NSCLC – increasingly relevant with newer targeted biological agents)
• assess fitness to undergo treatment.

**Staging and diagnosis**

**Chest X-ray**

Plain chest radiographs may show obvious evidence of lung cancer or non-specific appearances *(Box 24.57)*. In some cases, the initial radiograph is normal, either because the lesion is small, or because disease is confined to central structures.

**Box 24.57**

<td>Endoluminal tumour causes complete collapse of a lung and associated mediastinal shift, or collapse of a lobe or segment, resulting in volume loss on the affected side with raised hemidiaphragm/deviated trachea</td>
<td>Carcinoma spreads through the lymphatic channels of the lung to give rise to lymphangitis carcinomatosa; in bronchial carcinoma this is usually unilateral and associated with striking dyspnoea. Bilateral lymphangitis should prompt investigation for a primary site other then lung, such as breast, stomach or colon</td>
</tr>
</tbody>
</table>

| Normal | A normal film does not rule out an underlying tumour. A minority of tumours are confined to the central airways and mediastinum without obvious change on the plain chest X-ray. Although investigation of isolated haemoptysis with a normal chest X-ray is often negative, a normal chest X-ray should not discourage further investigation, especially in smokers over the age of 40 years |

Computed tomography
CT indicates the extent of disease. Imaging should include the liver and adrenal glands, which
are common sites for metastases. The International Association for the Study of Lung Cancer (IASLC) has devised the most widely used staging definitions, which are based on CT imaging of tumour size (T), nodal involvement (N) and metastases (M), along with prognostic data. These have been recently updated based on an extensive review of survival in over 80,000 patients (Box 24.58).

Using CT criteria, lymph nodes that are <1 cm in diameter are not classed as being enlarged, yet they can still contain malignant cells. With increasing size, the positive predictive value of CT in detecting malignant nodes increases; however, it cannot be assumed that enlarged nodes are definitely malignant and further staging tests should be performed if there are no distant metastases and the primary tumour is thought to be eligible for curative treatment. These tests would include direct sampling of affected nodes and PET to assess distant spread of cancer.

**Positron emission tomography–computed tomography**

This is the investigation of choice for characterizing the extent of mediastinal nodal involvement and highlighting distant metastases either not visualized or indeterminate on CT (see p. 1070). Most commonly, PET images are combined with CT for best correlation. Negative predictive value is high but a positive node on PET–CT should prompt sampling for
confirmation of the presence of malignant cells, as the positive predictive value is relatively low.

**Other imaging modalities**

MRI is not useful for the diagnosis of primary lung tumours other than in Pancoast tumours with nerve invasion or in the assessment of chest wall involvement prior to surgery.

**Fibreoptic bronchoscopy**

This technique is used to define the bronchial anatomy and to obtain biopsy and cytological specimens *(Fig. 24.43)*. If the carcinoma involves the first 2 cm of either main bronchus, the tumour is inoperable, as there would be insufficient resection margins for pneumonectomy. Widening and loss of the sharp angle of the carina indicate the presence of enlarged subcarinal lymph nodes, either malignant or reactive. These can be biopsied ‘blind’ by passage of a needle through the bronchial wall.

![FIGURE 24.43](image) Bronchoscopic view of a bronchial carcinoma obstructing a large bronchus.

**Percutaneous aspiration and biopsy**

Peripheral lung lesions cannot be seen by fibreoptic bronchoscopy. Samples are obtained by aspiration or biopsy through the chest wall under CT guidance. The most common complication is pneumothorax (around 10% of patients), especially if the mass is deep in the lung, as opposed to lesions next to the parietal pleura. Mild haemoptysis occurs in <5%. Implantation metastases do not occur.
Endobronchial ultrasound
A fibreoptic scope with ultrasound probe is used in the staging of lung cancer, to visualize the majority of mediastinal nodes (not all of which are accessible surgically via mediastinoscopy or mediastinotomy) and then allow fine-needle aspiration.

Endoscopic ultrasound via the oesophagus can also be used with the added advantage of enabling sampling of the left adrenal gland, and posterior and inferior mediastinal lymph node groups. Figure 24.44 shows the lymph node areas that are commonly involved and sampled in the staging investigations.

Ultrasound-guided supraclavicular node sampling
In selected cases, where staging suggests that N3 nodes are involved, even where supraclavicular nodes are not palpable, ultrasound fine-needle aspiration can be diagnostic.

Video-assisted thoracoscopic surgery
Large effusions with evidence of pleural thickening are amenable to biopsy and drainage via minimally invasive surgery. This technique is particularly useful, as pleurodesis to prevent recurrence of effusion can be performed at the same time.

Other investigations
These include a full blood count for the detection of anaemia, and biochemistry for liver involvement, hypercalcaemia and hyponatraemia.
Assessing fitness for treatment
Before radical treatment, an assessment of fitness for treatment should be carried out. This work-up should include full lung function testing with transfer capacity, and if cardiovascular disease is present, cardiopulmonary exercise testing, stress echo or, occasionally, preoperative angiography.

Management
Treatment of lung cancer (see also p. 630) involves several different modalities and should be planned by a multidisciplinary team. Unfortunately, the majority of patients have incurable disease at presentation, or have significant co-morbidities that preclude radical treatment. Box 24.59 shows the mean survival based on tumour stage for NSCLC and squamous cell carcinoma: only 25–30% patients are still alive 1 year after diagnosis and only 6–8% after 5 years.

Surgery
Surgery is performed in early-stage NSCLC (stages I, II and selected IIIA) with curative intent. Many patients with stage III disease are treated with chemoradiation with a view to
‘downstaging’ disease and rendering it amenable to surgical resection. Where surgical staging of resected lung cancer demonstrates nodal involvement, patients require adjuvant chemotherapy.

**Radiation therapy for cure**

In selected patients with adequate lung function and early-stage NSCLC, high-dose radiotherapy or continuous hyperfractionated accelerated regimens (CHART) provide a good alternative to surgical resection with almost comparable outcomes. It is the treatment of choice if surgery is not possible due to co-morbidities. Radiation pneumonitis (defined as an acute infiltrate precisely confined to the radiation area and occurring within 3 months of radiotherapy) develops in 10–15% of cases. Radiation fibrosis, a fibrotic change occurring within a year or so of radiotherapy and not precisely confined to the radiation area, occurs to some degree in all cases. These complications usually cause no problems.

In patients with significant cardiovascular or respiratory co-morbidities and early stage I disease, stereotactic radiotherapy can be used. In the same patient group, radiofrequency ablation is used – an image-guided technique using heat to destroy small peripheral tumours.

**Radiation treatment for symptoms**

Radiation therapy has a role in palliation of symptoms from lung cancer. Bone and chest wall pain from metastases or direct invasion, haemoptysis, occluded bronchi and superior vena cava obstruction respond favourably to irradiation in the short term. Radiotherapy is also given at the end of chemotherapy to consolidate treatment in small-cell lung cancer.

**Chemotherapy and targeted therapy**

This is discussed on page 630. Adjuvant chemotherapy with radiotherapy improves response rate and extends median survival in non-small-cell cancer.

Newer targeted agents (p. 630) against epidermal growth factor receptors, tyrosine kinases and anaplastic lymphoma kinase (ALK) in NSCLC (in particular, adenocarcinoma) offer better outcomes in selected patients and can also be used where intravenous chemotherapy offers unacceptable toxicity or as second-line chemotherapy.

**Laser therapy, endobronchial irradiation and tracheobronchial stents**

These techniques are used in the palliation of inoperable lung cancer in selected patients with tracheobronchial narrowing from intraluminal tumour or extrinsic compression causing disabling breathlessness, intractable cough and complications, including infection, haemoptysis and respiratory failure.

A **neodymium-Yag (Nd-Yag) laser** passed through a fibreoptic bronchoscope can be used to vaporize inoperable fungating intraluminal carcinoma involving short segments of trachea or main bronchus. Benign tumours, strictures and vascular lesions can also be treated effectively with immediate relief of symptoms.

**Endobronchial irradiation (brachytherapy)** is useful for the treatment of both intraluminal
tumour and malignant extrinsic compression. A radioactive source is afterloaded into a catheter placed adjacent to the carcinoma under fibroptic bronchoscope control. Radiation dose falls rapidly with distance from the source, minimizing damage to adjacent normal tissue. Reduction in endoscopically assessed tumour size occurs in 70–95% of cases.

**Tracheobronchial stents** made of silicone or in the form of expandable metal springs are available for insertion into strictures caused by tumour, external compression, or weakening and collapse of the tracheobronchial wall.

### Palliative care

Patients dying of cancer of the lung need attention to their overall wellbeing (see p. 31). Much can be done to make the individual's remaining life symptom-free and as active as possible. Furthermore, compared with patients who have fatal cancers at other sites, patients with lung cancer tend to remain relatively independent and pain-free, but they die more rapidly once they reach the terminal phase. Patient and relatives both require psychological and emotional support, a task that should be shared between the respiratory teams, the primary care team and the nurses, social workers, hospital chaplains and doctors who make up the palliative care team.

### Secondary tumours

Metastases in the lung are very common and usually present as round shadows (1.5–3.0 cm in diameter). They are usually detected on chest X-ray in patients already diagnosed as having carcinoma, but can be the first presentation. Typical sites for the primary tumour include the kidney, prostate, breast, bone, gastrointestinal tract, cervix or ovary.

Metastases nearly always develop in the parenchyma and are often relatively asymptomatic, even when the chest X-ray shows extensive pulmonary metastases. Rarely, metastases develop within the bronchi, when they often present with haemoptysis.

Carcinoma, particularly of the stomach, pancreas and breast, can involve mediastinal glands and spread along the lymphatics of both lungs (lymphangitis carcinomatosis), leading to progressive and severe breathlessness. On the chest X-ray, bilateral lymphadenopathy is seen, together with streaky basal shadowing fanning out over both lung fields.

Occasionally, a pulmonary metastasis is detected as a **solitary round shadow** on chest X-ray in an asymptomatic patient. The most common primary tumour to do this is a renal cell carcinoma.

The differential diagnosis includes:

- primary bronchial carcinoma
- tuberculoma
- benign tumour of the lung
- hydatid cyst.

Single pulmonary metastases can be removed surgically but, as CT scans usually show the
presence of small metastases undetected on chest X-ray, detailed imaging, including PET scanning and assessment, is essential before undertaking surgery.

Investigation of solitary pulmonary nodules

With the increased use of CT scanning for other conditions, there has been greater incidental detection of asymptomatic, small, sub-centimetre nodules. The majority of these are benign; however, radiological follow-up should be arranged at intervals, determined by the size of the nodule in millimetres and the risk of developing malignancy (i.e. high risk associated with either current or previous smoking history, occupational exposure to carcinogens or family history of lung cancer; low risk if the patient never smoked and there was no occupational exposure to potential carcinogens or relevant family history).

Screening for lung cancer

A large trial carried out in the USA has demonstrated a 20% mortality benefit from low-dose helical CT screening for lung cancer in high-risk populations of smokers/ex-smokers between the ages of 55 and 74. A similar trial is under way in Europe. It is likely that CT screening will be employed in the future.

Benign tumours

Pulmonary hamartoma

This is the most common benign tumour of the lung and is usually seen on the X-ray as a very well-defined round lesion 1–2 cm in diameter in the periphery of the lung. Growth is extremely slow but the tumour can reach several centimetres in diameter. Rarely, it arises from a major bronchus and causes obstruction.

Bronchial carcinoid

This rare tumour resembles an intestinal carcinoid tumour and is locally invasive, eventually spreading to mediastinal lymph nodes and finally to distant organs. It is a highly vascular tumour that projects into the lumen of a major bronchus, causing recurrent haemoptysis. It grows slowly and eventually blocks the bronchus, leading to lobar collapse. As foregut derivatives, bronchial carcinoids produce adrenocorticotropic hormone (ACTH) but do not usually produce the 5-hydroxytryptamine that is seen in midgut or hindgut carcinoid tumours. Staging of carcinoid tumours is the same as for NSCLC.

Cylindroma, chondroma and lipoma

These are extremely rare tumours that grow in the bronchus or trachea, causing obstruction.
Tracheal tumours

Benign tumours include squamous papilloma, leiomyoma, haemangiomas and tumours of neurogenic origin.

Further reading

Disorders of the Chest Wall and Pleura

Trauma

Trauma to the thoracic wall can cause penetrating wounds and lead to pneumothorax or haemothorax.

Rib fractures

Rib fractures are caused by trauma or coughing (particularly in the elderly), and can occur in patients with osteoporosis. Pathological rib fractures are due to metastatic spread (most often from carcinoma of the bronchus, breast, kidney, prostate or thyroid). Ribs can also become involved by a mesothelioma. Fractures may not be readily visible on a postero-anterior chest X-ray, so lateral X-rays and oblique views may be necessary.

Pain prevents adequate chest expansion and coughing, and this can lead to pneumonia.

*Treatment* is with adequate oral analgesia, by local infiltration or an intercostal nerve block.

Two fractures in one rib can lead to a flail segment with paradoxical movement: that is, part
of the chest wall moves inwards during inspiration. This can produce inefficient ventilation and may require intermittent positive-pressure ventilation, especially if several ribs are similarly affected.

Rupture of the trachea or a major bronchus
Rupture of the trachea or a major bronchus can occur during deceleration injuries, leading to pneumothorax, surgical emphysema, pneumomediastinum and haemoptysis. Surgical emphysema is caused by air leaking into the subcutaneous connective tissue; this can also occur after the insertion of an intercostal drainage tube. A pneumomediastinum occurs when air leaks from the lung inside the parietal pleura and extends along the bronchial walls.

Rupture of the oesophagus
Rupture of the oesophagus (see p. 374) leads to mediastinitis, usually with mixed bacterial infection. This is a serious complication of external injury, endoscopic procedures, bougienage or necrotic carcinoma, and requires antibacterial chemotherapy.

Lung contusion
This causes widespread fluffy shadows on the chest X-ray owing to intrapulmonary haemorrhage. It may give rise to acute respiratory distress syndrome (see pp. 1167–1169).

Kyphoscoliosis
Kyphoscoliosis may be congenital, due to disease of the vertebrae such as TB or osteomalacia, or due to neuromuscular disease such as Friedreich's ataxia or poliomyelitis. The respiratory effects of severe kyphoscoliosis are often more pronounced than might be expected and respiratory failure and death often occur in the fourth or fifth decade. The abnormality should be corrected at an early stage if possible. Positive airway pressure ventilation delivered through a tightly fitting nasal mask is the treatment of choice for respiratory failure (see pp. 1165–1166).

Ankylosing spondylitis
Limitation of chest wall movement is often well compensated by diaphragmatic movement, and so the respiratory effects of this disease are relatively mild (see also p. 684). It is occasionally associated with upper lobe fibrosis.

Pectus excavatum and carinatum
Pectus excavatum causes few problems other than embarrassment about the deep vertical furrow in the chest, which can be corrected surgically. The heart is seen to lie well to the left on the chest X-ray. Pectus carinatum (pigeon chest) is often the result of rickets but is rarely
seen in the West. No treatment is required.

## Pleurisy

Pleurisy is pain arising from any disease of the pleura. The localized inflammation produces sharp localized pain, which is worse on deep inspiration, coughing and occasionally on twisting and bending movements. Common causes are pneumonia, pulmonary infarct and carcinoma. Rarer causes include rheumatoid arthritis and systemic lupus erythematosus.

**Epidemic myalgia (Bornholm disease)** is due to infection by Coxsackie B virus. This illness is common in young adults in the late summer and autumn, and is characterized by an upper respiratory tract illness followed by pleuritic pain in the chest and upper abdomen with tender muscles. The chest X-ray remains normal and the illness clears within a week.

## Mesothelioma

Mesothelioma (see also p. 1126) is usually associated with asbestos exposure. It is described with other pleural diseases caused by asbestosis in Box 24.54.

## Pleural effusion

A pleural effusion is an excessive accumulation of fluid in the pleural space. It can be detected on X-ray when ≥300 mL of fluid is present, and clinically, when ≥500 mL is present. The chest X-ray appearances (Fig. 24.45) range from obliteration of the costophrenic angle to dense homogeneous shadows occupying part or all of the hemithorax. Fluid below the lung (a subpulmonary effusion) can simulate a raised hemidiaphragm. Fluid in the fissures may resemble an intrapulmonary mass. The physical signs are shown in Box 24.57.
Diagnosis

This is by pleural aspiration (see p. 1073), usually done with ultrasound guidance. The fluid that accumulates may be a transudate or an exudate (Box 24.60).

Box 24.60

Light's criteria to diagnose an exudative effusion

- Pleural fluid protein: serum protein >0.5
- Pleural fluid LDH : serum LDH >0.6
- Pleural fluid LDH >²/₃ upper limit of normal for serum (105–333 IU/L)
  LDH, lactate dehydrogenase.

Transudates

Effusions that are transudates can be bilateral but are often larger on the right side. The protein content is <30 g/L, the lactate dehydrogenase (LDH) is <200 IU/L and the fluid to serum LDH ratio is <0.6. Causes include:

- heart failure
- hypoproteinaemia (e.g. nephrotic syndrome)
- constrictive pericarditis
• hypothyroidism
• ovarian tumours producing right-sided pleural effusion – Meigs syndrome.

**Exudates**
The protein content of exudates is >30 g/L and the LDH is >200 IU/L. Causes include:
• bacterial pneumonia (common)
• carcinoma of the bronchus and pulmonary infarction – fluid may be blood-stained (common)
• TB
• autoimmune rheumatic diseases
• post-myocardial infarction syndrome (rare)
• acute pancreatitis (high amylase content) (rare)
• mesothelioma (rare)
• sarcoidosis (very rare)
• yellow-nail syndrome (effusion due to lymphoedema) (very rare)
• familial Mediterranean fever (rare).

Pleural biopsy (see p. 1073) may be necessary if the diagnosis has not been established by simple aspiration.

**Management** is of the underlying condition unless the fluid is purulent (empyema), in which case drainage is mandatory.

---

**Management of malignant pleural effusions**
Malignant pleural effusions that reaccumulate and are symptomatic can be aspirated to dryness followed by the instillation of a sclerosing agent such as tetracycline or talc. Effusions should be drained slowly since rapid shift of the mediastinum causes severe pain and occasionally shock. This treatment produces only temporary relief.

---

**Chylothorax**
This is due to the accumulation of lymph in the pleural space, usually resulting from leakage from the thoracic duct following trauma or infiltration by carcinoma.

---

**Empyema**
This is the presence of pus in the pleural space and can be a complication of pneumonia (see p. 1104).

---

**Pneumothorax**
‘Pneumothorax’ means air in the pleural space. It may be spontaneous or occur as a result of trauma to the chest. Spontaneous pneumothorax is most common in young males, the male-to-female ratio being 6:1. It is caused by the rupture of a pleural bleb, usually apical, and is thought to be due to congenital defects in the connective tissue of the alveolar walls. Both lungs are affected with equal frequency. Often these patients are tall and thin. In patients over 40 years of age, the usual cause is underlying COPD. Rarer causes include bronchial asthma, carcinoma, breakdown of a lung abscess leading to bronchopleural fistula, and severe pulmonary fibrosis with cyst formation.

Pneumothorax may be localized if the visceral pleura has previously become adherent to the parietal pleura, or generalized if there are no pleural adhesions. Normally, the pressure in the pleural space is negative but this is lost once a communication is made with atmospheric pressure; the elastic recoil pressure of the lung then causes it to deflate partially. If the communication between the airways and the pleural space remains open, a bronchopleural fistula results. Once the communication between the lung and the pleural space is closed, air will be reabsorbed at a rate of 1.25% of the total radiographic volume of the hemithorax per day. Thus, a 50% collapse of the lung will take about 40 days to reabsorb completely once the air leak is closed.

It has been postulated that a valvular mechanism may develop through which air can be sucked into the pleural space during inspiration but not expelled during expiration. The intrapleural pressure remains positive throughout breathing, the lung deflates further, the mediastinum shifts, and venous return to the heart decreases, with increasing respiratory and cardiac embarrassment. This is called tension pneumothorax and is very rare, except in patients on positive pressure ventilation.

The usual presenting features are sudden onset of unilateral pleuritic pain or progressively increasing breathlessness. If the pneumothorax enlarges, the patient becomes more breathless and may develop pallor and tachycardia. There may be few physical signs if the pneumothorax is small.

The characteristic features and management are shown in Figure 24.46. The main aim is to return the patient to active life as soon as possible. The procedure for simple aspiration is shown in Box 24.61.

Box 24.61

Simple aspiration of pneumothorax

1. Explain the nature of the procedure and obtain consent.
2. Infiltrate 2% lidocaine down to the pleura in the second intercostal space in the mid-clavicular line.
3. Push a 3–4 cm 16-gauge cannula through the pleura.
4. Connect the cannula to a three-way tap and 50 mL syringe.
5. Aspirate up to 2.5 L of air. Stop if resistance to suction is felt or the patient coughs excessively.
6. Repeat the chest X-ray (in expiration) in the X-ray department.

Recurrence. One-third of patients will have a recurrence. Chemical pleurodesis with talc is used for patients when surgery is contraindicated. Bleb resection and pleurodesis are achieved using a video-assisted thoracoscopic (VATS) approach or, less often, by open thoracotomy.

Disorders of the Diaphragm

Diaphragmatic fatigue

The diaphragm can become fatigued if the force of contraction during inspiration exceeds 40% of the force it can develop in a maximal static effort. When this occurs acutely, in patients with exacerbations of COPD or cystic fibrosis, or in quadriplegics, positive-pressure ventilation is required. Further rehabilitation requires exercises to increase the strength and endurance of the diaphragm by breathing against resistance for 30 minutes a day.

Unilateral diaphragmatic paralysis

This is common and symptomless. The affected diaphragm is usually elevated and moves paradoxically on inspiration. It can be diagnosed by ultrasound when a sniff causes the paralysed diaphragm to rise, and the unaffected diaphragm to descend. Causes include:

- surgery
- carcinoma of the bronchus with involvement of the phrenic nerve
- neurological disease, including poliomyelitis, herpes zoster
- trauma to cervical spine, birth injury, subclavian vein puncture
- infection, such as TB, syphilis, pneumonia.

Bilateral diaphragmatic weakness or paralysis

This causes breathlessness in the supine position and is a cause of sleep apnoea leading to daytime headaches and somnolence. Tidal volume is decreased and respiratory rate increased. Vital capacity is substantially reduced when lying down, and sniffing causes a paradoxical inward movement of the abdominal wall best seen in the supine position. Causes include viral infections, multiple sclerosis, motor neurone disease, poliomyelitis, Guillain–Barré syndrome, quadriplegia after trauma, and rare muscle diseases. Treatment is either diaphragmatic pacing
or night-time assisted ventilation.

### Complete eventration of the diaphragm

This is a congenital condition (invariably left-sided) in which muscle is replaced by fibrous tissue. It presents as marked elevation of the left hemidiaphragm, sometimes associated with gastrointestinal symptoms. Partial eventration, usually on the right, causes a hump (often anteriorly) on the diaphragmatic shadow on X-ray.

### Diaphragmatic hernias

These are most commonly through the oesophageal hiatus but occasionally occur anteriorly, through the foramen of Morgagni, posterolaterally through the foramen of Bochdalek, or at any site following traumatic tears.

### Hiccups

Hiccups are due to involuntary diaphragmatic contractions with closure of the glottis and are extremely common. Occasionally, patients present with persistent hiccups. This can be as a result of diaphragmatic irritation (e.g. subphrenic abscess) or a metabolic cause (e.g. uraemia). Treatment for persistent hiccups is with gabapentin 300 mg or pregabalin 50 mg three times daily. The underlying cause should be treated, if known.

### Mediastinal Lesions

The mediastinum is defined as the region between the pleural sacs. It is additionally divided as shown in *Figure 24.47*. Tumours affecting the mediastinum are rare. Masses are detected very accurately on CT, as well as on MRI scan (*Fig. 24.48*).
Retrosternal or intrathoracic thyroid

The most common mediastinal tumour is a retrosternal or intrathoracic thyroid, which is nearly always an extension of the thyroid present in the neck. Enlargement of the thyroid by a colloid goitre or malignant disease, or, rarely, in thyrotoxicosis, can cause displacement of the trachea and oesophagus to the opposite side. Symptoms of compression develop insidiously before
producing the cardinal feature of dyspnoea. Flow–volume loops are useful to assess the physiological impact. Very occasionally, an intrathoracic thyroid may cause dysphagia or hoarseness and vocal cord paralysis due to stretching of the recurrent laryngeal nerve. The treatment is surgical removal.

### Thymic tumours (thymomas)

The thymus is large in childhood and occupies the superior and anterior mediastinum. It involutes with age but may be enlarged by cysts, which are rarely symptomatic, or by tumours, which may cause myasthenia gravis or compress the trachea or, rarely, the oesophagus. Surgery is the treatment of choice. Approximately half of the patients presenting with a thymic tumour have myasthenia gravis. Good syndrome, a combined defect in humoral and cellular immunity, is seen in 10% of thymomas.

### Pleuropericardial cysts

These cysts, which may be up to 10 cm in diameter, are filled with clear fluid. Some 70% of them are situated anteriorly in the cardiophrenic angle on the right side. Infection is rare and malignant change does not occur. The diagnosis is usually made by needle aspiration. No treatment is required, but these patients should be followed up, as an increase in cyst size suggests an alternative pathology; surgical excision is then advisable.

Critical care medicine

Introduction

Critical care medicine (or ‘intensive care medicine’) is concerned predominantly with the management of patients with acute life-threatening conditions (‘the critically ill’) in specialized units. In addition to emergency cases, intensive care units (ICUs) admit high-risk patients electively after major surgery (Box 25.1). Frequently, ICU staff provide care...
throughout the hospital in the form of *medical emergency teams and outreach care*. These teams are trained to recognize and provide resuscitation to patients who become critically ill on the ward and transport them safely to an ICU. Another role for these teams is to identify patients who are deteriorating on the ward and to intervene early, perhaps thereby preventing the need for intensive care admission. Intensive care medicine also encompasses the resuscitation and transport of those who become acutely ill or are injured in the community. Teamwork and a multidisciplinary approach are central to the provision of intensive care and this functions most effectively when directed and coordinated by committed specialists.

ICUs are usually reserved for patients with established or impending organ failure and provide facilities for the diagnosis, prevention and treatment of multiple organ dysfunction. They are fully equipped with monitoring and technical facilities, including an adjacent laboratory and ‘near-patient testing’ devices for the rapid determination of blood gases and simple biochemical data such as serum potassium, blood glucose and serum lactate levels. Technological advances have led to the development of more compact and complex mechanical ventilators that are adaptable to individual patient demands. Portable ultrasound and echocardiography equipment is commonly available. Patients receive continuous expert nursing care and the constant attention of appropriately trained medical staff.

High-dependency units (HDUs) offer a level of care intermediate between that available on the general ward and that provided in an ICU. They provide monitoring and support for patients with acute (or acute-on-chronic) single-organ failure and for those who are at risk of developing organ failure. They can also provide a ‘step-down’ facility for patients being discharged from intensive care.

The proportion of a hospital's resources dedicated to intensive care varies widely internationally. For example, the UK provides 6.6 ICU and HDU beds per 100,000 population, whereas Germany provides 29.2 such beds per 100,000 population.

Clinical Approach to the Critically Ill Patient

Recognition and diagnosis of critical illness

Early recognition, immediate resuscitation and stabilization are fundamental to the successful management of the critically ill. Previously stable ward patients may deteriorate rapidly. In order to facilitate identification of ‘at-risk’ patients on the ward and early referral to the critical care team, a number of early warning systems have been devised (e.g. the Modified Early Warning Score, MEWS; Box 25.2). These are based primarily on bedside recognition of deteriorating physiological variables and can be used to supplement clinical intuition. A MEWS score of ≥5 is associated with an increased risk of death and warrants immediate admission to ICU. Another example of a system used to trigger referral to a Medical Emergency Team (MET) is shown in Box 25.3 (see also pp. 1156–1161).

These early warning systems are not infallible and have not been universally implemented. It is therefore imperative that clinicians are trained to recognize critically ill patients at the bedside. The initial assessment may elicit obvious signs. The patient may be unduly agitated or, perhaps more worryingly, unresponsive. Of particular concern is the obtunded patient who is unable to protect their own airway from aspiration of gastric or oral contents. Snoring, grunting or other respiratory sounds may indicate an obstructed airway, which can be caused by posterior displacement of the tongue due to lax oropharyngeal musculature in a comatose patient, or perhaps by secretions pooling in the oropharynx in a patient with a depressed cough reflex. Obvious use of the accessory respiratory muscles and a tracheal tug are sensitive signs
of impending respiratory decompensation. Patients in severe respiratory distress frequently sit forwards, grip the sides of the bed and cannot complete sentences in a single breath. Review of the nursing observations may reveal a sudden deterioration in recorded variables, such as a sharp rise in temperature, increasing heart rate, a fall in blood pressure or decreased urine output.

**On examination**, cool peripheries in conjunction with diaphoresis indicate increased sympathetic drive and may be a sign of cardiogenic shock, hypovolaemia or hypoglycaemia. In contrast, flushed, warm peripheries may be a sign of a hyperdynamic circulation consistent with sepsis. **Abdominal catastrophes** are a common cause of an acute deterioration; an abdominal examination should always be performed and may reveal a distended, tender abdomen and often absent or altered bowel sounds consistent with a perforated viscus or ischaemic bowel. **Blood gas analysis** is usually readily available and should be performed as soon as possible. Acid–base status, haemoglobin concentration, blood glucose and electrolyte levels obtained from an arterial blood gas sample can all be helpful when assessing the cause and severity of an acute illness. Increased lactate levels usually indicate severe illness. An **electrocardiogram (ECG)** can allow the rapid diagnosis of treatable conditions, as can a portable chest X-ray.

Frequently, the precise underlying diagnosis is initially unclear but, in all cases, the immediate objective is to preserve life and prevent, reverse or minimize damage to vital organs such as the lungs, brain, kidneys and liver. A systematic approach to the recognition and initial treatment of acute illness should be adopted, as well as performance of investigations to search for the underlying cause. A rapid assessment of the physiological derangement should be carried out, followed by prompt institution of measures to support cardiovascular and respiratory function (following the ABC approach: Airway, Breathing, Circulation; see Fig. 25.23). The patient's condition and response to treatment should be closely monitored throughout. In practice, resuscitation, assessment and diagnosis usually proceed in parallel.

**General aspects of managing the critically ill**

Critically ill patients require multidisciplinary care with:

- **Intensive skilled nursing care** (in the UK, usually with a 1 : 1 nurse/patient ratio in an ICU (level 3 care) or 1 : 2 in a HDU (level 2 care)). Frequent clinical observations are required.

- **Specialized physiotherapy.** This should include chest physiotherapy, mobilization and rehabilitation.

- **Management of pain** and distress. There should be judicious administration of analgesics and sedatives (see p. 1164).

- **Constant reassurance and support.** Critically ill patients easily become disorientated; delirium (a transient alteration in consciousness, attention, orientation, perception or behaviour) is common. Delirium may be hypoactive, agitated (hyperactive) or a combination of the two. Pain, advanced age, sleep/sensory deprivation, sedative administration
(especially benzodiazepines), alcohol/drug withdrawal, neurological injury, severe illness and medical comorbidities all play a role. Patients with delirium are more difficult to wean from ventilation, are at greater risk of self-extubation and require larger doses of sedatives. Delirium has been associated with increased mortality and length of hospital stay. Treatment focuses on effective pain control, minimizing sensory deprivation and early mobilization. Avoid benzodiazepines and limit sedative administration. The use of newer sedative agents, such as the $\alpha_2$ agonist dexmedetomidine, may reduce the incidence of delirium and time on the ventilator.

**$H_2$-receptor antagonists or proton pump inhibitors.** These agents should be given in selected cases to reduce gastric acidity and prevent stress-induced ulceration. They may, however, encourage bacterial overgrowth in the upper gastrointestinal tract and predispose patients to ventilator-associated pneumonia (VAP) if these bacteria are aspirated.

**Compression stockings** (full-length and graduated), pneumatic compression devices and subcutaneous low-molecular-weight heparin. These help to prevent venous thrombosis.

**Mouth care.** Mouth care, particularly the use of chlorhexidine mouth washes, helps to reduce hospital-acquired infections and VAP by reducing the burden of pathogenic oral flora that may be aspirated into the respiratory tree. The recent introduction of chlorhexidine body washes may reduce the total carriage of resistant microorganisms.

**Prevention of constipation and pressure ulcers.**

**Organ support.** For example, inotropes and vasopressors may be required for cardiovascular support, invasive and non-invasive ventilation for respiratory failure, and dialysis for renal failure. Specialized units may provide extracorporeal membrane oxygenation (ECMO) for severe respiratory failure, mechanical support of the circulation for cardiac failure, and advanced liver support in the form of liver dialysis (e.g. the molecular adsorbent recirculation system, MARS).

**Nutritional support** (see pp. 212–216). Protein energy malnutrition is common in critically ill patients and is associated with muscle wasting, weakness, delayed mobilization, difficulty weaning from ventilation, immune compromise and impaired wound healing. **Enteral nutrition**, usually delivered via a fine-bore nasogastric tube, is preferred because it is less expensive, preserves gut mucosal integrity, is more physiological and is associated with fewer complications. However, the value of enteral nutrition early in the course of an acute illness remains uncertain, apart from giving small amounts of enteral feed to preserve gut viability.

If enteral feeding is not possible due to the gut dysmotility and malabsorption associated with critical illness, the alternative is **intravenous (parenteral) nutrition** (see p. 214). This is more invasive and expensive, and can be complicated by deranged liver function tests, hypertriglyceridaemia, hyperglycaemia and an increased susceptibility to hospital-acquired infections. Usually, hypocaloric enteral nutrition is continued for up to a week in previously well-nourished patients prior to considering parenteral nutrition. Administering parenteral
nutrition early in order to maintain caloric input and prevent an energy deficit may be detrimental.

Although all nutrition should contain carbohydrate, protein, lipids and some micronutrients, the precise optimal formulation is unclear. Supplementation with the amino acid glutamine has theoretical advantages and is recommended in some guidelines. The omega-3 fatty acids derived from fish oils also have potentially beneficial antioxidant activity but have not been convincingly shown to improve outcome, as has been the case for micronutrient supplementation with selenium, copper, manganese, zinc, iron and vitamins.

Many critically ill patients are at risk of developing a ‘re-feeding syndrome’ (see p. 194) when nutritional support is first initiated.

Critically ill patients commonly require intravenous insulin infusions, often in high doses, to combat insulin resistance and hyperglycaemia (which is associated with hospital-acquired infections, renal impairment and poor wound healing; see p. 1249). Although the use of intensive insulin therapy to achieve ‘tight glycaemic control’ (blood glucose level between 4.4 and 6.1 mmol/L) was initially shown to improve outcome, subsequent studies found that this approach is associated with an unacceptably high incidence of hypoglycaemia, and possibly increased mortality. Current recommendations suggest that blood glucose levels should be maintained below 8–10 mmol/L.

**Discharge from the ICU/HDU**

Discharge of patients from intensive care should normally be planned in advance and should ideally take place during normal working hours. Assessment with a quick SOFA is helpful (see p. 1154). Frequently, when the condition of critically ill patients improves, they are initially ‘stepped down’ to HDU (level 2) care. Premature or unplanned discharge from the ICU or HDU, especially during the night, has been associated with higher hospital mortality rates and should be avoided where possible. A summary including ‘points to review’ should be included in the clinical notes and there should be a detailed handover to the receiving team (medical and nursing). The intensive care team should continue to review the patient (who might deteriorate following discharge) on the ward and should be available at all times for advice on further management (e.g. tracheostomy care, nutritional support). In this way, deterioration and re-admission to intensive care (which is associated with a particularly poor outcome), or even cardiorespiratory arrest, might be avoided.

This chapter concentrates on cardiovascular, respiratory, renal and neurological problems. Many patients also have failure of other organs, such as the liver; treatment of these is dealt with in more detail in the relevant chapters.

**Applied Cardiorespiratory Physiology**

**Oxygen delivery and consumption**

Oxygen delivery (\(DO_2\)) ([Fig. 25.1](#)) is defined as the total amount of oxygen delivered to the tissues per unit time. It is dependent on the volume of blood flowing through the microcirculation per minute (i.e. the total cardiac output, \(\dot{Q}_t\)) and the amount of oxygen contained in that blood (i.e. the arterial oxygen content, \(C_{a\text{O}_2}\)). Oxygen is transported both in combination with haemoglobin and dissolved in plasma. The amount combined with haemoglobin is determined by the oxygen capacity of haemoglobin (usually taken as 1.34 mL of oxygen per gram of haemoglobin) and its percentage saturation with oxygen (\(SO_2\)). The volume dissolved in plasma depends on the partial pressure of oxygen (\(PO_2\)). Except when hyperbaric oxygen is administered, the amount of dissolved oxygen in plasma is insignificant.
Clinically, however, the utility of this global concept of oxygen delivery is limited because it fails to account for changes in the relative flow to individual organs and the distribution of flow through the microcirculation (i.e. the efficiency with which oxygen delivery is matched to the metabolic requirements of individual tissues or cells). Furthermore, some organs (such as the heart) have high oxygen requirements relative to their blood flow and may receive insufficient oxygen, even if the overall oxygen delivery is apparently adequate. Lastly, microcirculatory flow can be impaired by an increase in blood viscosity.

**Oxygenation of the blood**

**Oxyhaemoglobin dissociation curve**

The saturation of haemoglobin with oxygen is determined by the partial pressure of oxygen (PO$_2$) in the blood, the relationship between the two being described by the oxyhaemoglobin dissociation curve (Fig. 25.2). The sigmoid shape of this curve is significant for a number of reasons:

- Modest falls in the partial pressure of oxygen in the arterial blood ($P_aO_2$) may be tolerated (since oxygen content is relatively unaffected), provided that the percentage saturation remains above about 92%.
- Increasing the $P_aO_2$ to above normal has only a minimal effect on oxygen content unless hyperbaric oxygen is administered (when the amount of oxygen in solution in plasma becomes significant).
- Once on the steep slope of the curve (percentage saturation below about 90%), a small decrease in $P_aO_2$ can cause large falls in oxygen content, whereas increasing $P_aO_2$ only slightly, e.g. by administering 28% oxygen to a patient with chronic obstructive pulmonary disease (COPD), can lead to a useful increase in oxygen saturation and content.
FIGURE 25.2 The oxyhaemoglobin dissociation curve. \(\text{HbO}_2(\%)\) is the percentage saturation of haemoglobin with oxygen. The curve will move to the right in the presence of acidosis (metabolic or respiratory), pyrexia or an increased red cell 2,3-diphosphoglycerate (2,3-DPG) concentration. For a given arteriovenous oxygen content difference, the mixed venous \(P_O_2\) will then be higher. Furthermore, if the mixed venous \(P_O_2\) is unchanged, the arteriovenous oxygen content difference increases and more oxygen is off-loaded to the tissues (see p. 520). \(P_{50}\) (the \(P_O_2\) at which haemoglobin is half-saturated with \(O_2\)) is a useful index of these shifts – the higher the \(P_{50}\) (i.e. shift to the right), the lower the affinity of haemoglobin for \(O_2\), a, arterial point; v, venous point; x, arteriovenous oxygen content difference.

If the \(P_{CO_2}\) increases, the oxyhaemoglobin curve moves to the right, facilitating oxygen unloading to the tissues (Bohr effect).

The \(P_aO_2\) is influenced, in turn, by the alveolar oxygen tension (\(P_{A}O_2\)), the efficiency of pulmonary gas exchange, and the partial pressure of oxygen in mixed venous blood (\(P_{V}O_2\)).

**Alveolar oxygen tension (\(P_{A}O_2\))**

The partial pressures of inspired gases are shown in **Figure 25.3**. By the time the inspired gases reach the alveoli, they are fully saturated with water vapour at body temperature (37°C), which has a partial pressure of 6.3 kPa (47 mmHg), and contain \(CO_2\) at a partial pressure of approximately 5.3 kPa (40 mmHg); the \(P_{A}O_2\) is thereby reduced to approximately 13.4 kPa (100 mmHg).
The clinician can influence $P_AO_2$ by administering oxygen or by increasing the barometric pressure (hyperbaric therapy).

**Pulmonary gas exchange**

In *normal* subjects, there is a small alveolar–arterial oxygen difference ($P_{A-a}O_2$). This is due to:

- a small (0.133 kPa, 1 mmHg) pressure gradient across the alveolar membrane
- a small amount of blood (2% of total cardiac output) bypassing the lungs via the bronchial and thebesian veins
- a small degree of ventilation/perfusion mismatch.

Pathologically, there are three possible causes of an increased $P_{A-a}O_2$ difference:

- **Diffusion defect.** This is not a major cause of hypoxaemia, even in conditions such as lung fibrosis, in which the alveolar–capillary membrane is considerably thickened. Carbon dioxide is also not affected, as it is more soluble than oxygen.

- **Right-to-left shunts.** In certain congenital cardiac lesions or when a segment of lung is completely collapsed, a proportion of venous blood passes to the left side of the heart without taking part in gas exchange, causing arterial hypoxaemia. This hypoxaemia cannot be corrected by administering oxygen to increase the $P_AO_2$ because blood leaving normal alveoli is already fully saturated; further increases in $PO_2$ will not, therefore, significantly affect its oxygen content. On the other hand, because of the shape of the carbon dioxide dissociation curve (*Fig. 25.4*), the high $PCO_2$ of the shunted blood can be compensated for by over-
ventilating patent alveoli, thus lowering the CO₂ content of the effluent blood. Indeed, many patients with acute right-to-left shunts hyperventilate in response to the hypoxia and/or to stimulation of mechanoreceptors in the lung, so that their $P_aCO_2$ is normal or low.

![The carbon dioxide dissociation curve. Note that, in the physiological range, the curve is essentially linear.](image)

**FIGURE 25.4** The carbon dioxide dissociation curve. Note that, in the physiological range, the curve is essentially linear.

- **Ventilation/perfusion ($\dot{V}/Q$) mismatch** (see pp. 1063–1064). Diseases of the lung parenchyma (e.g. pneumonia, pulmonary oedema, acute lung injury) result in $\dot{V}/Q$ mismatch, producing an increase in alveolar dead space and hypoxaemia. The increased dead space can be compensated for by increasing overall ventilation. In contrast to the hypoxia resulting from a true right-to-left shunt, that due to areas of low $\dot{V}/Q$ can be partially corrected by administering oxygen and thereby increasing the $P_AO_2$, even in poorly ventilated areas of lung.

**Oxygen cascade**

Oxygen levels fall further as oxygen is unloaded into the tissues and diffuses to the mitochondria. Tissue oxygen content varies, depending on the distance travelled from the local capillary network. Some mitochondria continue to function at a $PO_2$ as low as 0.07 kPa (0.5 mmHg) (*Fig. 25.5*).
Mixed venous oxygen tension ($P_{V}O_2$) and saturation ($S_{V}O_2$)

The $P_{V}O_2$ is the partial pressure of oxygen in pulmonary arterial blood that has been thoroughly mixed during its passage through the right heart. Assuming $P_{a}O_2$ remains constant, $P_{V}O_2$ and $S_{V}O_2$ will fall if more oxygen has to be extracted from each unit volume of blood arriving at the tissues. A low $P_{V}O_2$ therefore indicates either that oxygen delivery has fallen or that tissue oxygen requirements have increased without a compensatory rise in cardiac output. If $P_{V}O_2$ falls, the effect of a given degree of pulmonary shunting on arterial oxygenation will be exacerbated. Thus, worsening arterial hypoxaemia does not necessarily indicate a deterioration in pulmonary function but might instead reflect a fall in cardiac output and/or a rise in oxygen consumption.

Conversely, a rise in $P_{V}O_2$ and $S_{V}O_2$ may reflect impaired tissue oxygen extraction (due to microcirculatory abnormalities) and/or reduced oxygen utilization (e.g. due to mitochondrial dysfunction), as seen in severe sepsis (see below).

Monitoring the oxygen saturation in central venous ($S_{CV}O_2$), rather than pulmonary artery blood is less invasive and may be a useful guide to the resuscitation of some critically ill patients (see p. 1161).

Adaptation to hypoxia

Acute exposure to severe hypoxia may lead to sudden death if the immediate adaptive responses fail to maintain mitochondrial oxygen delivery. Chronic exposure to low oxygen tension, on the other hand, allows time for compensatory mechanisms to develop. Amongst the
first is an acute increase in cardiac output, achieved primarily by increasing heart rate. Given the reciprocal relationship between the partial pressures of oxygen and carbon dioxide in the alveoli, as defined by the alveolar gas equation \(P_{A\text{O}_2} = P_{I\text{O}_2} - P_{A\text{CO}_2/R}\), an increase in respiratory rate serves to decrease alveolar \(PCO_2\) and thereby increase alveolar \(PO_2\) (see also Fig. 25.3). Over time, increased erythropoietin production stimulates haemoglobin synthesis, leading to a marked increase in haematocrit. Over the longer term, capillary bed density in specific tissues adjusts to the physiological demand. In those residing at altitude over generations, the hypoxic ventilatory drive and pulmonary vasoconstrictor response evolve to maximize oxygen uptake. In 2007, a series of arterial blood samples were obtained by a group of critical care doctors on the summit of Mount Everest (see more online). The project included a 4-month acclimatization period at altitude and the samples were eventually obtained at an altitude of 8400 m whilst breathing air. The average \(PaO_2\) was 3.2 kPa (24.6 mmHg). These figures neatly demonstrate features of both acute (hyperventilation) and chronic (increased haematocrit) acclimatization to hypobaric hypoxia.

Cardiac output

Cardiac output is the product of heart rate and stroke volume, and is affected by changes in either of these (Fig. 25.6).

Heart rate

When heart rate increases, the duration of systole remains essentially unchanged, whereas diastole, and thus the time available for ventricular filling, becomes progressively shorter and the stroke volume eventually falls. In the normal heart, this occurs at rates greater than about 160 beats per minute, but in those with cardiac pathology, especially when ventricular filling is restricted (e.g. mitral stenosis), stroke volume may fall at much lower heart rates. Furthermore, tachycardias cause a marked increase in myocardial oxygen consumption ($\dot{V}_mO_2$) and this may precipitate ischaemia in areas of the myocardium with restricted coronary perfusion. When the heart rate falls, a point is reached at which the increase in stroke volume is insufficient to compensate for bradycardia, and again cardiac output falls.

Alterations in heart rate are often caused by disturbances of rhythm (e.g. atrial fibrillation, complete heart block) in which ventricular filling is not augmented by atrial contraction, exacerbating the fall in stroke volume.

Stroke volume

The volume of blood ejected by the ventricle in a single contraction is the difference between the ventricular end-diastolic volume (VEDV) and ventricular end-systolic volume (VESV) (i.e. stroke volume = VEDV – VESV). The ejection fraction describes the stroke volume as a percentage of VEDV (i.e. ejection fraction = (VEDV – VESV)/VEDV × 100%) and is an indicator of myocardial performance.

Three interdependent factors determine the stroke volume (see p. 935).

Preload

This is defined as the tension of the myocardial fibres at the end of diastole, just before the onset of ventricular contraction, and is therefore related to the degree of stretch of the fibres. As the end-diastolic volume of the ventricle increases, tension in the myocardial fibres is increased and stroke volume rises (Fig. 25.7). Myocardial oxygen consumption ($\dot{V}_mO_2$) increases only slightly with an increase in preload (produced, for example, by a ‘fluid
challenge’, see below) and this is therefore the most efficient way of improving cardiac output.

**FIGURE 25.7** The Frank–Starling relationship: as preload is increased, stroke volume rises. If the ventricle is overstretched, stroke volume will fall (x). In myocardial failure, the curve is depressed and flattened. Increasing contractility, such as that due to sympathetic stimulation, shifts the curve upwards and to the left (z).

**Myocardial contractility**

This refers to the ability of the heart to perform work, independent of changes in preload and afterload. The state of myocardial contractility determines the response of the ventricles to changes in preload and afterload. Contractility is often reduced in critically ill patients, as a result of either pre-existing myocardial damage (e.g. ischaemic heart disease) or the acute disease process itself (e.g. sepsis). Changes in myocardial contractility alter the slope and position of the Starling curve; worsening ventricular performance is manifested as a depressed, flattened curve (Figs 25.7 and 23.5). Inotropic drugs can be used to increase myocardial contractility (see below).

**Afterload**

This is defined as the myocardial wall tension developed during systolic ejection. In the case of the left ventricle, the resistance imposed by the aortic valve, the peripheral vascular resistance and the elasticity of the major blood vessels are the major determinants of afterload. Ventricular wall tension will also be increased by ventricular dilatation, an increase in intraventricular pressure or a reduction in ventricular wall thickness.

**Decreasing** the afterload (through vasodilatation due to exercise, sepsis or vasodilating agents) can increase the stroke volume achieved at a given preload (Fig. 25.8), while reducing \( \dot{V}'_{\text{O}_2} \). The reduction in wall tension also leads to an increase in coronary blood flow, thereby improving the myocardial oxygen supply/demand ratio. Excessive reductions in afterload will
cause hypotension.

FIGURE 25.8 The effect of changes in afterload on the ventricular function curve. At any given preload, decreasing afterload increases the stroke volume.

Increasing the afterload (vasoconstriction due to increased sympathetic activity, vasoconstrictor agents), on the other hand, can cause a fall in stroke volume and an increase in \( \dot{V}_\text{O}_2 \).

Right ventricular afterload is normally negligible because the resistance of the pulmonary circulation is very low but is increased in pulmonary hypertension.

**Cardiovascular assessment and monitoring of critically ill patients**

As well as allowing immediate recognition of changes in the patient’s condition, monitoring can also be used to establish or confirm a diagnosis, gauge the severity of the condition, follow the evolution of the illness, guide interventions and assess the response to treatment. Invasive monitoring is generally indicated in the more seriously ill patients and in those who fail to respond to initial treatment. These techniques are, however, associated with a significant risk of complications, as well as additional costs and patient discomfort, and should therefore only be used when the potential benefits outweigh the dangers. Likewise, invasive devices should be removed as soon as possible.

**Assessment of tissue perfusion**

- **Pale, cold skin**, delayed capillary refill and the absence of visible veins in the hands and feet indicate poor perfusion. Although peripheral skin temperature measurements can help clinical evaluation, the earliest compensatory response to hypovolaemia or a low cardiac output, and the last to resolve after resuscitation, is vasoconstriction in the splanchnic region.

- **Metabolic acidosis with raised lactate concentration** suggests that tissue perfusion is sufficiently compromised to cause cellular hypoxia and anaerobic glycolysis. Persistent, severe lactic acidosis is associated with a very poor prognosis. In addition to being used as a
screen for cardiovascular insufficiency and poor tissue perfusion, lactate levels are frequently used to guide resuscitation. Extremely high lactate levels that do not respond to resuscitation are suggestive of reduced splanchnic blood flow and bowel ischaemia. In many critically ill patients, especially those with sepsis, lactic acidosis can also be caused by metabolic disorders unrelated to tissue hypoxia and can be exacerbated by reduced clearance owing to hepatic or renal dysfunction, as well as the administration of adrenaline (epinephrine).

- **Urinary flow** is a sensitive indicator of renal perfusion and haemodynamic performance.

**Blood pressure**

Alterations in blood pressure are often interpreted as reflecting changes in cardiac output. However, if there is vasoconstriction with a high peripheral resistance, the blood pressure may be normal, even when the cardiac output is reduced. Conversely, the vasodilated patient may be hypotensive, despite a very high cardiac output.

Hypotension jeopardizes perfusion of vital organs. The adequacy of blood pressure in an individual patient must always be assessed in relation to the premorbid value. Blood pressure is traditionally measured using a sphygmomanometer, but if rapid alterations are anticipated, continuous monitoring using an intra-arterial cannula is indicated (Box 25.4 and Fig. 25.9).

**Box 25.4**

**Radial artery cannulation**

** Technique**

1. Explain the procedure to the patient and, if possible, obtain consent.
2. Ask an assistant to support the patient's arm, with the wrist extended. (Gloves should be worn.)
3. Clean the skin with chlorhexidine. Take sterile precautions throughout the procedure.
4. Palpate the radial artery where it arches over the head of the radius.
5. In conscious patients, inject local anaesthetic to raise a weal over the artery, taking care not to puncture the vessel or obscure its pulsation.
6. Make a small skin incision over the proposed puncture site.
7. Use a small, parallel-sided cannula (20 gauge for adults, 22 gauge for children) in order to allow blood flow to continue past the cannula.
8. Insert the cannula over the point of maximal pulsation and advance it in line with the direction of the vessel at an angle of approximately 30°.
9. Look for ‘flashback’ of blood into the cannula, which indicates that the radial artery has been punctured.
10. To ensure that the shoulder of the cannula enters the vessel, lower the needle and cannula and advance them a few millimetres into the vessel.
11. Thread the cannula off the needle into the vessel and withdraw the needle.
12. Connect the cannula to a non-compliant manometer line filled with saline. Then connect this via a transducer and continuous flush device to a monitor, which records the arterial pressure.

**Complications**

- Thrombosis
- Loss of arterial pulsation
- Distal ischaemia, e.g. digital necrosis (rare)
- Infection
- Accidental injection of drugs – can produce vascular occlusion
- Disconnection – rapid blood loss

![Figure 25.9](image)

**Central venous pressure**

Assessment of central venous pressure (CVP) provides a fairly simple, but approximate, method of gauging the adequacy of a patient's circulating volume and may reflect the contractile state of the myocardium. The absolute value of the CVP is not as informative as its response to a fluid challenge (the infusion of 100–200 mL of fluid over a few minutes; Fig. 25.10). The hypovolaemic patient will initially respond to transfusion with little or no change in CVP, together with some improvement in cardiovascular function (falling heart rate, rising blood pressure, increased peripheral temperature and urine output). As the normovolaemic state is approached, the CVP may rise slightly and reach a plateau, while other cardiovascular values begin to stabilize. At this stage, volume replacement should be slowed, or even stopped, in order to avoid excessive transfusion (indicated by an abrupt and sustained rise in CVP, often
accompanied by some deterioration in the patient's condition). In cardiac failure, the venous pressure is usually high; the patient will not improve in response to volume replacement, which will cause a further, sometimes dramatic, rise in CVP.

The use of CVP to assess cardiovascular function, and the relationship between the response of the CVP to fluid challenge and the intravascular volume, are controversial. Many studies have failed to confirm this relationship and the use of CVP for this purpose is beginning to be supplanted by newer methods, particularly pulse contour analysis and oesophageal Doppler techniques (see below).

Central venous catheters are usually inserted via a percutaneous puncture of the subclavian or internal jugular vein using a guidewire technique (Box 25.5 and Figs 25.11 and 25.12). The objective is to place the tip of the catheter approximately at the junction of the superior vena cava and the right atrium. Usually, these catheters consist of more than one lumen, some of which may be used for drug or fluid administration. Central venous cannulae may also be inserted via the femoral vein; when this route is used, the tip of the cannula will lie in the inferior vena cava and pressure measurements will not be a reliable guide to the circulating volume. Guidewire techniques can also be used for inserting double-lumen cannulae for haemofiltration or pulmonary artery catheter introducers. The routine use of ultrasound to guide central venous cannulation reduces complication rates.

**Box 25.5**

**Internal jugular vein cannulation**

**Technique**

1. Explain the procedure to the patient and, if possible, obtain consent.
2. Place the patient head down to distend the central veins (this facilitates cannulation and minimizes the risk of air embolism but may exacerbate respiratory distress and is
dangerous in those with raised intracranial pressure).
3. Clean the skin with an antiseptic solution such as chlorhexidine. Take sterile precautions throughout the procedure.
4. Inject local anaesthetic (1% plain lidocaine) intradermally to raise a weal at the apex of a triangle formed by the two heads of sternomastoid with the clavicle at its base.
5. Make a small incision through the weal.
6. Insert the cannula or needle through the incision and direct it laterally, downwards and backwards, in the direction of the nipple until the vein is punctured just beneath the skin and deep to the lateral head of sternomastoid.

**Ultrasound-guided puncture is recommended to reduce the incidence of complications.**

7. Check that venous blood is easily aspirated.
8. Thread the cannula off the needle into the vein or pass the guidewire through the needle (see *Fig. 25.12*).
9. Connect the central venous pressure manometer line to a manometer/transducer.
10. Take a chest X-ray to verify that the tip of the catheter is in the superior vena cava and to exclude pneumothorax.

**Possible complications**

- Haemorrhage
- Accidental arterial puncture (carotid or subclavian)
- Pneumothorax
- Damage to thoracic duct on left
- Air embolism
- Thrombosis
- Catheter-related sepsis
The CVP is usually displayed continuously using a transducer and bedside monitor but, in the absence of such equipment, can be recorded intermittently using a manometer system. It is
essential for the recorded pressure always to be related to the level of the right atrium. Various landmarks are advocated (e.g. sternal notch with the patient supine; sternal angle or mid-axilla when the patient is at 45°), but the choice is largely immaterial, provided the landmark is used consistently in an individual patient.

**Left atrial pressure**

In uncomplicated cases, careful interpretation of the CVP may provide a reasonable guide to the filling pressures of both sides of the heart. In many critically ill patients, however, there is a disparity in function between the two ventricles. Most commonly, left ventricular performance is worse, so that the left ventricular function curve is displaced downwards and to the right (Fig. 25.13). High right ventricular filling pressures, with normal or low left atrial pressures, are less common but occur with right ventricular dysfunction and with raised pulmonary vascular resistance (i.e. right ventricular afterload), such as in acute respiratory failure and pulmonary embolism.

![Diagram of LV and RV function curves](image)

**FIGURE 25.13** Left ventricular (LV) and right ventricular (RV) function curves in a patient with left ventricular dysfunction. Since the stroke volume of the two ventricles must be the same (except, perhaps, for a few beats during a period of circulatory adjustment), left atrial pressure (LAP) must be higher than right atrial pressure (RAP). Moreover, an increase in stroke volume (x) produced by expanding the circulatory volume may be associated with a small rise in RAP (y) but a marked increase in LAP (z).

**Pulmonary artery pressures**

A ‘balloon flotation catheter’ enables reliable catheterization of the pulmonary artery. These ‘Swan–Ganz’ catheters can be inserted centrally (see Fig. 25.11) or through the femoral vein, or via a vein in the antecubital fossa. Passage of the catheter from the major veins, through the chambers of the heart into the pulmonary artery and into the wedged position, is monitored and guided by the pressure waveforms recorded from the distal lumen (Box 25.6 and Fig. 25.14). A chest X-ray should always be obtained to check the final position of the catheter (Fig.
Box 25.6

Passage of a pulmonary artery balloon flotation catheter

The catheter is passed through the chambers of the heart into the ‘wedged’ position.
1. Explain the procedure to the patient and, if possible, obtain consent.
2. Insert a balloon flotation catheter through a large vein (see text).
3. Look for respiratory oscillations once the catheter is in the thorax. Advance it further towards the lower superior vena cava/right atrium (see Fig. 25.14A), where pressure oscillations become more pronounced. Then inflate the balloon and advance the catheter.
4. When the catheter is in the right ventricle (see Fig. 25.14B), there is no dicrotic notch and the diastolic pressure is close to 0. Return the patient to the horizontal, or slightly head-up, position before advancing the catheter further.
5. When the catheter reaches the pulmonary artery (see Fig. 25.14C), a dicrotic notch appears and there is elevation of the diastolic pressure. Advance the catheter further with the balloon inflated.
6. Reappearance of a venous waveform indicates that the catheter is ‘wedged’. Deflate the balloon to obtain the pulmonary artery pressure. Inflate the balloon intermittently to obtain the pulmonary artery occlusion pressure (also known as pulmonary artery or capillary ‘wedge’ pressure; see Fig. 25.14D).

**FIGURE 25.14** Passage of pulmonary artery balloon flotation catheter through the chambers of the heart. The catheter is passed into the ‘wedged’ position to measure the pulmonary artery occlusion pressure (see Box 25.6). PA, pulmonary artery; RA, right artery; RV, right ventricle.
Once in place, the balloon is deflated and the pulmonary artery mean, systolic and end-diastolic pressures (PAEDP) can be recorded. The pulmonary artery occlusion pressure (PAOP; previously referred to as the pulmonary artery or capillary ‘wedge’ pressure) is measured by re-inflating the balloon, thereby propelling the catheter distally until it impacts in a medium-sized pulmonary artery. In this position, there is a continuous column of fluid between the distal lumen of the catheter and the left atrium, so that the PAOP is usually a reasonable reflection of left atrial pressure.

The technique is generally safe; the majority of complications, such as ‘knotting’, valve trauma and pulmonary artery rupture (which can be fatal), are related to user inexperience.

**Cardiac output**

Cardiac output can be continuously monitored using a modified pulmonary artery catheter that transmits low-energy heat from a heating element in the catheter into the surrounding blood. A ‘thermodilution curve’ is constructed by measuring dissipation of the heat using a thermistor located distal to the heating coil. The dissipation of heat is directly proportional to the cardiac output. These catheters also optically measure and continuously display $S\text{v}O_2$.

In general, pulmonary artery catheters may help the clinician to optimize cardiac output and oxygen delivery, while minimizing the risk of volume overload. They can also be used to guide the rational use of inotropes and vasoactive agents, and are particularly helpful in patients with pulmonary hypertension. The unselective use of this monitoring device in the absence of evidence-based haemodynamic goals does not, however, lead to improved outcomes and less invasive techniques are preferred, except in the most complex cases (e.g. high-risk cardiac surgery).
Less invasive techniques for assessing cardiac function and guiding volume replacement

Arterial pressure variation as a guide to hypovolaemia

Systolic arterial pressure decreases during the inspiratory phase of intermittent positive pressure ventilation (see p. 1163). The magnitude of this cyclical variability has been shown to correlate more closely with hypovolaemia than other monitored variables, including CVP. Systolic pressure (or pulse pressure) variation during mechanical ventilation can therefore be used as a simple and reliable guide to the adequacy of the circulatory volume. The response to fluid loading can also be predicted simply by observing the changes in pulse pressure during passive leg-raising.

Oesophageal Doppler

Stroke volume, cardiac output and myocardial function can be assessed non-invasively using Doppler ultrasonography. A probe is passed into the oesophagus to monitor velocity waveforms from the descending aorta continuously (Fig. 25.16). Although reasonable estimates of stroke volume, and hence cardiac output, can be obtained, the technique is best used for trend analysis rather than for making absolute measurements. Oesophageal Doppler probes can be inserted quickly and easily, and are particularly valuable for perioperative optimization of the circulating volume and cardiac performance in the unconscious patient. They are contraindicated in patients with oropharyngeal/oesophageal pathology.
Arterial waveform analysis

Lithium dilution/pulse contour analysis does not require pulmonary artery catheterization or instrumentation of the oesophagus and is suitable for use in conscious patients. A bolus of lithium chloride is administered via a central venous catheter and the change in arterial plasma lithium concentration is detected by a lithium-sensitive electrode. This sensor can be connected to an existing arterial cannula via a three-way tap. A small battery-powered peristaltic pump is used to create a constant blood flow through the sensor and over the electrode tip. The cardiac output determined in this way can be used to calibrate an arterial pressure waveform (‘pulse contour’) analysis programme that will continuously monitor changes in cardiac output. Devices that use uncalibrated pulse contour analysis to estimate cardiac output are also available.

Other devices utilize a thermodilution technique, where a small volume of cold fluid is injected into a large central vein and a temperature washout curve is detected via a sensor in a modified arterial line. Following this calibration, beat-to-beat cardiac output is generated by computer-based analysis of the arterial pressure waveform.

As with pulse pressure variation, stroke volume variation, determined by oesophageal Doppler or arterial waveform analysis, can be used to guide fluid replacement.

Echocardiography

Echocardiography is being used increasingly often to provide immediate diagnostic information about cardiac structure and function (myocardial contractility, ventricular filling) in the critically ill patient. Although transoesophageal echocardiography (TOE) may be
preferred because of its superior image clarity (Fig. 25.17), transthoracic probes are increasingly used on general ICUs.

**Key points in monitoring cardiac function**

These are shown in *Box 25.7*.

**Further reading**

---

**Box 25.7**

**Key points in monitoring cardiac function**

- If there is disagreement between clinical signs and a monitored variable, it should be assumed that the monitor is incorrect until all sources of potential error have been checked and eliminated
- Changes and trends in monitored variables are more informative than a single reading
- Use non-invasive monitoring where possible
- Remove invasive devices as soon as possible

---

**Disturbances of Acid–Base Balance**

The physiology of acid–base control is discussed on pages 174–176. Acid–base disturbances can be described in relation to *Figure 9.14* (which shows $P_a\text{CO}_2$ plotted against arterial [H+]).

Both acidosis and alkalosis can occur, each of which is either metabolic (primarily affecting
the bicarbonate component of the system) or respiratory (primarily affecting $P_a\text{CO}_2$). Compensatory changes may also be apparent. In clinical practice, arterial [H+] values outside the range 18–126 nmol/L (pH 6.9–7.7) are rarely encountered.

Blood gas and acid–base values (normal ranges) are shown in Box 25.8. (For blood gas analysis, see pp. 1161–1162.)

### Respiratory acidosis

This is caused by retention of carbon dioxide. The $P_a\text{CO}_2$ and [H+] rise. A chronically raised $P_a\text{CO}_2$ is compensated by renal retention of bicarbonate, and the [H+] returns towards normal. A constant arterial bicarbonate concentration is then usually established within 2–5 days. This represents a primary respiratory acidosis with a compensatory metabolic alkalosis (see p. 177). Common causes of respiratory acidosis include ventilatory failure and COPD (type II respiratory failure, where there is a high $P_a\text{CO}_2$ and a low $P_a\text{O}_2$; see p. 1161).

### Respiratory alkalosis

In this case, the reverse occurs and there is a fall in $P_a\text{CO}_2$ and [H+], often with a small reduction in bicarbonate concentration. If hypocarbia persists, some degree of renal compensation may occur, producing a metabolic acidosis, although in practice this is unusual. A respiratory alkalosis may be produced, intentionally or unintentionally, when patients are mechanically ventilated; it may also be seen in patients with hypoxaemic (type I) respiratory failure (see p. 1161), those with spontaneous hyperventilation, and those living at high altitudes (see online, ‘Adaptation to hypoxia’, for an example of a partly compensated respiratory alkalosis secondary to extreme hypoxaemia).
**Metabolic acidosis**

Metabolic acidosis (see p. 177) may be due to excessive acid production, often lactate and $\text{H}^+$ (lactic acidosis), as a consequence of anaerobic metabolism during an episode of shock or following cardiac arrest. A metabolic acidosis may develop as a consequence of chronic renal failure or in diabetic ketoacidosis. It can also follow the loss of bicarbonate from the gut or from the kidney in renal tubular acidosis. Respiratory compensation for a metabolic acidosis is usually slightly delayed because the blood–brain barrier initially prevents the respiratory centre from sensing the increased blood $[\text{H}^+]$. Following this short delay, however, the patient hyperventilates and ‘blows off’ carbon dioxide to produce a compensatory respiratory alkalosis. There is a limit to this respiratory compensation, since, in practice, values for $P_a\text{CO}_2$ less than about 1.4 kPa (11 mmHg) are rarely achieved. Spontaneous respiratory compensation cannot occur if the patient's ventilation is controlled or if the respiratory centre is depressed: for example, by drugs or head injury.

**Metabolic alkalosis**

This can be caused by loss of acid – for example, from the stomach with nasogastric suction, or in high intestinal obstruction, or excessive administration of absorbable alkali. Overzealous treatment with intravenous sodium bicarbonate is sometimes implicated. Respiratory compensation for a metabolic alkalosis is often slight, and it is rare to encounter a $P_a\text{CO}_2$ above 6.5 kPa (50 mmHg), even with severe alkalosis.

**Shock, Sepsis and Acute Disturbances of Haemodynamic Function**

Shock is the term used to describe acute circulatory failure with inadequate or inappropriately distributed tissue perfusion, resulting in generalized cellular hypoxia and/or an inability of the cells to utilize oxygen.

**Aetiology of shock**

Abnormalities of tissue perfusion can result from:
- failure of the heart to act as an effective pump
- mechanical impediments to forward flow
- loss of circulatory volume
- abnormalities of the peripheral circulation.

The causes of shock are shown in **Box 25.9**; see also page 1154 for definitions of sepsis. Often, shock can result from a combination of these factors (e.g. in sepsis, distributive shock is frequently complicated by hypovolaemia and myocardial depression).
Causes of shock

Hypovolaemic
- Exogenous losses (e.g. haemorrhage, burns)

Cardiogenic
- ‘Myocardial failure’ (e.g. ischaemic myocardial injury)

Obstructive
- Obstruction to cardiac outflow (e.g. pulmonary embolus)
- Restricted cardiac filling (e.g. cardiac tamponade, tension pneumothorax)

Distributive
- (e.g. sepsis, anaphylaxis)
- Vascular dilatation
- Sequestration
- Arteriovenous shunting
- Maldistribution of flow
- Myocardial depression

Pathophysiology

The sympatho-adrenal response to shock
Hypotension stimulates the baroreceptors, and to a lesser extent the chemoreceptors, causing increased sympathetic nervous activity with ‘spill-over’ of noradrenaline (norepinephrine) into the circulation. Later, this is augmented by the release of catecholamines (predominantly, adrenaline (epinephrine)) from the adrenal medulla. The resulting vasoconstriction, together with increased myocardial contractility and heart rate, help to restore blood pressure and cardiac output (Fig. 25.18).
FIGURE 25.18 The sympato-adrenal response to shock. The effect of increased catecholamines is shown on the left of the diagram, and the release of angiotensin and aldosterone on the right. Both mechanisms help to maintain the cardiac output and blood pressure in shock.

Reduced perfusion of the renal cortex stimulates the juxtaglomerular apparatus to release renin. This converts angiotensinogen to angiotensin I, which, in turn, is converted in the lungs and by the vascular endothelium to the potent vasoconstrictor angiotensin II. Angiotensin II also stimulates secretion of aldosterone by the adrenal cortex, causing sodium and water retention (see p. 728). This helps to restore the circulating volume (see p. 150).

The neuroendocrine response

- There is release of pituitary hormones, such as adrenocorticotrophic hormone (ACTH), vasopressin (antidiuretic hormone, ADH) and endogenous opioid peptides. (In septic shock, there may be a relative deficiency of vasopressin.)
- There is release of cortisol, which causes fluid retention and antagonizes insulin.
- There is release of glucagon, which raises the blood sugar level.

Although absolute adrenocortical insufficiency (e.g. due to bilateral adrenal haemorrhage or necrosis in meningococcal infection) is rare, there is evidence that patients with septic shock have a blunted response to exogenous ACTH (so-called ‘relative’ or ‘occult’ adrenocortical
insufficiency), and that this could be associated with an impaired vasoconstrictor response to noradrenaline (norepinephrine) and a worse prognosis. The diagnosis, causes and clinical significance of this phenomenon remain unclear.

**Release of immune mediators**

Severe infection (often with bacteraemia or endotoxaemia), the presence of large areas of damaged tissue (e.g. following trauma or extensive surgery), hypoxia or prolonged/repeated episodes of hypoperfusion can trigger a dysfunctional immune response with alterations in leucocyte activation and release of a variety of potentially damaging ‘mediators’ (see also pp. 136–138). Although an appropriate immune response is clearly beneficial when targeted against local areas of infection or necrotic tissue, the disseminated, dysregulated response observed in some patients can lead to shock and organ failure. This immune response can be complex, with features of upregulation and downregulation of both the innate and the adaptive immune pathways present at different stages of the illness. Characteristically, the later phase is typified by a period of immune suppression, which, in some cases, may be profound and during which the patient is at increased risk of developing secondary infections.

**Microorganisms and their toxic products**

In sepsis/septic shock, the innate immune response (Fig. 25.19) and inflammatory cascade are triggered by the recognition of pathogen-associated molecular patterns (PAMPs), including bacterial and fungal DNA, cell-wall components (e.g. endotoxin) and/or exotoxins (antigenic proteins produced by bacteria such as staphylococci, streptococci and Pseudomonas).
**Endotoxin** is a lipopolysaccharide (LPS) derived from the cell wall of Gram-negative bacteria and is a potent trigger of the innate immune response. The lipid A portion of LPS can be bound by a protein normally present in human serum known as lipopolysaccharide-binding protein (LBP). The LBP–LPS complex attaches to the cell surface marker CD14 and, combined with a secreted protein (MD2), this complex then binds to a member of the toll-like receptor family (TLR4), which transduces the activation signal into the cell. These receptors act through an adaptor molecule, myeloid differentiation factor 88 (MyD88), to regulate the activity of the nuclear transcription factor NFκB, which then passes into the nucleus, where it binds to DNA and promotes the synthesis of a wide variety of immune mediators. Gram-positive bacteria have cell-wall components that are similar in structure to LPS (e.g. lipoteichoic acid), and can also trigger a systemic inflammatory response, probably through similar (TLR2) but not identical pathways (Fig. 25.19).
Toxic products of tissue injury (surgery and trauma)

Following traumatic or surgical tissue injury, inflammatory pathways may be triggered by damage-associated molecular patterns (DAMPS), such as DNA fragments. Of particular importance is circulating mitochondrial DNA (mtDNA), which retains homology with bacterial DNA in terms of methylation patterns across nucleotides and can be ‘mistaken’ by the immune system for bacterial DNA. The patient then initiates an immune response apparently almost identical to that observed following bacterial invasion. This is why distributive shock secondary to infection can be difficult to distinguish clinically from that caused by a ‘sterile’ insult such as severe trauma or surgery.

Cytokines and other immune mediators

An array of cytokines (small proteins released by cells that have specific effects on the interactions between cells, on communications between cells or on the behaviour of cells), chemokines (a family of signalling cytokines that induce chemotaxis in nearby cells), prostaglandins, leukotrienes (see Fig. 24.30), heat shock proteins, adhesion molecules and endothelial derived vasoactive factors are induced, particularly during distributive shock. These include pro-inflammatory cytokines (tumour necrosis factor alpha, TNF-α, and interferon gamma, IFN-γ), anti-inflammatory cytokines (interleukin 10, IL-10), mediators promoting extracellular extravasation (intracellular adhesion molecule 1, ICAM-1) (see Fig. 8.9) and vasodilatation (inducible nitric oxide synthase, iNOS; Fig. 25.20). Although there was initial enthusiasm for treatments that dampened the immune response (e.g. high-dose steroids and anti-TNF-α compounds) in cases of distributive shock secondary to infection (septic shock), these strategies failed to improve survival and were sometimes associated with worse outcomes.

![FIGURE 25.20 Synthesis and biochemical action of nitric oxide (NO). cGMP, cyclic guanosine monophosphate; GTP, guanosine triphosphate.](image)

Activation of the complement cascade
Fragments of C3 act as opsonins and co-stimulatory molecules that assist lymphocytes with the adaptive immune response, while small peptides derived from C3, C4 and C5 cause leucocyte chemotaxis, release of cytokines and increased vascular permeability (see p. 124).

**Influence of genetic variation**

Individuals vary considerably in their susceptibility to infection, as well as their ability to recover from apparently similar infections, illnesses or traumatic insults. There is evidence to suggest that inter-individual variations in susceptibility to, and outcome from, sepsis can be partly explained by genetic variation.

**Haemodynamic and microcirculatory changes**

The dominant haemodynamic feature of severe sepsis/septic shock is peripheral vascular failure with:

- vasodilatation
- maldistribution of regional blood flow
- abnormalities in the microcirculation (**Fig. 25.21**):
  - ‘stop-flow’ capillaries (flow is intermittent)
  - ‘no-flow’ capillaries (capillaries are obstructed)
  - failure of capillary recruitment
  - increased capillary permeability with interstitial oedema.

Although these **vascular and microvascular abnormalities** may partly account for the reduced oxygen extraction often seen, particularly in septic shock, there is also a **primary defect of cellular oxygen utilization** caused by mitochondrial dysfunction (see above). Initially, before hypovolaemia supervenes, or when therapeutic replacement of the circulating volume has been adequate, **cardiac output is usually high and peripheral resistance is low**. These changes may be associated with impaired oxygen consumption, a reduced arteriovenous oxygen content difference, an increased $S_{\text{vO}_2}$ and a lactic acidosis (so-called ‘**tissue dysoxia**’). Vasodilatation and increased vascular permeability also occur in anaphylactic shock.

The glycocalyx consists of a tight, negatively charged, extremely thin meshwork of proteoglycans on the luminal surface of the endothelium. Oxidative stress, free radicals and
endotoxaemia all have specific detrimental effects on the glycocalyx that promote fluid movement into the tissues. Widespread, ‘pitting’, peripheral oedema is often seen in the most seriously ill patients.

**Activation of the coagulation system**

The immune response to shock, tissue injury and infection is frequently associated with systemic activation of the clotting cascade, leading to platelet aggregation, widespread microvascular thrombosis and inadequate tissue perfusion.

Initially, the production of prostaglandin I\(_2\) (PGI\(_2\)) by the capillary endothelium is impaired. Cell damage (e.g. to the vascular endothelium) leads to exposure to tissue factor (see p. 565), which triggers coagulation. In severe cases, these changes are compounded by elevated levels of plasminogen activation inhibitor type 1, which impairs fibrinolysis, as well as by deficiencies in physiological inhibitors of coagulation (including antithrombin, proteins C and S, and tissue factor-pathway inhibitor). Antithrombin and protein C have a number of anti-inflammatory properties, whereas thrombin is pro-inflammatory. This procoagulant state can lead to end-artery thrombosis and digital and mesenteric ischaemia. Following clot formation, plasminogen is converted to plasmin, which breaks down thrombus, liberating fibrin/fibrinogen degradation products (FDPs). Fibrin formation and fibrinolysis continue unabated and in parallel, leading to a ‘consumptive’ coagulopathy known as *disseminated intravascular coagulation (DIC)*. Circulating levels of FDPs and D-dimers are therefore increased, the thrombin time, PTT and PT are prolonged, and platelet and fibrinogen levels fall. Clinically, the patient will bleed from trivial venepuncture sites but, paradoxically, may still be at risk of thrombosis. Activation of the coagulation cascade can be confirmed by demonstrating increased plasma levels of D-dimers. The development of DIC often heralds the onset of multiple organ failure. In some cases, a microangiopathic haemolytic anaemia develops. DIC is relatively uncommon but is associated particularly with septic shock, especially when due to meningococcal infection (see p. 281). Management of the *underlying cause* is most urgent. Supportive treatment may include infusions of fresh frozen plasma, platelets, cryoprecipitate when fibrinogen levels are low, and occasionally factor VIII concentrates.

**Clinical features of shock and sepsis**

Although many clinical features are common to all types of shock, the causes may be distinguished by the associated haemodynamic changes (*Box 25.10*) and by examination.

**Box 25.10**

**Haemodynamic changes in shock**

**Hypovolaemic shock**
Low central venous pressure (CVP) and pulmonary artery occlusion pressure (PAOP)
- Low cardiac output
- Increased systemic vascular resistance

**Cardiogenic shock**

**Signs of myocardial failure**
- Increased systemic vascular resistance
- CVP and PAOP high (except when hypovolaemic)

**Cardiac tamponade**

**Parallel increases in CVP and PAOP**
- Low cardiac output
- Increased systemic vascular resistance

**Pulmonary embolism**

**Low cardiac output**
- High CVP, high pulmonary artery pressure but low PAOP
- Increased systemic vascular resistance

**Anaphylaxis**

**Low systemic vascular resistance**
- Low CVP and PAOP
- High cardiac output

**Septic shock**

**Low systemic vascular resistance**
- Low CVP and PAOP
- Cardiac output usually high
- Myocardial depression – low ejection fraction
- Stroke volume maintained by ventricular dilatation
- Cardiac output maintained or increased by tachycardia

**Hypovolaemic shock**

- **Inadequate tissue perfusion:**
  - Skin: cold, pale, slate-grey, slow capillary refill, ‘clammy’.
  - Kidneys: oliguria, anuria.
  - Brain: drowsiness, confusion and irritability.

- **Increased sympathetic tone:**
– Tachycardia, narrowed pulse pressure, ‘weak’ or ‘thready’ pulse.
– Sweating.
– Blood pressure: may be maintained initially (despite up to a 25% reduction in circulating volume if the patient is young and fit) but hypotension later supervenes.

• **Lactic acidosis:** compensatory tachypnoea.
  Extreme hypovolaemia may be associated with bradycardia.

**Cardiogenic shock**
The signs in cardiogenic shock (see p. 989) are the same as for hypovolaemic shock, with the addition of myocardial failure: for example, raised jugular venous pressure (JVP), pulsus alternans, ‘gallop’ rhythm, basal crackles and pulmonary oedema.

**Obstructive shock**
Again, the signs are as for hypovolaemic shock with the following additions:
• Elevated JVP.
• Pulsus paradoxus and muffled heart sounds in cardiac tamponade.
• Perhaps signs of pulmonary embolism (see pp. 1031–1035).

**Distributive shock: anaphylactic shock (See pp. 143–144.)**
• Signs of profound vasodilatation:
  – Warm peripheries.
  – Low blood pressure.
  – Tachycardia.
• Erythema, urticaria, angio-oedema, pallor, cyanosis.
• Bronchospasm, rhinitis.
• Oedema of the face, pharynx and larynx.
• Pulmonary oedema.
• Hypovolaemia due to vascular leak.
• Nausea, vomiting, abdominal cramps, diarrhoea.
  Ideally, 10 mL of clotted blood should be taken within 45–60 minutes of the reaction for confirmation of the diagnosis: for example, by measurement of mast cell tryptase. Serum should be separated and stored at −20°C. Follow-up of these patients is essential.

**Distributive shock: sepsis and septic shock (see p. 221)**

**Definition of sepsis (adapted from 3rd International Consensus: Sepsis-3)**
• *Sepsis* is defined as life-threatening organ dysfunction caused by a dysregulated host response to infection.
Organ dysfunction can be identified by an acute change in the Sequential Organ Failure Assessment score (SOFA) of >2 points following infection. The baseline SOFA score can be assumed to be zero in patients not known to have pre-existing organ dysfunction. However, a SOFA score ≥2 reflects an overall mortality risk of approximately 10% in a general hospital population with suspected infection. Patients presenting with modest dysfunction can deteriorate further.

The SOFA severity score ([http://clincalc.com/IcuMortality/SOFA.aspx](http://clincalc.com/IcuMortality/SOFA.aspx)) is derived from:

- Respiratory system – the ratio of arterial oxygen tension to fraction of inspired oxygen \( \left( \frac{\text{PaO}_2}{\text{FiO}_2} \right) \)
- Cardiovascular system – amount of vasoactive medication necessary to prevent hypotension
- Hepatic system – bilirubin level
- Coagulation system – platelet concentration
- Neurologic system – Glasgow coma score (see p. 825)
- Renal system – serum creatinine or urine output

The mean and the highest scores are most predictive of mortality. An increase of 30% is associated with a high mortality of about 50%. (This score has been endorsed by the Society of Critical Care Medicine (SCCM) and the European Society of Intensive Care Medicine (ESICM) as a tool to facilitate the identification of patients at risk of dying from sepsis.)

A quick SOFA (qSOFA), which is derived from an alteration in mental status (Glasgow coma score), a systolic blood pressure of <100 mmHg or a respiratory rate of >22/min, can be quickly done at the bedside and can identify a patient with suspected infection likely to have a prolonged stay in ICU.

**Septic shock** is a subset of sepsis in which underlying circulatory and cellular/metabolic abnormalities are profound enough to substantially increase mortality.

- Patients with septic shock can be identified with a clinical construct of sepsis with persisting hypotension requiring vasopressors to maintain MAP (mean arterial pressure) ≥65 mmHg and having a serum lactate level >2 mmol/L (18 mg/dL) despite adequate volume resuscitation. With these criteria, hospital mortality is in excess of 40%.

**Symptoms and signs**

- Pyrexia and rigors, or hypothermia (unusual, but more common in the elderly and associated with worse prognosis).
- Nausea, vomiting.
- Vasodilatation, warm peripheries.
- Bounding pulse.
- Rapid capillary refill.
- Hypotension, low diastolic pressure, widened pulse pressure.
• Occasionally, signs of cutaneous vasoconstriction.
• Other signs:
  – Jaundice.
  – Coma, stupor.
  – Bleeding due to coagulopathy (e.g. from vascular puncture sites, gastrointestinal tract and surgical wounds).
  – Rash and meningism.
  – Hyperglycaemia; in more severe cases, hypoglycaemia.

The diagnosis of sepsis is easily missed, particularly in the elderly, when the classical signs may not be present. Some clues to the diagnosis may include mild confusion, tachycardia, tachypnoea, unexplained hypotension, a reduction in urine output, a rising plasma creatinine and glucose intolerance.

The clinical signs of sepsis (triggered by PAMPS) are not always associated with invasive infection and can occur with non-infectious processes such as pancreatitis, cardiopulmonary bypass, severe trauma or major surgery (triggered by DAMPS; see p. 1152). The term ‘systemic inflammatory response syndrome’ (SIRS) has been superseded in favour of SOFA, which has a better predictive value for in-hospital mortality.

Sepsis and multiple organ failure (multiple organ dysfunction syndrome)

Sepsis is being diagnosed with increasing frequency and is now the most common cause of death in non-coronary adult ICUs. The estimated incidence of severe sepsis has varied from 77 to 300 cases per 100 000 of the population. The most common cause is community-acquired pneumonia (Fig. 25.22). Mortality rates are high (between 20% and 60%) and are closely related to the severity of illness and the number of organs that fail. Although some early deaths are caused by cardiovascular collapse, advances in ICU care and supportive therapy have reduced early deaths, and now most of those who die are overwhelmed by persistent or recurrent sepsis, with fever, intractable hypotension and failure of several organs.
Sequential failure of vital organs occurs progressively over days or weeks, although the pattern of organ dysfunction is variable. In many cases, the lungs are the first to be affected (acute respiratory distress syndrome, ARDS; see below) in association with cardiovascular instability and deteriorating renal function. Secondary pulmonary infection, complicating ARDS, frequently acts as a further stimulus to the immune response.

Liver dysfunction may develop later. Gastrointestinal failure, with an inability to tolerate enteral feeding and paralytic ileus, is common. Ischaemic colitis, acalculous cholecystitis, pancreatitis and gastrointestinal haemorrhage may also occur. Features of central nervous system dysfunction include impaired consciousness and disorientation, progressing to coma. Characteristically, these patients initially have a hyperdynamic circulation with vasodilatation and a high cardiac output, associated with an increased metabolic rate. Eventually, however, cardiovascular collapse supervenes. It is now often possible to support such patients for weeks or months; most now die following a decision to withdraw or not to escalate treatment (see pp. 1171–1172).

Metabolic response to trauma, major surgery and severe infection

This response (Box 25.11) is initiated and controlled by the neuroendocrine system and various cytokines (e.g. IL-6) acting in concert, and is characterized initially by an increase in energy expenditure (‘hypermetabolism’; see also p. 212). Gluconeogenesis is stimulated by increased glucagon and catecholamine levels, while hepatic mobilization of glucose from
glycogen is increased. Catecholamines inhibit insulin release and reduce peripheral glucose uptake. Combined with elevated circulating levels of other insulin antagonists such as cortisol, and downregulation of insulin receptors, these changes mean that the majority of patients are hyperglycaemic (‘insulin resistance’). Later, hypoglycaemia may be precipitated by depletion of hepatic glycogen stores and inhibition of gluconeogenesis. Free fatty acid synthesis is also increased, leading to hypertriglyceridaemia.

### Box 25.11

**The metabolic response to trauma, major surgery and severe infection**

- ↑ Energy expenditure
- ↑ Gluconeogenesis
- ↑ Mobilization of glucose from glycogen
- Insulin resistance and hyperglycaemia
- ↑ Free fatty acid synthesis
- ↑ Protein breakdown
- ↑ Liver synthesis of acute phase reactants

Protein breakdown is initiated to provide energy from amino acids, and hepatic protein synthesis is preferentially augmented to produce the ‘acute phase reactants’. The amino acid glutamine (which is indispensable in this situation) is mobilized from muscle for use as a metabolic fuel in rapidly dividing cells such as leucocytes and enterocytes. Glutamine is also required for hepatic production of the free radical scavenger glutathione. When severe and prolonged, this catabolic response can lead to considerable weight loss. Protein breakdown is associated with wasting and weakness of skeletal and respiratory muscle, prolonging the need for mechanical ventilation and delaying mobilization. Tissue repair, wound healing and immune function are also compromised.

### Management of shock and sepsis

A delay in recognizing a shocked patient and in initiating resuscitation and specific treatments ([Fig. 25.23](#)) (particularly antibiotics when infection is the underlying cause) is associated with substantially increased morbidity and mortality.
A patent airway must be maintained and oxygen given, as is standard for any acutely ill patient. If necessary, an oropharyngeal airway is inserted to alleviate oropharyngeal obstruction. Some patients may require insertion of an endotracheal tube to prevent aspiration of gastric contents, and those with impending respiratory arrest will require immediate mechanical ventilation.

The underlying cause of shock should be sought and corrected where possible; for example, haemorrhage should be controlled or infection eradicated. In patients with septic shock, every effort must be made to identify the source of infection and isolate the causative organism. A thorough history, clinical examination and imaging (X-rays, ultrasonography or computed...
tomography (CT) scanning) should be undertaken. Appropriate samples (urine, sputum, cerebrospinal fluid (CSF), pus drained from abscesses) should be taken for microscopy, culture and sensitivities. Several blood cultures should be performed and empirical, broad-spectrum antibiotic therapy (see pp. 234–245) should be commenced within the first hour of recognition of sepsis. If an organism is isolated later, therapy can be adjusted appropriately. The choice of antibiotic depends on the likely source of infection, previous antibiotic therapy and known local resistance patterns, as well as on whether infection was acquired in hospital or in the community. Abscesses must be drained and infected indwelling catheters removed.

Whatever the aetiology of the haemodynamic abnormality:

- **Tissue blood flow** must be restored promptly by achieving and maintaining an adequate cardiac output.

- **Arterial blood pressure** must be sufficient to maintain perfusion of vital organs.

- **Published guidelines** for adult patients suffering septic shock should be followed. These advocate targeting a mean arterial pressure (MAP) of >65 mmHg, CVP of 8–12 mmHg (>12 mmHg if mechanically ventilated), a urine output of >0.5 mL/kg per hour and an $S_{\text{cv}}O_2$ of ≥70% (or $S_{\text{v}}O_2$ of ≥65%) as the initial goals of resuscitation.

**Preload and volume replacement**

Optimizing preload is the most efficient way of increasing cardiac output. Volume replacement is obviously essential in hypovolaemic shock but is also required in anaphylactic and septic shock because of vasodilatation, sequestration of blood and loss of circulating volume because of vascular leak.

In obstructive shock, high filling pressures may be required to maintain an adequate stroke volume. Even in cardiogenic shock, careful volume expansion may, on occasions, lead to a useful increase in cardiac output. On the other hand, patients with severe cardiac failure, in whom ventricular filling pressures are markedly elevated, often benefit from measures to reduce preload (and afterload), such as the administration of vasodilators and diuretics (see below). Adequate perioperative volume replacement also reduces morbidity and mortality in high-risk surgical patients.

The circulating volume must be replaced quickly (in minutes, not hours) in order to reduce tissue damage and prevent acute kidney injury. Fluid is administered via wide-bore intravenous cannulae to allow large volumes to be given quickly, and the effect is continuously monitored. This involves observing improvements in clinical signs (urine output, consciousness, peripheral perfusion), biochemical variables (falling lactate levels) or increases in stroke volume using the methods discussed earlier (e.g. arterial waveform analysis).

Volume overload, which leads to cardiac dilatation, a reduction in stroke volume, a risk of pulmonary oedema and compromised renal perfusion, must be avoided. Pulmonary and peripheral oedema is more likely in seriously ill patients receiving large-volume fluid resuscitation because of a low colloid osmotic pressure (usually due to a low serum albumin),
disruption of the alveolar–capillary membrane, microcirculatory changes and destruction of the endothelial glycocalyx.

**Choice of fluid for volume replacement**

**Blood**

This is conventionally given for haemorrhagic shock as soon as it is available. In extreme emergencies, group-specific crossmatch can be performed in minutes (see p. 555). When available and not contraindicated, blood salvage may be employed for those with severe ongoing bleeding. Unmatched blood is frequently administered in trauma patients presenting *in extremis* to the emergency department.

Transfusion of whole blood has largely been replaced by red cell concentrates (see p. 559). The use of leucodepleted blood is considered to be safer in terms of immune-mediated transfusion reactions, disease transmission and immune suppression. Although red cell transfusion can augment oxygen-carrying capacity, and hence global oxygen delivery, transfusion of old stored red blood cells, which become spherical rather than biconcave, and poorly deformable with increased adhesiveness, can compromise microvascular flow. Moreover, the precise objective of blood transfusion will differ depending on the circumstance. In the case of traumatic or intraoperative haemorrhagic shock, many now favour ‘hypotensive resuscitation’ until surgical control of the bleeding has been achieved. This partial resuscitation has been shown to reduce the rate of bleeding and allows the surgeon a greater chance of achieving definitive haemostasis. Once the patient is stable, higher haemoglobin and blood pressure targets may be pursued.

The absolute haemoglobin target in critically ill patients has changed with increasing awareness of the subtle detrimental immune effects associated with transfusing allogeneic blood. In patients not actively bleeding and without significant cardiovascular risk factors, it is usual to transfuse in order to achieve a target haemoglobin level of ≥70 g/L (‘restrictive transfusion strategy’). In patients with significant coronary artery disease or limited respiratory reserve, a target level of 90 g/L (‘liberal transfusion strategy’) may be more appropriate. Previously healthy individuals can tolerate haemoglobin levels as low as 40 g/L before displaying signs of cardiac ischaemia.

**Massive blood transfusion** can be defined as a volume of >8–10 units of red cells transfused within a 24-hour period, and **massive haemorrhage** as a loss of ≥50% of blood volume within 3 hours or a rate of blood loss exceeding 150 mL/min.

Complications of blood transfusion are discussed on pages 555–559.

Special problems arise as a result of massive transfusion:

- **Temperature changes.** Bank blood is stored at 4°C; transfusion may result in hypothermia, peripheral vеноconstriction (which slows the rate of infusion) and arrhythmias. If possible, blood should be warmed during massive transfusion and in those at risk of hypothermia (e.g. during prolonged major surgery with open body cavity).

- **Coagulopathy.** Stored blood has virtually no effective platelets or clotting factors. Massive
transfusions that frequently include large volumes of colloid/crystalloid can therefore contribute to a coagulopathy that often needs to be treated by replacing clotting factors with fresh frozen plasma and administering platelet concentrates. Many massive transfusion protocols now advocate a balanced ratio of transfusion of units of red cells to units fresh frozen plasma to units platelets (e.g. 1 : 1 : 1), especially in the treatment of severe traumatic haemorrhage. Cryoprecipitate may also play a key role in securing haemostasis. Recombinant factor VIIa may occasionally be indicated in those with uncontrollable bleeding. Prothrombin complex concentrates have some advantages compared with FFP, in that they do not need to be crossmatched or thawed.

**Hypocalcaemia.** Citrate in stored blood binds calcium ions. During rapid transfusion, total body ionized calcium levels may be reduced, causing myocardial depression and exacerbating coagulation defects. This is uncommon in practice but can be corrected by administering 10 mL of 10% calcium chloride intravenously. Routine treatment with calcium is not recommended.

**Increased oxygen affinity.** In stored blood, the red cell 2,3-bisphosphoglycerate (2,3-BPG) content is reduced, so that the oxyhaemoglobin dissociation curve is shifted to the left. The oxygen affinity of haemoglobin is therefore increased and oxygen unloading is impaired. Red cell levels of 2,3-BPG are substantially restored within 12 h of transfusion.

**Hyperkalaemia.** Plasma potassium levels rise progressively as blood is stored. However, hyperkalaemia is rarely a problem, as rewarming of the blood increases red cell metabolism; the sodium pump becomes active and potassium levels fall.

**Microembolism.** Microaggregates in stored blood may obstruct the pulmonary capillaries. This process is thought by some to contribute to acute lung injury.

**Immunity.** Blood transfusion has subtle detrimental effects on the host immune system and has been implicated in an increased susceptibility to develop nosocomial infections and an increase in the risk of cancer recurrence.

### Crystalloids and colloids

The choice of intravenous fluid for resuscitation and the relative merits of crystalloids or colloids have long been controversial. Crystalloid solutions are cheap and convenient to use. However, they are not completely free of side-effects, as large volumes of solutions with high chloride content, such as 0.9% saline, can cause a hyperchloraemic acidosis and are associated with a greater risk of renal impairment. Balanced solutions, such as compound sodium lactate or plasmalyte, may be preferred (see Box 9.8).

In critically ill patients, resuscitation with equivalent volumes of either 0.9% saline or the colloid 4% albumin has been shown to result in similar outcomes.

**Polygelatin solutions** have an average molecular weight of 35,000, which is iso-osmotic with plasma. They are cheap and do not interfere with crossmatching. Large volumes can be administered, as clinically significant coagulation defects are unusual and renal function is not significantly impaired. However, because they readily cross the glomerular basement
membrane, their half-life in the circulation is only approximately 4 hours and they can promote an osmotic diuresis. These solutions may be useful during the acute phase of resuscitation, especially when volume losses are continuing. Allergic reactions can, however, occur.

**Hydroxyethyl starches (HES)** are available as numerous preparations with differing half-lives. Elimination of HES occurs primarily via the kidneys following hydrolysis by amylase. HES are stored in the reticuloendothelial system, apparently without causing functional impairment, but skin deposits have been associated with persistent pruritus. HES, especially the higher-molecular-weight fractions, have anticoagulant properties, can increase the risk of acute kidney injury and have been associated with an increased mortality. **HES should no longer be used in critically ill patients.**

**Human albumin solution (HAS)** is a natural colloid that has been used for volume replacement in shock and burns, and for the treatment of hypoproteinaemia. HAS is not generally recommended for routine volume replacement because supplies are limited and other cheaper solutions are equally effective. Some use HAS to expand the circulating volume in patients who are hypoalbuminaemic.
Myocardial contractility and inotropic agents

Myocardial contractility can be impaired by many factors, such as hypoxaemia and hypocalcaemia, as well as by some drugs (e.g. beta-blockers, antiarrhythmics and sedatives).

**Severe metabolic acidosis** conventionally is said to depress myocardial contractility and limit the response to vasopressor agents. Attempted correction of acidosis with intravenous sodium bicarbonate, however, generates additional carbon dioxide, which diffuses across cell membranes, producing or exacerbating intracellular acidosis. Other disadvantages of bicarbonate therapy include sodium overload and a left shift of the oxyhaemoglobin dissociation curve. Ionized calcium levels may be reduced and, combined with the fall in intracellular pH, this may impair myocardial performance. Treatment of lactic acidosis should therefore concentrate on correcting the cause. Bicarbonate should only be administered to correct **extreme persistent metabolic acidosis** (see pp. 179–180).

If the signs of shock persist despite adequate volume replacement, and perfusion of vital organs is jeopardized, inotropic/vasopressor agents should be administered to improve cardiac output and blood pressure. Vasopressor therapy may also be required to maintain perfusion in those with life-threatening hypotension, even when volume replacement is incomplete. All inotropes increase myocardial oxygen consumption, particularly if a tachycardia develops, and this can lead to an imbalance between myocardial oxygen supply and demand, with the development or extension of ischaemic areas. Inotropes should therefore be used with especial caution, particularly in cardiogenic shock following myocardial infarction and in known ischaemic heart disease.

Many of the most seriously ill patients become increasingly resistant to the effects of pressor agents, an observation attributed to ‘downregulation’ of adrenergic receptors and nitric oxide-induced ‘vasoplegia’ (see p. 1159).

All inotropic agents should be administered via a large central vein and their effects continually monitored (Box 25.12).

Adrenaline (epinephrine)
Adrenaline stimulates both α- and β-adrenergic receptors but β effects predominate at low doses. Heart rate and cardiac index increase, while peripheral resistance is reduced. If there is an associated increase in perfusion pressure, urine output may improve. Adrenaline at higher doses can cause excessive (α-mediated) vasoconstriction with reductions in splanchnic flow, and cardiac output may fall. Prolonged high-dose administration can cause peripheral gangrene and lactic acidosis. The minimum effective dose of adrenaline should therefore be used for as short a time as possible.

Noradrenaline (norepinephrine)
This is predominantly an α-adrenergic agonist. It is particularly useful in patients with
hypotension and a low systemic vascular resistance, such as is seen in septic shock. There is a risk of producing excessive vasoconstriction with impaired organ perfusion and increased afterload, particularly if noradrenaline is administered when fluid resuscitation is inadequate and the circulating volume is reduced.

**Dopamine**
The haemodynamic effects of dopamine are dose-dependent. At low doses, dopamine is a positive inotrope with vasodilator actions on the renal and splanchnic circulation. Higher doses may be complicated by tachycardia, arrhythmias and vasoconstriction. Dopamine may be used as an alternative to noradrenaline in patients with a low risk of tachyarrhythmia and absolute or relative bradycardia.

**Dopexamine**
Dopexamine is an analogue of dopamine that activates $\beta_2$ receptors, as well as DA$_1$ and DA$_2$ receptors. Dopexamine is a weak positive inotrope but a powerful splanchnic vasodilator, reducing afterload and improving blood flow to vital organs, including the kidneys. It has been used as an adjunct to the perioperative management of high-risk surgical patients (see below).

**Dobutamine**
Dobutamine is closely related to dopamine and has predominantly $\beta_1$ activity. Dobutamine has no specific effect on the renal vasculature but urine output often increases as cardiac output and blood pressure improve. It reduces systemic vascular resistance, as well as improving cardiac performance, thereby decreasing afterload and ventricular filling pressures. Dobutamine is therefore useful in patients with cardiogenic shock and cardiac failure. In septic shock, it can be used to increase cardiac output and oxygen delivery.

**Phosphodiesterase inhibitors (e.g. milrinone, enoximone)**
These agents have both inotropic and vasodilator properties. Because the phosphodiesterase type III inhibitors bypass the $\beta$-adrenergic receptor they do not cause tachycardia and are less arrhythmogenic than $\beta$ agonists. They are useful in patients with receptor ‘downregulation’, those receiving beta-blockers, those being weaned from cardiopulmonary bypass and those with cardiac failure.

**Vasopressin**
Patients with septic shock have inappropriately low circulating levels of vasopressin. Low-dose vasopressin can increase blood pressure and systemic vascular resistance in patients with vasodilatory septic shock and a high cardiac output unresponsive to other vasopressors (‘vasoplegia’). Low-dose vasopressin is sometimes added to conventional vasopressors in patients with septic shock.

**Levosimendan**
Levosimendan is a myofilament calcium sensitizer. Unlike other inotropes, levosimendan does not exert its action through increases in intracellular Ca\(^{2+}\) and, as a result, does not impair diastolic relaxation of the heart. Levosimendan binds to troponin C with high affinity but only during systole when the intracellular calcium concentration is high. Levosimendan has phosphodiesterase inhibitor actions but these are not thought to be clinically significant. The dose is usually infused over 24 hours but, significantly, a long-acting metabolite of levosimendan has similar calcium-sensitizing actions, maintaining the inotropic effect of levosimendan once an infusion is stopped. Adverse cardiovascular effects of levosimendan include tachycardia and hypotension; as a consequence, the addition of a vasopressor may be required.

**Summary for use of inotropic and vasopressor agents**

A combination of dobutamine and noradrenaline (norepinephrine) is used for the management of patients who are *shocked with a low systemic vascular resistance* (e.g. septic shock).

- Dobutamine is given to achieve an optimal cardiac output.
- Noradrenaline, sometimes supplemented by vasopressin, is used to restore an adequate blood pressure by reducing vasodilatation.

In *vasodilated septic patients* with an adequate cardiac output, noradrenaline can be used alone. There is evidence to suggest that adrenaline (epinephrine) may be equally safe and effective as a dobutamine/noradrenaline combination. Because of its potency, adrenaline is particularly useful in patients with *refractory hypotension*. Phosphodiesterase inhibitors can be used in the management of cardiac failure, especially when associated with pulmonary hypertension, and perioperatively in those undergoing cardiac surgery. Dobutamine is an alternative that is also used in septic patients with fluid overload or myocardial failure. Dopamine is used much less frequently than in the past. The role of levosimendan in the management of shock has yet to be established but it may be useful in resistant cardiogenic shock.

**Targeting haemodynamics and oxygen transport**

Although resuscitation has conventionally aimed at achieving normal haemodynamics, many of the critically ill patients that survive have raised values for cardiac output, \(DO_2\) and \(VO_2\). However, elevation of \(DO_2\) and \(VO_2\) to these ‘supranormal’ levels following admission to intensive care produces no benefit and may be harmful. *Early* goal-directed therapy to resuscitate patients in the emergency room, aimed at maintaining a central venous oxygen saturation of more than 70%, does not appear to improve outcome in patients with severe sepsis or septic shock.

**High-risk surgical patients**

These patients benefit from intensive perioperative monitoring and circulatory support (*Box 25.13*). In particular, maintenance of an adequate circulating volume and postoperative
admission to a critical care area are advocated. Many believe that volume replacement and administration of inotropes or vasopressors should be guided by monitoring of stroke volume/cardiac output, usually using an oesophageal Doppler or pulse contour analysis. The value of the routine use of inodilators such as dopexamine remains unclear.

**Box 25.13**

**Patients at risk of developing perioperative multiorgan failure**

- The elderly
- Patients with co-morbidity, especially limited cardiorespiratory reserve
- Patients with trauma to two body cavities requiring multiple blood transfusions
- Patients undergoing surgery involving extensive tissue dissection, e.g. oesophagectomy, pancreatectomy, aortic aneurysm surgery
- Patients undergoing emergency surgery for intra-abdominal or intrathoracic catastrophic states, e.g. faecal peritonitis, oesophageal perforation

**Vasodilator therapy**

In selected cases, afterload reduction is used to increase stroke volume and decrease myocardial oxygen requirements by reducing the systolic ventricular wall tension. Vasodilatation (see p. 987) also decreases heart size and the diastolic ventricular wall tension, so that coronary blood flow is improved. The relative magnitude of the falls in preload and afterload depends on the pre-existing haemodynamic disturbance, concurrent volume replacement and the agent selected (see below). Vasodilators also improve microcirculatory flow.

Vasodilator therapy can be particularly helpful in patients with cardiac failure in whom the ventricular function curve is flat (see Fig. 25.7), so that falls in preload have only a limited effect on stroke volume. This form of treatment, combined in selected cases with inotropic support, is therefore useful in cardiogenic shock and in the management of patients with cardiogenic pulmonary oedema or mitral regurgitation.

- **Sodium nitroprusside** (SNP) dilates arterioles and venous capacitance vessels, as well as the pulmonary vasculature, by donating nitric oxide. SNP therefore reduces the afterload and preload of both ventricles and can improve cardiac output and the myocardial oxygen supply/demand ratio. The effects of SNP are rapid in onset and spontaneously reversible within a few minutes of discontinuing the infusion. Cyanide poisoning is a risk with high-dose, prolonged infusions.

- **Nitroglycerine** (NTG), at low doses, is predominantly a venodilator, but as the dose is increased, it also causes arterial dilatation, thereby decreasing both preload and afterload. Nitrates are particularly useful in the treatment of cardiac failure with pulmonary oedema and are usually used in combination with intravenous furosemide. NTG reduces pulmonary
vascular resistance, an effect that can be exploited in patients with a low cardiac output secondary to pulmonary hypertension.

**Mechanical support of the myocardium**

Intra-aortic balloon counterpulsation (IABCP) is the technique used most widely for mechanical support of the failing myocardium. It is discussed on pages 961–962. In specialized centres, ventricular assist devices and veno-arterial extra-corporeal membrane oxygenation (ECMO; see below) may be used in the treatment of cardiac failure.

**Adjunctive treatment**

Initial attempts to combat the high mortality associated with sepsis concentrated on cardiovascular and respiratory support in the hope that surgery, antibiotics and the patient's own defences would eradicate the infection. Despite some success, mortality rates remained unacceptably high. So far, attempts to improve outcome by modulating the immune response (including high-dose steroids) or neutralizing endotoxin *(Box 25.14)* have proved disappointing and, in some cases, may even have been harmful.

---

**Box 25.14**

**Some therapeutic strategies for sepsis tested in randomized, controlled, phase II/III trials**

- Granulocyte–monocyte colony stimulating factor
- Toll-like receptor/endotoxin antagonists
- Bactericidal permeability-increasing protein
- Tissue necrosis factor (TNF) antibodies
- Soluble TNF receptors
- Interleukin-1 receptor antagonists
- Platelet-activating factor antagonists
- Nitric oxide synthase inhibition
- Antithrombin III
- Activated protein C
- Low-dose steroids

The administration of relatively low ‘stress’ doses of hydrocortisone to selected patients with refractory vasopressor-resistant septic shock may assist shock reversal and perhaps improve outcome.

The **aim of current sepsis guidelines** (see ‘Further reading’) is to combine evidence-based interventions with early effective resuscitation (aimed especially at achieving an adequate
circulating volume, combined with the rational use of inotropes and/or vasoactive agents to maintain blood pressure, cardiac output and oxygen transport), in order to create ‘bundles of care’ delivered within specific time limits.

Respiratory Failure

(See also Chapter 24.)

Classification and aetiology

The respiratory system consists of a gas-exchanging organ (the lungs) and a ventilatory pump (respiratory muscles/thorax), either or both of which can fail and precipitate respiratory failure. Respiratory failure occurs when pulmonary gas exchange is sufficiently impaired to cause hypoxaemia with or without hypercarbia. In practical terms, respiratory failure is present when the $P_{a}O_{2}$ is $<8$ kPa (60 mmHg) or the $P_{a}CO_{2}$ is $>7$ kPa (55 mmHg). It can be divided into:

• type I respiratory failure, in which the $P_{a}O_{2}$ is low and the $P_{a}CO_{2}$ is normal or low

• type II respiratory failure, in which the $P_{a}O_{2}$ is low and the $P_{a}CO_{2}$ is high.

**Type I or ‘acute hypoxaemic’ respiratory failure** occurs with diseases that damage lung tissue. Hypoxaemia is due to right-to-left shunts or $\bar{V}/\bar{Q}$ mismatch. Common causes include pneumonia, acute lung injury, cardiogenic pulmonary oedema and lung fibrosis.

**Type II or ‘ventilatory failure’** occurs when alveolar ventilation is insufficient to remove the volume of carbon dioxide being produced by tissue metabolism. Inadequate alveolar ventilation may be due to reduced ventilatory effort, inability to overcome an increased resistance to ventilation, failure to compensate for an increase in dead space and/or carbon dioxide production, or a combination of these factors. The most common cause is COPD. Other causes include chest-wall deformities, respiratory muscle weakness (e.g. Guillain–Barré syndrome) and depression of the respiratory centre (e.g. drug overdose).

Deterioration in the mechanical properties of the lungs and/or chest wall increases the work of breathing and the oxygen consumption/carbon dioxide production of the respiratory muscles. Respiratory muscle fatigue is a factor in the pathogenesis of respiratory failure.

Clinical assessment

The general assessment and recognition of an acutely ill ward patient have been discussed above on pages 1139–1140. A clinical assessment of respiratory distress should be made on the following criteria:

• the use of accessory muscles of respiration

• intercostal recession

• tachypnoea

• tachycardia

• sweating

• pulsus paradoxus (rarely present)
• inability to speak, unwillingness to lie flat
• agitation, restlessness, diminished conscious level
• asynchronous respiration (a discrepancy in the timing of movement of the abdominal and thoracic compartments)
• paradoxical respiration (abdominal and thoracic compartments move in opposite directions)
• respiratory alternans (breath-to-breath alteration in the relative contribution of intercostal/accessory muscles and the diaphragm).

**Blood gas analysis** should be performed to guide oxygen therapy and to provide an objective assessment of the severity of the respiratory failure. The most sensitive clinical indicator of increasing respiratory difficulty is a rising respiratory rate. Measurement of **tidal volume** is a less sensitive indicator. **Vital capacity** is often a better guide to deterioration and is particularly useful in patients with respiratory inadequacy that is due to neuromuscular problems such as the Guillain–Barré syndrome or myasthenia gravis, in which the vital capacity decreases as weakness worsens. Measurement of **forced expiratory volume in 1 second** (*FEV*₁) is useful in the assessment of patients suffering acute asthma attacks.

### Monitoring

**Pulse oximetry**

Lightweight oximeters can be applied to an earlobe or finger. They measure the changing amount of light transmitted through the pulsating arterial blood and provide a continuous, non-invasive assessment of arterial oxygen saturation (*S*ₚ*O*₂). These devices are reliable and easy to use, and do not require calibration.

Pulse oximetry is not a sensitive guide to changes in oxygenation. An *S*ₚ*O*₂ within normal limits in a patient receiving supplemental oxygen does not exclude the possibility of hypoventilation with carbon dioxide retention. Readings can be inaccurate in those with poor peripheral perfusion.

**Blood gas analysis**

Normal values of blood gas analysis are shown in **Box 25.8**. See online for examples of partially compensated respiratory alkalosis.

Errors can result from malfunctioning of the analyser or incorrect sampling of arterial blood. Disposable pre-heparinized syringes are available for blood gas analysis.

• The sample should be analysed immediately. Alternatively, the syringe should be immersed in iced water (the end having first been sealed with a cap) to prevent the continuing metabolism of white cells causing a reduction in *P*O₂ and a rise in *P*CO₂.

• Air almost inevitably enters the sample. The gas tensions within these air bubbles will equilibrate with those in the blood, thereby lowering the *P*CO₂ and usually raising the *P*O₂ of
the sample. However, provided the bubbles are ejected immediately by inverting the syringe and expelling the air that rises to the top of the sample, their effect is insignificant.

Interpretation of the results of blood gas analysis can be considered in two separate parts:

- disturbances of acid–base balance (see pp. 176 and 1149–1150)
- alterations in oxygenation.

Correct interpretation requires a knowledge of the patient’s clinical history and age, the inspired oxygen concentration and any other relevant treatment (e.g. the ventilator settings for those on mechanical ventilation or the administration of sodium bicarbonate). The oxygen content of the arterial blood is determined by the percentage saturation of haemoglobin with oxygen. The relationship between the latter and the $P_aO_2$ is determined by the oxyhaemoglobin dissociation curve (see Fig. 25.2).

$PaO_2/FI O_2$ ratio

This calculated variable is a simple approximation to the $P_{A-a}O_2$ and can be used to assess the severity of respiratory failure (see p. 1143). It is calculated by taking the arterial $PO_2$ in mmHg and dividing by the $FI O_2$ expressed as a fraction of 1. The ‘P/F’ ratio has been used to define respiratory impairment in patients with ARDS (see pp. 1167–1168).

Capnography

Continuous breath-by-breath analysis of the expired carbon dioxide concentration can be used to:

- Confirm tracheal intubation.
- Continuously monitor end-tidal $PCO_2$, which approximates to $P_aCO_2$ in normal subjects.
- Detect apparatus malfunction.
- Detect acute alterations in cardiorespiratory function (e.g. sudden fall in cardiac output).

Management

Standard management of patients with respiratory failure includes:

- administration of supplemental oxygen through a patent airway
- treatment for distal airways obstruction
- measures to limit pulmonary oedema
- control of secretions
- treatment of pulmonary infection.

The load on the respiratory muscles should be reduced by improving lung mechanics.
Correction of abnormalities that may lead to respiratory muscle weakness, such as hypophosphataemia and malnutrition, is also necessary.

**Oxygen therapy**

**Methods of oxygen administration**

Oxygen is initially given via a face mask. In the majority of patients (except those with COPD with chronically elevated $P_{a}CO_{2}$), the precise concentration of oxygen given is not vital and oxygen can therefore be given by a ‘variable performance’ device such as a simple face mask or nasal cannulae (*Fig. 25.24*).

![Fig. 25.24 Methods of administering supplemental oxygen to the unintubated patient. A. Simple face mask. B. Nasal cannulae. C. Mask with reservoir bag and non-rebreathing valve.](image)

With these devices, the inspired oxygen concentration varies from about 35% to 55%, with oxygen flow rates of between 6 and 10 L/min. Nasal cannulae are often preferred because they are less claustrophobic and do not interfere with feeding or speaking, but they can cause ulceration of the nasal or pharyngeal mucosa and the inspired oxygen concentration is diluted by mouth breathing. Higher concentrations of oxygen can be administered by using a mask with a reservoir bag attached (*Fig. 25.24C*). *Figure 25.24* should be compared with the fixed-performance mask shown in *Figure 24.25*; the oxygen concentration can be controlled with the latter and it is used in patients with COPD and chronic type II failure. The hazards of reducing hypoxic drive can be overemphasized and are less dangerous when the patient is in a critical care unit; *remember*, severe hypoxaemia is more dangerous than hypercapnia.

**Oxygen toxicity**

Experimentally, mammalian lungs have been shown to be damaged by continuous exposure to high concentrations of oxygen, but oxygen toxicity in humans is less well proven. Nevertheless, it is reasonable to assume that high concentrations of oxygen might damage the lungs, and so the lowest inspired oxygen concentration compatible with adequate arterial oxygenation should be used. Although dangerous hypoxia should never be tolerated through a fear of pulmonary oxygen toxicity, oxygen saturations between 90 and 92% are probably adequate for most
patients and there is some suggestion that targeting higher oxygen saturations using greater concentrations of inspired oxygen may be detrimental. There has also been concern that, in some circumstances (e.g., following myocardial infarction), hyperoxia associated with routine administration of supplemental oxygen may be harmful, perhaps because of associated vasoconstriction, and it is now not routinely given.

Respiratory support
If, despite the above measures, the patient continues to deteriorate or fails to improve, the institution of some form of respiratory support is necessary (Box 25.15). Non-invasive ventilation via a mask or hood (see p. 1166) can be used, particularly in respiratory failure due to COPD, but in many critically ill patients, invasive ventilation through an endotracheal tube or tracheostomy is required.

</table>
Intermittent positive pressure ventilation (IPPV) is achieved by intermittently inflating the lungs with a positive pressure delivered by a mechanical ventilator. There have been a number of refinements and modifications to the manner in which positive pressure is applied to the airway, and to the interplay between the patient's respiratory efforts and mechanical assistance (see pp. 1165–1166).

Controlled mechanical ventilation (CMV), with the abolition of spontaneous breathing, rapidly leads to atrophy of respiratory muscles, so that assisted modes that are triggered by the patient's inspiratory efforts (see below) are preferred.

The rational use of mechanical ventilation depends on a clear understanding of its potential beneficial effects, as well as the dangers.

Beneficial effects of mechanical ventilation

- **Relief from exhaustion.** Mechanical ventilation reduces the work of breathing, ‘rests’ the respiratory muscles and relieves the extreme exhaustion present in patients with respiratory failure; this exhaustion may culminate in respiratory arrest.

- **Effects on oxygenation.** Application of positive pressure can prevent or reverse atelectasis. In those with severe pulmonary parenchymal disease, the lungs may be very stiff and the work of breathing is therefore greatly increased. Under these circumstances, the institution of respiratory support significantly reduces total body oxygen consumption; consequently, $P_{a}O_{2}$ and thus $P_{a}O_{2}$ may improve. Because ventilated patients are connected to a leak-free circuit, it is possible to administer high concentrations of oxygen (up to 100%) accurately and to apply a positive end-expiratory pressure (PEEP). In selected cases, the latter may reduce shunting and increase $P_{a}O_{2}$ (see below).

- **Improved carbon dioxide elimination.** By adjusting the minute volume, the $P_{a}CO_{2}$ can usually be controlled.

Indications for mechanical ventilation

- **Acute respiratory failure,** with signs of severe respiratory distress (e.g. respiratory rate >40 breaths/min, inability to speak, patient exhaustion) persisting despite maximal therapy. Confusion, restlessness, agitation, a decreased conscious level, a rising $P_{a}CO_{2}$ (>8 kPa, >60 mmHg) and extreme hypoxaemia (<8 kPa, <60 mmHg), despite oxygen therapy, are further indications.

- **Acute ventilatory failure** due, for example, to myasthenia gravis or Guillain–Barré syndrome. Mechanical ventilation should usually be instituted when the vital capacity has fallen to 10 mL/kg or less. This will avoid complications such as atelectasis and infection, as well as preventing respiratory arrest. The tidal volume and respiratory rate are relatively insensitive indicators of respiratory failure in the above conditions and change late in the course of the disease. A high $P_{a}CO_{2}$ (particularly if rising) is an indication for urgent mechanical ventilation.

Not all patients with respiratory failure and/or a reduced vital capacity require ventilation;
clinical assessment of each individual case is essential. The patient's general condition, degree of exhaustion, level of consciousness and ability to protect the airway are often more useful than blood gas values.

Other indications include:

- postoperative ventilation in high-risk patients
- head injury: to avoid hypoxia and hypercarbia, which increase cerebral blood flow and intracranial pressure (see below)
- trauma: chest injury and lung contusion
- severe left ventricular failure with pulmonary oedema
- coma with breathing difficulties, e.g. following drug overdose.

**Institution of invasive respiratory support**

This requires tracheal intubation. If the patient is conscious, the procedure must be fully explained and written consent obtained before anaesthesia is induced. The complications of tracheal intubation are given in *Box 25.16*.

---

**Box 25.16**

**Complications of tracheal intubation**
### Complication | Comments
--- | ---
**Immediate** |  
Trauma to the upper airway  
Tube in oesophagus | Affects lips, teeth, gums, trachea  
Gives rise to hypoxia and abdominal distension  
Detected by absence of capnography trace  
Requires immediate removal, bag-mask ventilation with oxygen and re-insertion of the tracheal tube  

Tube in one or other (usually the right) main bronchus | Avoid by checking both lungs are being inflated, i.e. both sides of the chest move and air entry is heard bilaterally on auscultation  
Obtain chest X-ray to check position of tube and to exclude lung collapse

**Early** |  
Migration of the tube out of the trachea  
Leaks around the tube  
Obstruction of tube because of kinking or secretions | These are dangerous complications  
The patient becomes distressed and cyanosed, and has poor chest expansion  
The following should be performed immediately:  
- Manual inflation with 100% oxygen  
- Tracheal suction  
- Check position of tube  
- Deflation of cuff  
- Check tube for ‘kinks’ or blockage with secretions or blood (common)  
If no improvement, remove tube, ventilate with face mask and then insert new endotracheal tube

**Late** |  
Sinusitis  
Mucosal oedema and ulceration  
Laryngeal injury  
Tracheal narrowing and fibrosis  
Tracheomalacia

Intubating patients in severe respiratory failure is a hazardous undertaking and should be performed only by experienced staff. In extreme emergencies, it may be preferable to ventilate the patient by hand using an oropharyngeal airway and a face mask with added oxygen until experienced help arrives. An alternative is insertion of a laryngeal mask airway.

Intubating a critically ill patient is very different to intubating a patient in the operating theatre prior to elective surgery. The patient is usually hypoxic and hypercarbic, with increased sympathetic activity; the stimulus of laryngoscopy and intubation can precipitate dangerous arrhythmias, bradycardia and even cardiac arrest. Except in an extreme emergency, therefore, the ECG and oxygen saturation should be monitored, and the patient pre-oxygenated with 100% oxygen before intubation. Resuscitation drugs should be immediately available. If time allows, the circulating volume should be optimized and, if necessary, inotropes commenced before attempting intubation. In some cases, it is appropriate to establish intra-arterial and CVP monitoring before instituting mechanical ventilation, although many patients will not tolerate the supine or head-down position. In some deeply comatose patients, no sedation is required, but in the majority, a short-acting intravenous anaesthetic agent, usually with an opiate followed by muscle relaxation, will be necessary. Capnography must be used to confirm tracheal intubation.

**Sedation, analgesia and muscle relaxation**
Most critically ill patients will require analgesia and many will receive sedatives. The combination of an opiate with a benzodiazepine or propofol is often used to facilitate mechanical ventilation and to obtund the physiological response to stress. Heavy sedation is indicated in those with severe respiratory failure, especially since ‘lung-protective’ ventilatory strategies (see p. 1166) are inherently uncomfortable. A few may require neuromuscular blockade. It is recognized, however, that minimizing sedation levels using ‘sedation scores’ and ‘daily wakening’, or even the avoidance of sedatives altogether, often in combination with spontaneous breathing modes of respiratory support (see pp. 1165–1166), is associated with reductions in the duration of mechanical ventilation and more rapid discharge from the ICU and hospital.

**Tracheostomy**

Tracheostomy may be required for the long-term control of excessive bronchial secretions, and in those with a chronically reduced conscious level in order to maintain an airway and protect the lungs if pharyngeal and laryngeal reflexes are impaired. Tracheostomy is also performed when intubation is likely to be prolonged, for patient comfort, reduction of sedation requirements and facilitation of weaning from mechanical ventilation.

Tracheostomy was once performed only in the operating room by a surgeon but it is now usual for this procedure to be carried out by intensive care specialists in the ICU using a percutaneous dilatational approach. This approach is quicker, less resource-intensive, safe and associated with a greatly reduced wound infection rate.

A life-threatening obstruction of the upper respiratory tract that cannot be bypassed with an endotracheal tube can be relieved by a *cricothyroidotomy*, which is safer, quicker and easier to perform than a formal tracheostomy.

Tracheostomy has a small but significant mortality rate. Complications associated with the technique are shown in **Box 25.17**.

---

**Box 25.17**

**Complications of tracheostomy**

The complications shown for tracheal intubation (see **Box 26.16**) plus:

**Early**

- Death
- Pneumothorax
- Haemorrhage
- Hypoxia
- Hypotension
- Cardiac arrhythmias
- Tube misplaced in pretracheal subcutaneous tissues
• Subcutaneous emphysema

**Intermediate**

• Mucosal ulceration
• Erosion of tracheal cartilages (can cause tracheo-oesophageal fistula)
• Erosion of innominate artery (occasionally leads to fatal haemorrhage)
• Stomal infection
• Pneumonia

**Late**

• Failure of stoma to heal
• Tracheal granuloma
• Tracheal stenosis at level of stoma, cuff or tube tip
• Collapse of tracheal rings at level of stoma
• Cosmetic factors

**Complications associated with mechanical ventilation**

**Airway complications**

See **Boxes 25.16** and **25.17**.

**Disconnection, failure of gas or power supply, mechanical faults**

These are unusual but dangerous. A method of manual ventilation, a face mask and oxygen must always be available by the bedside.

**Cardiovascular complications**

The application of positive pressure to the lungs and thoracic wall impedes venous return and distends alveoli, thereby ‘stretching’ the pulmonary capillaries and causing a rise in pulmonary vascular resistance. Both of these mechanisms can produce a fall in cardiac output.

**Respiratory complications**

Mechanical ventilation can be complicated by a deterioration in gas exchange because of \( \dot{V}/\dot{Q} \) mismatch, fluid retention and collapse of peripheral alveoli. Traditionally, the latter was prevented by using high tidal volumes (10–12 mL/kg) but high inflation pressures, with over-distension of compliant alveoli, perhaps exacerbated by the repeated opening and closure of distal airways, can disrupt the alveolar–capillary membrane. There is an increase in microvascular permeability and release of inflammatory mediators, leading to ‘**ventilator-associated lung injury**’. Extreme over-distension of the lungs during mechanical ventilation with high tidal volumes and high airway pressures can rupture alveoli and cause air to dissect
centrally along the perivascular sheaths. This ‘barotrauma’ and ‘volutrauma’ may be complicated by pneumomediastinum, subcutaneous emphysema, pneumoperitoneum, pneumothorax and intra-abdominal air. The risk of pneumothorax is increased in those with destructive lung disease (e.g. necrotizing pneumonia, emphysema), asthma or fractured ribs.

A tension pneumothorax can be rapidly fatal in ventilated patients. Suggestive signs include the development or worsening of hypoxia, hypercarbia, respiratory distress and an unexplained increase in airway pressure, as well as hypotension and tachycardia, sometimes accompanied by a rising CVP. Examination may reveal unequal chest expansion, mediastinal shift away from the side of the pneumothorax (deviated trachea, displaced apex beat) and a hyper-resonant hemithorax. Although breath sounds are often diminished over the pneumothorax, this sign can be misleading in ventilated patients. If there is time, the diagnosis can be confirmed by chest X-ray prior to definitive treatment with chest tube drainage.

**Ventilator-associated pneumonia**

Hospital-acquired pneumonia occurs in as many as one-third of patients receiving mechanical ventilation and is associated with a significant increase in length of stay and mortality. The diagnosis is difficult and controversial because many ventilated patients develop a pyrexia, and infiltrates on the chest X-ray that may not be infective are common. The measurement of serum procalcitonin, a marker of severe bacterial infections, may be helpful. Various organisms may be isolated, such as aerobic Gram-negative bacilli (e.g. *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, *Escherichia coli*, *Acinetobacter* spp.) and *Staphylococcus aureus*, including meticillin-resistant *Staph. aureus* (MRSA). Deciding whether an organism that has been isolated is causing ventilator-associated pneumonia or is simply colonizing the respiratory tract can also be difficult. Leakage of infected oropharyngeal secretions past the tracheal tube cuff is thought to be largely responsible for ventilator-associated pneumonia. Bacterial colonization of the oropharynx may be promoted by regurgitation of colonized gastric fluid and so the risk of ventilator-associated pneumonia can be reduced by nursing patients in the semi-recumbent, rather than the supine, position and by oropharyngeal decontamination. Treatment is with an appropriate broad-spectrum antibiotic, which can be modified if a causative organism is isolated.

**Techniques for respiratory support**

(See Box 25.15.)

**Controlled mechanical ventilation**

Controlled mechanical ventilation (CMV) is used when respiratory efforts are absent or have been abolished.

Ventilation involves one of two types:

- **Volume-controlled ventilation.** The tidal volume and respiratory rate are preset on the ventilator. The airway pressure varies according to both the ventilator setting and the patient's lung mechanics (airways resistance and compliance).
• **Pressure-controlled ventilation.** Both the inspiratory pressure and the respiratory rate are preset but the tidal volume varies according to the patient's lung mechanics.

**Positive end-expiratory pressure**

A positive airway pressure can be maintained at a chosen level throughout expiration using a threshold resistor valve in the expiratory limb of the circuit. Positive end-expiratory pressure (PEEP) re-expands under-ventilated lung units, and redistributes lung water from the alveoli to the perivascular interstitial space, thereby reducing shunt and increasing $P_{a}O_{2}$. The inevitable rise in mean intrathoracic pressure associated with the application of PEEP may, however, further impede venous return, increase pulmonary vascular resistance and reduce cardiac output. The fall in cardiac output can be ameliorated by expanding the circulating volume, although, in some cases, inotropic or vasopressor support is required. Thus, although arterial oxygenation is often improved by the application of PEEP, a simultaneous fall in cardiac output can lead to a reduction in total oxygen delivery.

Traditionally, the application of PEEP was considered only if it proved difficult to achieve adequate oxygenation of arterial blood despite raising the inspired oxygen concentration above 50%. Low levels of PEEP (5–7 cmH$_2$O) are now used in the majority of mechanically ventilated patients in order to maintain lung volume, as well as in those with basal atelectasis and in selected cases with airways obstruction.

**Continuous positive airway pressure**

The application of continuous positive airway pressure (CPAP) achieves for the spontaneously breathing patient what PEEP does for the ventilated patient. Oxygen and air are delivered under pressure via an endotracheal tube, a tracheostomy, a tightly fitting face mask or a hood *(Fig. 25.25)*. Not only can CPAP improve oxygenation, but also the lungs become more compliant and the work of breathing is reduced.
An alternative is to use a very high flow of oxygen and air delivered via large-diameter nasal prongs to create a modest amount of CPAP. This system is often better tolerated, communication is easier and the patient can eat. Commencing therapy with high-flow nasal prongs in patients with type I respiratory failure may be equivalent to, or more effective than, non-invasive ventilation in preventing patient deterioration and avoiding subsequent invasive ventilation. However the application of positive airway pressure is compromised if the patient mouth-breathes.

**Pressure support ventilation**

In pressure support ventilation (PSV), spontaneous breaths are augmented by a preset level of positive pressure (usually between 5 and 20 cmH₂O), triggered by the patient's spontaneous respiratory effort and applied for a given fraction of inspiratory time or until inspiratory flow falls below a certain level. Tidal volume is determined by the set pressure, the patient's effort and pulmonary mechanics. The level of pressure support can be reduced progressively as the patient improves.

**Intermittent mandatory ventilation**

The intermittent mandatory ventilation (IMV) technique allows the patient to breathe spontaneously between the ‘mandatory’ tidal volumes delivered by the ventilator. These mandatory breaths are timed to coincide with the patient's own inspiratory effort (synchronized intermittent mandatory ventilation, or SIMV). SIMV can be used with or without CPAP, and spontaneous breaths may be assisted with pressure support ventilation.

**‘Lung-protective’ ventilation**

This is designed to avoid exacerbating or perpetuating lung injury by avoiding over-distension of alveoli, minimizing airway pressures, and preventing the repeated opening and closure of
distal airways. Alveolar volume is maintained with PEEP, and sometimes by prolonging the inspiratory phase, while tidal volumes are limited to 6–8 mL/kg ideal bodyweight. Peak airway pressures should not exceed 35–40 cmH₂O. An alternative is to deliver a constant preset inspiratory pressure for a prescribed time in order to generate a low tidal volume at reduced airway pressures (‘pressure-limited’ mechanical ventilation). Respiratory rate can be increased to improve CO₂ removal and avoid severe acidosis (H⁺ >63 nmol/L; pH < 7.2), but hypercarbia is frequent and should usually be accepted (‘permissive hypercarbia’). Both techniques can be used with SIMV. Ventilation with low tidal volumes has been shown to improve outcome in patients with ARDS (see pp. 1168–1169). Lung-protective ventilation should be used in almost all patients undergoing mechanical ventilation.

**High-frequency oscillation**

High-frequency oscillation (HFO) is administered using a purpose-designed ventilator. With HFO, there is no bulk flow of gas; rather, gas oscillates to and fro at rates of 60–3000 cycles/min with a Vₜ of 1–3 mL/kg. Both inspiration and expiration are actively controlled with a sine wave pump. The mechanism of gas exchange is not fully understood but lung volume is well maintained and oxygenation may be improved. Whilst this is a well-established and proven treatment in the neonatal ICU, there is some doubt as to its usefulness in adults with acute respiratory failure.

**Extracorporeal gas exchange**

In patients with severe refractory respiratory failure, pumped, high-flow, veno-venous bypass through a membrane lung is used in specialized centres to achieve adequate oxygenation and increase CO₂ removal (extracorporeal membrane oxygenation, ECMO). Extracorporeal carbon dioxide removal (ECCO₂-R) is more easily administered, and uses lower flow rates to provide effective CO₂ removal but less efficient oxygenation. Both techniques have been used to reduce ventilation requirements, thereby minimizing further ventilation-induced lung damage and encouraging resolution of the lung injury.

**Non-invasive ventilation**

Non-invasive ventilation (NIV) is suitable for patients who are conscious, cooperative and able to protect their airway; they must also be able to expectorate effectively. Positive pressure is applied to the airways using a tight-fitting full-face/nasal mask or a hood. The most popular ventilators for this purpose are those that deliver bi-level positive airway pressure (BiPAP), which are simple to use, cheap and flexible. With the latter technique, inspiratory and expiratory pressure levels and times are set independently and unrestricted spontaneous respiration is possible throughout the respiratory cycle. BiPAP can also be patient-triggered. There is a reduced risk of ventilator-associated pneumonia and improved patient comfort, with preservation of airway defence mechanisms, speech and swallowing (which allows better nutrition). Spontaneous coughing and expectoration are not hampered, permitting effective
physiotherapy, and sedation is usually unnecessary. Institution of non-invasive respiratory support can rest the respiratory muscles, reduce respiratory acidosis and breathlessness, improve clearance of secretions and re-expand collapsed lung segments. The intubation rate, length of ICU and hospital stay, and, in some categories of patient, mortality may all be reduced. NIV is particularly useful in acute hypercapnic respiratory failure associated with COPD, provided the patient is not profoundly hypoxic or obtunded. NIV may also be valuable as a means of avoiding tracheal intubation in immunocompromised patients with acute respiratory failure. Evidence suggests that early NIV after extubation of hypercapnic patients with respiratory disorders can reduce the risk of subsequent respiratory failure and mortality. **Box 25.18** shows some indications for the use of NIV when standard medical treatment has failed.

**Box 25.18**

**Some indications for, and contraindications to, the use of non-invasive ventilation (NIV)**

**Indications**

- Acute exacerbation of chronic obstructive pulmonary disease (H+ >44 nmol/L; pH <7.35)
- Cardiogenic pulmonary oedema
- Chest wall deformity/neuromuscular disease (hypercapnic respiratory failure)
- Obstructive sleep apnoea
- Severe pneumonia (see **Box 24.30**)
- Asthma (occasionally)
- Weaning patients from invasive ventilation

**Some contraindications**

- Facial or upper airway surgery
- Reduced conscious level
- Inability to protect the airway

**Weaning**

Weakness and wasting of respiratory muscles are inevitable consequences of the catabolic response to critical illness and are often exacerbated by the reduction in respiratory work during mechanical ventilation (‘disuse atrophy’). Often, abnormalities of gas exchange and lung mechanics persist. Not surprisingly, therefore, many patients experience difficulty in resuming unsupported spontaneous ventilation. In a significant proportion of patients who have
undergone a prolonged period of respiratory support, the situation is further complicated by the development of a neuropathy, a myopathy or both.

**Neuromuscular weakness complicating critical illness**

Polyneuromyopathies have most often been described in association with persistent sepsis and multiple organ failure.

*Critical illness polyneuropathy* is characterized by a primary axonal neuropathy involving both motor and, to a lesser extent, sensory nerves. Clinically, the initial manifestation is often difficulty in weaning the patient from respiratory support. There is muscle wasting, the limbs are weak and flaccid, and deep tendon reflexes are reduced or absent. Cranial nerves are relatively spared. Nerve conduction studies confirm axonal damage. The CSF protein concentration is normal or minimally elevated. These findings differentiate critical illness neuropathy from Guillain–Barré syndrome, in which nerve conduction studies nearly always show evidence of demyelination and CSF protein is usually high.

The cause of critical illness polyneuropathy is not known and there is no specific treatment. Weaning from respiratory support and rehabilitation are likely to be prolonged. With resolution of the underlying critical illness, recovery can be expected after 1–6 months but weakness and fatigue frequently persist.

*Critical illness myopathies* can also occur, often in association with a neuropathy. A severe quadriplegic myopathy has been associated particularly with the administration of steroids and muscle relaxants to mechanically ventilated patients who have acute, severe asthma.

**Criteria for weaning patients from mechanical ventilation**

Clinical assessment is the best way of deciding whether a patient can be weaned from the ventilator. The patient's conscious level, mood and cardiovascular performance, as well as the effects of drugs, must all be taken into account. A subjective evaluation by an experienced clinician of the patient's response to a short period of spontaneous breathing (spontaneous breathing trial) is the most reliable predictor of weaning success or failure. Objective criteria are based on an assessment of pulmonary gas exchange (blood gas analysis), lung mechanics and muscular strength.

**Techniques for weaning**

Patients who have received mechanical ventilation for <24–48 hours, e.g. after elective major surgery, can usually resume spontaneous respiration immediately and no weaning process is required. This procedure can also be adopted for those who have been ventilated for longer periods but who tolerate a spontaneous breathing trial and clearly fulfil objective criteria for weaning. Techniques of weaning include the following:

- The traditional method is to allow the patient to breathe entirely spontaneously for a short time, following which respiratory support is resumed. The periods of spontaneous breathing are gradually increased and the periods of respiratory support are progressively reduced. Initially, it is usually advisable to ventilate the patient throughout the night. This method can
be stressful and tiring for both patients and staff, although it is sometimes successful when other methods have failed.

- SIMV (see p. 1166) involves a progressive reduction in the frequency of mandatory breaths. Spontaneous breaths are usually pressure-supported.
- Gradual reduction of the level of pressure support is thought to be the preferred technique.
- CPAP (see p. 1165–1166) can prevent the alveolar collapse, hypoxaemia and fall in compliance that might otherwise occur when patients start to breathe spontaneously. It is therefore used during weaning with SIMV or pressure support, during spontaneous breathing trials and in spontaneously breathing patients prior to extubation.
- Tracheostomy is often used to facilitate weaning from mechanical ventilation.
- Non-invasive respiratory support (BiPAP, CPAP) can be used following extubation to prevent respiratory failure and re-intubation.

**Extubation and tracheostomy decannulation**

These should not be performed until patients can cough, swallow and protect their own airway, and are sufficiently alert to be cooperative. Patients who fulfil these criteria can be extubated, provided their respiratory function has improved sufficiently to sustain spontaneous ventilation indefinitely. Similar considerations guide the elective removal of tracheostomy tubes.

The ratio of respiratory rate (in breaths/minute) to tidal volume (in litres) can be used to predict which patients will tolerate extubation, provided all other preconditions have been met. This ‘rapid shallow breathing index’ quantifies the clinical assessment of a patient who breathes slowly and comfortably with adequate tidal volumes. A score of <100 is a relatively good predictor of extubation success.

Acute Respiratory Distress Syndrome

Definition and aetiology

The acute respiratory distress syndrome (ARDS; Box 25.19) can be defined as follows:

- **Respiratory distress.**
- **Stiff lungs** (reduced pulmonary compliance resulting in high inflation pressures).
- **Chest X-ray:** new bilateral, diffuse, patchy or homogeneous pulmonary infiltrates.
- **Cardiac factors:** no apparent cardiogenic cause of pulmonary oedema (pulmonary artery occlusion pressure <18 mmHg if measured or no clinical evidence of left atrial hypertension).
- **Gas exchange abnormalities:**
  - mild: $P_{a}O_{2}/F_{I}O_{2}$ ratio 300–200 mmHg
  - moderate: $P_{a}O_{2}/F_{I}O_{2}$ 200–100 mmHg
  - severe: $P_{a}O_{2}/F_{I}O_{2}$ ratio <100 mmHg

all with a PEEP ≥5 cmH$_{2}$O (Berlin definition) (in all cases, despite normal arterial carbon dioxide tension).

ARDs can occur as a non-specific reaction of the lungs to a wide variety of direct
pulmonary and indirect non-pulmonary insults. By far the most common predisposing factor is sepsis, and 20–40% of patients with severe sepsis will develop ARDS (Box 25.19).

Pathogenesis and pathophysiology

ARDS can be viewed as an early manifestation of a generalized inflammatory response with endothelial dysfunction and is therefore frequently associated with the development of multiple organ dysfunction syndrome (MODS; see p. 1155).

Non-cardiogenic pulmonary oedema

This is the cardinal feature of ARDS and is the first and clinically most evident sign of a generalized increase in vascular permeability caused by the microcirculatory changes and release of immune mediators described previously (see pp. 1151–1153), with activated neutrophils playing a key role. The pulmonary epithelium is also damaged in the early stages, reducing surfactant production, predisposing to alveolar collapse and lowering the threshold for alveolar flooding.

Pulmonary hypertension

Pulmonary hypertension, sometimes complicated by right ventricular failure (see p. 1030), is a common feature of ARDS. Initially, mechanical obstruction of the pulmonary circulation may occur as a result of vascular compression by interstitial oedema, while local activation of the coagulation cascade leads to thrombosis and obstruction in the pulmonary microvasculature. Later, pulmonary vasoconstriction may develop in response to increased autonomic nervous activity and circulating substances such as catecholamines and thromboxane. Those vessels supplying alveoli with low oxygen tensions constrict (the ‘pulmonary hypoxic vasoconstrictor response’), diverting pulmonary blood flow to better-oxygenated areas of lung, thus limiting the degree of shunt.

Haemorrhagic intra-alveolar exudate

This exudate is rich in platelets, fibrin, fibrinogen and clotting factors, and may inactivate surfactant and stimulate inflammation, as well as promoting hyaline membrane formation and the migration of fibroblasts into the air spaces.

Resolution, fibrosis and repair

Within days of the onset of lung injury, formation of a new epithelial lining is under way and activated fibroblasts accumulate in the interstitial spaces. In some cases, there is progressive interstitial fibrosis. In those who recover, the lungs are substantially remodelled.

Physiological changes

Shunt and dead space increase, compliance falls and there is evidence of airflow limitation. Although the lungs in ARDS are diffusely injured, the pulmonary lesions, when identified as
densities on a CT scan, are predominantly located in dependent regions (Fig. 25.26). This is partly explained by the effects of gravity on the distribution of extravascular lung water and areas of lung collapse. Pleural effusions are common.

![Image](image1)

Computed tomography scan of the lung showing ground-glass opacification in non-dependent regions, with atelectasis and consolidation in dependent regions. There are small pleural effusions. B. The same patient as shown in A using soft-tissue window settings to demonstrate small bilateral effusions layering in the dependent region of both hemithoraces. (From Hinds CJ, Watson JD. Intensive Care: A Concise Textbook, 3rd edn. Edinburgh: Saunders; 2008, with permission. Courtesy of Dr SPG Padley)

### Clinical features

The first sign of the development of ARDS is often an unexplained tachypnoea, followed by increasing hypoxaemia with central cyanosis and breathlessness. Fine crackles are heard throughout both lung fields. Later, the chest X-ray shows bilateral diffuse shadowing, interstitial at first, but subsequently with an alveolar pattern and air bronchograms (Fig. 25.27). The differential diagnosis includes cardiac failure and lung fibrosis.
FIGURE 25.27 Chest radiograph appearances in acute respiratory distress syndrome. Bilateral diffuse alveolar shadowing with air bronchograms and no cardiac enlargement.

Management
This is based on treatment of the underlying condition (e.g. eradication of sepsis), supportive measures, and avoidance of complications such as ventilator-induced lung injury and ventilator-associated pneumonia.

Mechanical ventilation
This is the cornerstone of management; strategies designed to minimize ventilator-induced lung injury and encourage lung healing should be used (see p. 1166).

Pulmonary oedema limitation
Pulmonary oedema formation should be limited by fluid restriction, the use of diuretics and, if these measures fail, prevention of fluid overload by haemofiltration. The aim should be to achieve a consistently negative fluid balance.

Prone position
When the patient is changed from the supine to the prone position, lung densities in the dependent region are redistributed and shunt fraction is reduced. More uniform alveolar ventilation, caudal movement of the diaphragm, redistribution of perfusion and recruitment of collapsed alveoli all contribute to the improvement in gas exchange. Repeated position changes between prone and supine allow reductions in airway pressures and the inspired oxygen fraction. Recent findings suggest that proning early in the course of the disease process
and spending longer periods prone than supine are associated with substantial mortality benefits.

**Inhaled nitric oxide**

This vasodilator, when inhaled, may improve matching by increasing perfusion of ventilated lung units, as well as reducing pulmonary hypertension. It has been shown to improve oxygenation in so-called ‘responders’ with ARDS but has not been shown to increase survival.

**Aerosolized prostacyclin**

This appears to have similar effects to inhaled nitric oxide and is easier to deliver. As with inhaled nitric oxide, the response to aerosolized prostacyclin is, however, variable; although it improves oxygenation, its effect on outcome is unclear.

**Aerosolized surfactant**

Surfactant replacement therapy reduces morbidity and mortality in neonatal respiratory distress syndrome and is beneficial in animal models of ARDS. In adults with ARDS, however, the value of surfactant administration remains uncertain.

**Steroids**

Administration of steroids to patients with persistent ARDS does not appear to improve outcome.

**Prognosis**

Mortality from ARDS has fallen over the last decade, from around 60% to between 20% and 40%, perhaps as a consequence of improved general care, lung-protective ventilation strategies, the increasing use of management protocols, and attention to infection control and nutrition. Prognosis is, however, still very dependent on aetiology. When ARDS occurs in association with intra-abdominal sepsis, mortality rates remain very high, whereas much lower mortality rates are to be expected in those with ‘primary’ ARDS (pneumonia, aspiration, lung contusion). Mortality rises with increasing age and failure of other organs. Most of those dying with ARDS do so as a result of MODS and haemodynamic instability rather than impaired gas exchange.

**Further reading**

### Acute Kidney Injury

Acute kidney injury (AKI) is a common and serious complication of critical illness, and is strongly associated with increased morbidity and mortality. The presence and severity of AKI are now formally classified by relative increases in serum creatinine and/or a persistent reduction in urine output (see Box [20.27](#)).

The importance of preventing renal injury by rapid and effective resuscitation, the avoidance of nephrotoxic drugs (especially non-steroidal anti-inflammatory drugs, NSAIDs), and control of infection cannot be overemphasized. While shock and sepsis are the most common causes of AKI in the critically ill, causes requiring specific treatment should be excluded, especially urinary tract obstruction and acute intrinsic renal disease such as rapidly progressive glomerulonephritis (see p. 772).

Acutely, oliguria often accompanies shock and renal hypoperfusion and should prompt attempts to optimize cardiovascular function by expanding the circulating volume and restoring blood pressure, with restoration of urine output a good indicator of successful resuscitation. However, when AKI is established, urine output is often normal or high due to impaired concentrating capacity, so that development of oliguria then implies almost complete loss of renal function; in this case, continued fluid resuscitation will be ineffective and potentially harmful.

There is no evidence to support specific pharmacological interventions to prevent or treat AKI; in particular, low-dose dopamine is ineffective for preventing or reversing renal impairment in sepsis (see p. 772). Thus, treatment of those developing or at risk of AKI should focus on prompt resuscitation with fluid and/or vasopressor therapy, as well treatment of the underlying causes of shock and sepsis. If these measures fail to reverse oliguria, loop diuretics such as furosemide (see p. 156) may be used to treat or prevent fluid overload. However, there is no evidence that diuretics alter the clinical course of AKI, and renal replacement therapy (RRT) should not be delayed if indicated.

In AKI, RRT is indicated for refractory fluid overload, major electrolyte disturbances (especially hyperkalaemia), severe acidosis and, less often, uraemia. There is no evidence to support commencement of RRT for less severe AKI in the absence of these indications. Continuous renal replacement therapy (CRRT; see p. 773) is associated with greater haemodynamic stability and better control of fluid balance than intermittent haemodialysis, while use of peritoneal dialysis is unsatisfactory in critically ill patients (although this may be an option in resource-limited environments). Thus, CRRT is now the preferred method of renal support in the critically ill.

In critical illness complicated by AKI, if the underlying problems resolve, renal function
usually recovers over a period of a few days to several weeks. However, there is good evidence to suggest that, after recovery, subtle defects in renal function persist, so that patients requiring RRT in the ICU have a significantly increased risk of developing chronic kidney disease in the months and years after critical illness.

**Neurocritical Care**

**Physiology**

Neurones are particularly susceptible to acute ischaemic/hypoxic insults, as they have very limited capacity for anaerobic metabolism and are irreversibly lost when blood flow is restricted for as little as 3–8 minutes.

Within the rigid vault of the skull are housed the intracranial contents, which consist of brain parenchyma, blood and CSF. The intracranial pressure (ICP, pressure within the skull) is approximately 7–15 mmHg in a resting, supine adult. Changes in intra-abdominal and intrathoracic pressures, such as occur during coughing or a Valsalva manoeuvre, may result in transient increases in ICP that are of no consequence. The *Monro–Kellie doctrine* states that, because the cranial compartment is rigid, any increase in the volume of one of the intracranial constituents (blood, CSF, brain tissue) must be compensated by a decrease in the volume of the others. As space-occupying lesions expand or brain tissue swells, the rise in ICP is limited by displacement of CSF and venous blood from the intracranial compartment. Once these compensatory mechanisms are exhausted, further increases in intracranial volume cause exponentially greater increases in ICP (*Fig. 25.28*).
In health, autoregulation maintains constant cerebral blood flow over a range of blood pressures. However, these mechanisms are lost following significant intracranial injury, and cerebral blood flow then becomes directly dependent on cerebral perfusion pressure (CPP). CPP is calculated as the MAP minus the ICP. Occasionally, a very high CVP, greater than the ICP, will also reduce CPP (Fig. 25.29).

**Clinical assessment**
The causes of coma are listed in Box 21.27. Conscious level should be documented and any changes noted. The Glasgow Coma Scale (GCS) score (Box 21.26) is widely used as a semi-quantitative, yet crude, means of gauging the level of consciousness. Assessment of the airway is of particular importance. Patients with airway obstruction due to lax oropharyngeal musculature should be managed as discussed on page 1156. Similarly, patients without a cough or gag reflex may need to be intubated in order to protect the airway. Pupillary signs are crucial. Documentation of pupillary size and reactivity is crucial. A unilaterally dilated pupil that reacts sluggishly or not at all is frequently a sign of increasing ICP. This is caused by compression of the IIIrd cranial nerve by herniating brain; if untreated, it can be rapidly fatal. Immediate treatments to decrease ICP (Box 25.20) are required whilst a CT scan of the brain is obtained. In some situations, patients may be taken directly to the operating theatre in order to alleviate the raised ICP and to remove expanding space-occupying lesions such as a haematoma. Small or pinpoint pupils may be a sign of mid-brain injury or opioid overdose. New focal neurological signs should be sought, such as cranial nerve palsies, limb weakness or hemiparesis. Seizures should be recognized and treated appropriately (see p. 826).

## Box 25.20

### Measures to control raised intracranial pressure and prevent secondary brain injury

- Control/restoration of blood pressure
- Control of intracranial pressure:
  - Reduction of intracranial blood volume
  - Mechanical ventilation
  - Sedation
  - Unobstructed venous drainage
  - Control of cerebral oedema
  - Osmotic diuretics (e.g. mannitol)
  - Loop diuretic (e.g. furosemide)
- Other measures:
  - Removal of cerebrospinal fluid via intraventricular catheter
  - Decompressive craniectomy
  - Excision of brain tissue
- Control of seizure activity

## Monitoring

Regular clinical assessments by the bedside nurse are essential, including Glasgow Coma Scale score and pupillary size and reaction to light at least every hour. Neurological assessments are inevitably limited in patients requiring sedation and mechanical ventilation. In
these patients, invasive monitoring of ICP may be necessary.

**Invasive ICP monitoring devices** may be extradural, subdural, subarachnoid, intraparenchymal or intraventricular (**Fig. 25.30**). The external ventricular drain (EVD) is the most difficult to insert, particularly when increased ICP causes the ventricles to collapse. EVDs are normally placed through the non-dominant (usually right) hemisphere into the lateral ventricle in the operating theatre. Their main advantage over the other monitoring devices is that they can also be used to treat raised ICP by draining CSF from the ventricular system. They are more prone to infection, however.

![Image of brain ventricles with various monitoring devices](https://example.com/ventricular-monitoring)

**FIGURE 25.30** Methods for measuring intracranial pressure.

**Multi-electrode electroencephalography (EEG) monitors** give both a waveform and an analogue display that can help in the diagnosis of non-convulsive seizures and are also useful in monitoring the depth of sedation.

**Oximeter-tipped catheters** can be placed via the internal jugular vein and advanced in a cranial direction to lie in the jugular bulb just external to the skull. These ‘jugular bulb oximetry’ catheters monitor venous saturation in blood leaving the brain and give an indication of the balance between cerebral oxygen supply and demand. Measurements can be interpreted similarly to the mixed venous oxygen content (see pp. 1143–1144).

**Cerebral oximetry** uses near-infrared spectroscopy (NIRS) technology to estimate the oxygenation of a small portion of the cerebral cortex. Adhesive pads that both emit and capture near-infrared light waves are placed over the frontal cortex. Cerebral oximetry can provide an early warning of decreased cerebral oxygen delivery.

### Management

Because little can be done to reverse the immediate primary brain injury and irreversible loss of neurones that occur as a direct consequence of intracerebral haemorrhage, infarct or
traumatic brain injury, ICU care is focused on minimizing secondary brain injury (Box 25.20). This commonly occurs as a result of increases in ICP and consequent decreases in CPP. Cerebral oedema, expanding mass lesions (e.g. haemorrhage), prolonged seizure activity and hypercarbia (which causes cerebral vasodilatation) are all examples of mechanisms leading to secondary injury. Neurocritical care has therefore focused on monitoring ICP and maintaining CPP. The Brain Trauma Foundation (BTF) guidelines state that an ICP of <20 mmHg and a CPP of between 50 and 70 mmHg should be the aim, with vasopressors and fluid given as required in conjunction with supportive care; the latter should include airway protection, maintenance of normocarbia, reduction of the risk of nosocomial infections and prevention of thromboembolic complications.

**Outcomes**

**Withholding and withdrawing treatment**

(See also Ch. 3.)

For many critically ill patients, intensive care is undoubtedly life-saving and resumption of a normal lifestyle is to be expected. It is also widely accepted that the elective admission of high-risk patients into an ICU or HDU, particularly in the immediate postoperative period, can minimize morbidity and mortality and lower costs, as well as reducing the demands on medical and nursing personnel on general wards. In the most seriously ill patients, however, mortality rates are high and a significant number die soon after discharge from the ICU. Mortality rates are particularly high in those who require re-admission to intensive care. Moreover, patients surviving a prolonged ICU admission often do not regain their premorbid functional status, and longer-term mortality rates (for at least 5 years post discharge) remain higher than in a general population matched for age and illness severity. Many centres have established specialist follow-up clinics to address long-term sequelae of critical illness.

Inappropriate use of intensive care facilities has other implications. The patient may experience unnecessary suffering and loss of dignity, while relatives may also have to endure considerable emotional pressures. In some cases, treatment may simply prolong the process of dying or sustain life of dubious quality, and in others the risks of interventions outweigh the potential benefits. Lastly, intensive care is expensive, particularly for those with the worst prognosis, and resources are limited.

To ensure both a humane approach to the management of critically ill patients and the appropriate use of limited resources, it is necessary to:

- avoid admitting patients who cannot benefit from intensive care
- limit further aggressive therapy when the prognosis is clearly hopeless.

Such decisions are extremely difficult; every case must be assessed individually, taking into
account previous health and quality of life, primary diagnosis, medium- and long-term prognosis of the underlying condition, and survivability of the acute illness. Age alone should not be the sole consideration. When in doubt, active measures should continue but with regular review in the light of response to treatment and any other changes. Decisions to limit therapy, not to resuscitate or to withdraw treatment should be made jointly by the ICU medical staff, the primary physician or surgeon, the nurses and, if possible, the patient, normally in consultation with the patient's family. Limitation of active treatment is not the cessation of medical or nursing care; rather, a caring approach must be adopted to ensure a dignified death, free of pain and distress, with support for family and friends (see p. 41).

Scoring systems
A variety of scoring systems have been developed that can be used to evaluate the severity of a patient's illness. Some have included an assessment of the patient's previous state of health and the severity of the acute disturbance of physiological function (acute physiology, age, chronic health evaluation, or APACHE; and the simplified acute physiology score, or SAPS). Other systems have been designed for particular categories of patient (e.g. the injury severity score for trauma victims). The APACHE and SAPS scores are widely applicable and have been extensively validated. They can accurately quantify the severity of illness and predict the overall mortality for large groups of critically ill patients, and are therefore useful for defining the ‘case mix’ of patients when auditing a unit's clinical activity, for comparing results nationally or internationally, and for characterizing groups of patients in clinical studies. Although the APACHE and SAPS methodologies can also be used to estimate risks of mortality, no scoring system has yet been devised that can predict with certainty the outcome in an individual patient. They must not, therefore, be used in isolation as a basis for limiting or discontinuing treatment.

Brain death and organ donation
Brain death means ‘the irreversible loss of the capacity for consciousness combined with the irreversible loss of the capacity to breathe’. Both of these are essentially functions of the brainstem. Death, if thought of in this way, can arise either from causes outside the brain (i.e. respiratory and cardiac arrest) or from causes within the cranial cavity. With the advent of mechanical ventilation, it became possible to support such a dead patient temporarily, although, in all cases, cardiovascular failure eventually supervenes and progresses to asystole.

Before deciding on a diagnosis of brainstem death, it is essential for certain preconditions and exclusions to be fulfilled.

Preconditions
• The patient must be in apnoeic coma (i.e. unresponsive and on a ventilator, with no spontaneous respiratory efforts).
• Irremediable structural brain damage due to a disorder that can cause brainstem death must
have been diagnosed with certainty (e.g. head injury, intracranial haemorrhage).

Exclusions

• The possibility that unresponsive apnoea is the result of poisoning, sedative drugs or neuromuscular blocking agents must be excluded.
• Hypothermia must be excluded as a cause of coma. The central body temperature should be >35°C.
• There must be no significant metabolic or endocrine disturbance that could produce or contribute to coma or cause it to persist.
• There should be no profound abnormality of the plasma electrolytes, acid–base balance or blood glucose levels.

Diagnostic tests for the confirmation of brainstem death

All brainstem reflexes are absent in brainstem death.

The following tests should not be performed in the presence of seizures or abnormal postures.

• Oculocephalic reflexes should be absent. In a comatose patient whose brainstem is intact, the eyes will rotate relative to the orbit (i.e. doll’s eye movements will be present). In a brainstem-dead patient, when the head is rotated from side to side, the eyes move with the head and therefore remain stationary relative to the orbit.
• The pupils are fixed and unresponsive to bright light. Both direct and consensual light reflexes are absent. The size of the pupils is irrelevant, although most often they will be dilated.
• Corneal reflexes are absent.
• There are no vestibulo-ocular reflexes on caloric testing (see p. 810).
• There is no motor response within the cranial nerve territory to painful stimuli applied centrally or peripherally. Spinal reflex movements may be present.
• There is no gag or cough reflex in response to pharyngeal, laryngeal or tracheal stimulation.
• Spontaneous respiration is absent. The patient should be ventilated with 100% O₂ (or 5% CO₂ in 95% O₂) for 10 min and then temporarily disconnected from the ventilator for up to 10 min. Oxygenation is maintained by insufflation with 100% oxygen via a catheter placed in the endotracheal tube. The patient is observed for any signs of spontaneous respiratory efforts. A blood gas sample should be obtained during this period to ensure that the $P_aCO_2$ is sufficiently high to stimulate spontaneous respiration (>6.7 kPa, 50 mmHg).

The examination should be performed and repeated by two senior doctors.

In the UK, it is not considered necessary to perform confirmatory tests, such as EEG or carotid and vertebral angiography.

The primary purpose of establishing a diagnosis of brainstem death is to demonstrate beyond
doubt that it is futile to continue mechanical ventilation and other life-supporting measures.

In suitable cases, and provided the assent of relatives has been obtained (easier if the patient was carrying an organ donor card or is on the organ donor register), the organs of those in whom brainstem death has been established may then be retrieved whilst the heart is still beating and be used for transplantation.

Organ donation may be possible in situations where ongoing life-sustaining treatment in the ICU is deemed futile and a decision is reached in conjunction with the family (and, in rare circumstances, the patient) to withdraw treatments such as invasive ventilation and inotropes that are simply delaying an inevitable death. If the patient and family wish to consider organ donation, then withdrawal of life-sustaining therapies usually occurs in a planned fashion and often in the operating department suite. If the patient does indeed die in a relatively brief period, then organ retrieval may occur immediately following a cardiac death.

Both of these situations require rapport and trust to be established with the family, and many hospitals have a separate team of nurse specialists to help the families through these very difficult situations. In the UK, each region has a transplant coordinator who can help with the process, as well as providing information, training and advice about organ donation. These transplant coordinators should be informed of all patients undergoing brainstem testing and all patients in whom withdrawal of life-sustaining treatment is being considered, so that all families and patients can be offered the opportunity to donate organs if they so wish. The medical teams involved in the ICU care of the patient and those involved in the organ retrieval process must remain completely independent.

Introduction

The endocrine system consists of glands that exert their actions at distant parts of the body via the production of biologically active hormones secreted into the bloodstream. Unlike the neurological system, which produces an immediate response, the endocrine system typically has a slower and longer-lasting effect on the body. The main endocrine glands are the pituitary, thyroid, adrenals, gonads, parathyroids and pancreas, and the common endocrine problems seen in clinical practice are shown in Figure 26.1 (see p. 1177). The pituitary gland, a pea-sized structure situated at the base of the brain, plays a key role in the control and feedback mechanisms of the endocrine system and has been termed the ‘conductor of the endocrine orchestra’.

Clinical Approach to the Patient with Endocrine Disease

History

Hormones produce widespread effects in the body, and states of hormonal deficiency or excess typically present with symptoms that are generalized, diffuse and non-specific. Symptoms of tiredness, weakness or lack of energy or drive, and changes in appetite or thirst are common presentations. Other typical ‘hormonal’ symptoms include changes in body size and shape, problems with libido and potency, periods or sexual development, and changes in the skin (dryness, greasiness, acne, bruising, thinning or thickening) and hair (loss or excess). The
differential diagnosis is often wide but endocrine disorders should be always considered when assessing a patient with any of these common complaints.

The past, family and social histories are essential for making the diagnosis, planning appropriate management and interpreting results of borderline hormonal blood tests.

• The past history should include previous surgery or radiation involving endocrine glands, menstrual history, pregnancy, and growth and development in childhood.

• A full drug history will identify common iatrogenic endocrine problems *(Box 26.1)*.

*Drugs causing gynaecomastia are listed in Box 26.29. Amiodarone may cause both hypo- or hyperthyroidism. ACE, angiotensin-converting enzyme; CBG, cortisol-binding globulin.

- A family history of autoimmune disease, endocrine disease including tumours, diabetes and cardiovascular disease is frequently relevant, and knowledge of family members' height, weight, body habitus, hair growth and age of sexual development may aid interpretation of the patient's own symptoms.

**Examination**
A full general examination is essential to endocrine assessment because endocrine disorders affect all organ systems. Weight, height, body mass index (BMI), blood pressure and general habitus should all be documented, together with the presence or absence of specific signs of deficiency or excess of individual hormone axes (signs of hyper- or hypothyroidism, acromegaly, Cushing syndrome or Addison's disease).

In people with suspected pituitary disease, visual fields and adjacent cranial nerves should be assessed clinically. In thyroid disease, the presence of goitre or thyroid eye disease should be documented. Skin changes may give clinical clues, including pigmentation (Addison's and Nelson's), vitiligo (autoimmune endocrinopathies), acanthosis nigricans (polycystic ovary syndrome (PCOS) and diabetes), skin thinning (Cushing's, hypogonadism) or thickening (acromegaly, PCOS), and bruising and striae (Cushing's). Hirsutism is a key sign in women and signs of hair loss from the head (following a change in thyroid function, androgen excess in women or normal virilization in men) or from the body, axillary and pubic areas (hypogonadism) may occur in both sexes.

In children, height and pubertal status are an essential part of the clinical examination.

Specific clinical signs associated with particular endocrine diseases are discussed in detail in the appropriate sections.

**Common endocrine conditions**

The most common endocrine disorders, excluding obesity (see pp. 206–212) and diabetes mellitus (p. 1241), are:

- thyroid disorders: hypothyroidism, hyperthyroidism, goitre
- menstrual disorders and/or hirsutism, usually due to PCOS
- hypogonadism in association with erectile dysfunction
- osteoporosis and metabolic bone disease
- subfertility
- disorders of growth or puberty.

With the advent of more frequent and detailed head and abdominal scans, another common endocrine referral is for investigation of incidental findings: for example, an empty sella or an incidentaloma, either pituitary or adrenal; all patients require endocrine review and investigation.

While most other endocrine conditions are uncommon, they often affect younger people and are usually curable or completely controllable with appropriate therapy.

**Aetiology of endocrine disease**

Aetiological mechanisms common to many endocrine disorders are described below.

**Autoimmune disease**
Organ-specific autoimmune diseases can affect every major endocrine organ (Box 26.2). They are characterized by the presence of specific antibodies in the serum, often present years before clinical symptoms are evident, usually more common in women and have a strong genetic component, often with an identical-twin concordance rate of 50% and with human leucocyte antigen (HLA) associations (see individual diseases). Several of the autoantigens have been identified.

**Note:** Other related diseases include myasthenia gravis and autoimmune liver diseases.

Endocrine tumours

Most endocrine tumours are benign, although a cytological or histological diagnosis may be needed if there is clinical or radiological suspicion of malignancy. Clinical presentation depends on whether the tumour is functional or non-functional, the latter presenting only as a
mass clinically or on imaging. Palpable thyroid nodules are common, and mass effects are a frequent presentation of pituitary adenomas, but the increased use of high-resolution ultrasound and detailed cross-sectional imaging has revealed a very high prevalence of asymptomatic, incidentally discovered thyroid, adrenal and pituitary lesions, commonly termed ‘incidentalomas’ (see p. 1229).

Functional tumours cause their effects via excess secretion of the relevant hormone. While often considered to be ‘autonomous’ – that is, independent of the physiological control mechanisms – many functional tumours do show evidence of feedback occurring at a higher ‘set-point’ than normal (e.g. adrenocorticotrophic hormone (ACTH) secretion from a corticotroph adenoma). This is relevant in the dynamic assessment of endocrine diseases, such as in the differential diagnosis of Cushing syndrome.

Endocrine adenomas typically present in a single gland, although rarer multiple endocrine neoplasia (MEN) syndromes exist that are due to very specific mutations of a single gene, such as the mutations of the RET proto-oncogene in MEN 2 or the MEN1 gene mutation in MEN 1 (see p. 1239). The diagnosis of some endocrine tumours, particularly at a young age, or the identification of a family history should prompt discussion about genetic screening.

Enzyme defects
The biosynthesis of most hormones involves many stages. Deficient or abnormal enzymes can lead to absent or reduced production of the secreted hormone. In general, severe deficiencies present early in life with obvious signs; partial deficiencies usually present later with mild signs or are only evident under stress. An example of an enzyme deficiency is congenital adrenal hyperplasia (CAH), whose molecular basis has also been identified as mutations or deletions of the gene encoding the relevant enzymes (see p. 1228).

Receptor abnormalities
There are rare conditions in which hormone secretion and control are normal but the receptors are defective; thus, if androgen receptors are defective, normal levels of androgen will not produce masculinization (e.g. androgen insensitivity syndrome). There are also a number of rare syndromes of diabetes and insulin resistance from receptor abnormalities (see p. 1249); other examples include nephrogenic diabetes insipidus, pseudohypoparathyroidism and thyroid hormone resistance, which can cause an unusual pattern of thyroid blood results.

Hormonal activity
Synthesis, storage and release of hormones
Hormones may be of several chemical structures: polypeptide, glycoprotein, steroid or amine. Hormone release is the end-product of a long cascade of intracellular events. In the case of polypeptide hormones, neural or endocrine stimulation of the cell leads to increased transcription from DNA to a specific messenger RNA (mRNA), which is, in turn, translated to
the peptide product. This is often in the form of a precursor molecule that may itself be biologically inactive. This ‘prohormone’ is then further processed before being packaged into granules, in the Golgi apparatus. These granules are then transported to the plasma membrane before release, which is itself regulated by a complex combination of intracellular regulators. Hormone release may be in a brief spurt caused by the sudden stimulation of granules, often induced by an intracellular Ca\(^{2+}\)-dependent process, or it is ‘constitutive’ (immediate and continuous secretion).

**Plasma transport**

Most classical hormones are secreted into the systemic circulation. In contrast, hypothalamic releasing hormones are released into the pituitary portal system so that much higher concentrations of the releasing hormones reach the pituitary than occur in the systemic circulation.

Many hormones are bound to proteins within the circulation. In most cases, only the free (unbound) hormone is available to the tissues and thus biologically active. This binding serves to buffer against very rapid changes in plasma levels of the hormone, and some binding protein interactions are also involved in the active regulation of hormone action. Many tests of endocrine function measure total rather than free hormone, which can give rise to difficulties in interpretation when binding proteins are altered in disease states or by drugs.

Binding proteins comprise both specific, high-affinity proteins of limited capacity, such as thyroxine-binding globulin (TBG), cortisol-binding globulin (CBG), sex-hormone-binding globulin (SHBG) and insulin-like growth factor (IGF)-binding proteins (e.g. IGF-BP3), and other less specific, low-affinity ones, such as prealbumin and albumin.

**Hormone action and receptors**

Hormones act by binding to specific receptors in the target cell. Most hormone receptors are proteins with complex tertiary structures. The structure of the hormone-binding domain of the receptor complements the tertiary structure of the hormone, while changes in other parts of the receptor in response to hormone binding are responsible for the effects of the activated receptor within the cell. The structure of common hormones and their receptors is described under individual hormone axes.

Hormone receptors are broadly divided into:

- **cell surface or membrane receptors**: typically, transmembrane receptors that contain hydrophobic sections spanning the lipid-rich plasma membrane and which trigger internal cellular messengers (see also pp. 88–90)

- **nuclear receptors**: typically, bind hormones and translocate them to the nucleus, where they bind hormone response elements of nuclear DNA via characteristic amino-acid sequences (e.g. so-called ‘zinc fingers’; see p. 98).

Abnormal receptors are an occasional cause of endocrine disease (see pp. 116–117).

**Mechanisms of hormone-receptor action**
Common structural mechanisms of hormone-receptor action are illustrated in Figure 7.12 (p. 97) and include:

- **G-protein coupled receptors (7-transmembrane or serpentine receptors).** These bind hormones on their extracellular domain and activate the membrane G-protein complex with their intracellular domain. The activated complex may then:
  - stimulate cyclic AMP (cAMP) generation by adenylate cyclase – activating further intracellular kinases and leading to phosphorylation
  - activate phospholipase C (PLC), leading to generation of inositol 1,4,5-triphosphate (IP$_3$) and release of intracellular calcium – in turn, leading to calmodulin-dependent kinase activity and phosphorylation
  - lead to diacylglycerol (DAG) activation of C-kinase and subsequent protein phosphorylation.
  Most peptide hormones act via G-protein coupled receptors.

- **Dimeric transmembrane receptors.** These receptors, from several receptor superfamilies, bind hormone in their extracellular components (sometimes causing the dimerization of the receptor monomer) and directly phosphorylate intracellular messengers via their intracellular components, leading to a variety of intracellular activation cascades. Growth hormone, prolactin and IGF-1 act via this type of receptor.

- **Lipid-soluble molecules.** These pass through the cell membrane and typically bind with their nuclear receptors in the cell cytoplasm before translocation of the activated hormone–receptor complex to the nucleus; here, it binds to nuclear DNA, often in combination with a multi-component complex of promoters, inhibitors and transcription factors. This interaction usually leads to increased transcription of the relevant gene product. Steroid and thyroid hormones act via this type of receptor.

**Hormone release and binding to receptors**

The activation of intracellular kinases, phosphorylation, release of intracellular calcium and other ‘second messenger’ pathways, and the direct stimulation of DNA transcription result in some or all of the following:

- stimulation or release of pre-formed hormone from storage granules
- stimulation or synthesis of hormone and other cellular components
- opening or closing of ion or water channels in the cell membrane (e.g. calcium channels or aquaporin water channels)
- activation or deactivation of other DNA binding proteins, leading to stimulation or inhibition of DNA transcription.

In each case, binding of the hormone to its receptor is the first step in a complex cascade of interrelated intracellular events, which eventually lead to the overall effects of that hormone on cellular function.

*The sensitivity and/or number of receptors* for a hormone are often decreased after
prolonged exposure to a high hormone concentration, the receptors thus becoming less sensitive (‘downregulation’, e.g. angiotensin II receptors, β-adrenoceptors). The reverse is true when stimulation is absent or minimal, the receptors showing increased numbers or sensitivity (‘upregulation’).

Control and feedback

Most hormone systems are under tight regulatory control (typically by the hypothalamic–pituitary (HP) axis) by a system known as negative feedback. An example of the negative feedback system in the hypothalamic–pituitary–thyroid (HPA) axis is demonstrated in Figure 26.2 and described here:

- Thyrotrophin-releasing hormone (TRH) is secreted in the hypothalamus and travels via the portal system to the pituitary, where it stimulates the thyrotrophs to produce thyroid-stimulating hormone (TSH).
- TSH is secreted into the systemic circulation, where it stimulates increased thyroidal iodine uptake by the thyroid, and the synthesis and release of thyroxine (T\textsubscript{4}) and triiodothyronine (T\textsubscript{3}).
- Serum levels of T\textsubscript{3} and T\textsubscript{4} are increased by TSH; in addition, the conversion of T\textsubscript{4} to T\textsubscript{3} (the more active hormone) in peripheral tissues is stimulated by TSH.
- T\textsubscript{3} and T\textsubscript{4} then enter cells, where they bind to nuclear receptors and promote increased metabolic and cellular activity.
- Levels of T\textsubscript{3}, from the blood and from local conversion of T\textsubscript{4}, are sensed by receptors in the pituitary and the hypothalamus. If they rise above normal, TRH and TSH production is suppressed, leading to reduced T\textsubscript{3} and T\textsubscript{4} secretion.
- Peripheral T\textsubscript{3} and T\textsubscript{4} levels fall to normal.
- If, however, T\textsubscript{3} and T\textsubscript{4} levels are low – for example, after thyroidectomy, increased amounts of TRH and TSH are secreted, stimulating the remaining thyroid to produce more T\textsubscript{3} and T\textsubscript{4}; blood levels of T\textsubscript{3} and T\textsubscript{4} may be restored to normal, at the expense of increased TSH drive, reflected by a high TSH level: ‘compensated euthyroidism’.
- Conversely, in thyrotoxicosis, when factors other than TSH itself are maintaining high T\textsubscript{3} and T\textsubscript{4} levels, the same mechanisms lead to suppression of TSH secretion.
Primary and secondary gland failure
It is useful in clinical endocrinology to distinguish between ‘primary’ disease of the end-organ gland (e.g. that due to autoimmune destruction, atrophic change, infiltration or surgical removal of the gland) and ‘secondary’ disorders of the same axis, caused by disease of the pituitary gland. An understanding of the negative feedback system is key to interpreting endocrine blood results and diagnosing the site of the disease process in clinical practice. In general terms:

- **‘Primary’ hormone deficiency** due to a disease process in the endocrine end-organ (thyroid, adrenal or gonad) will lead to a loss of negative feedback and subsequent elevation in the corresponding anterior pituitary hormone.
- In ‘secondary gland failure’, there are low or ‘inappropriately normal’ levels of the pituitary trophic hormone in the face of a low end-organ hormone level. For example, if a patient has low circulating free $T_3$ ($fT_3$) and $T_4$ levels in the context of a low TSH, pituitary disease should be suspected.

Hormone excess
Abnormal hormone excess due to a disease process in the primary endocrine gland, or excess
amount of exogenous hormone, will lead to increased negative feedback and suppression of the corresponding pituitary hormones. For example, in autoimmune hyperthyroidism, the free fT$_3$ and T$_4$ levels are elevated in the context of a suppressed TSH. Equally, the presence of a non-suppressed plasma pituitary hormone in the context of excess primary hormone implies that the pituitary, rather than the primary gland itself, is the cause. For example, in pituitary-driven Cushing's disease, cortisol levels are elevated but ACTH is not suppressed.

**Hormone resistance**

In certain situations, receptor abnormalities can give rise to abnormal negative feedback due to hormone resistance, which can lead to an unusual pattern of blood results. For example, thyroid hormone resistance, due to mutations in the thyroid hormone receptor, is characterized by an elevation in thyroid hormones with a non-suppressed TSH. With this pattern of thyroid results, the clinician should also consider the rare diagnosis of a TSH-secreting pituitary tumour, in addition to the possibility of assay issues.

**Measurement of hormones**

Hormones are measured in routine clinical practice by biochemical assays in the laboratory. It is possible to measure pituitary trophic hormones and the hormones produced by the end-organ glands, but hypothalamic hormones are not routinely measured in practice because of their low concentration and local action within the HP axis. Circulating levels of most hormones are very low (10$^{-9}$–10$^{-12}$ mol/L) and cannot be measured by simple chemical techniques. Hormones are therefore usually measured by immunoassays, which rely on highly specific polyclonal or monoclonal antibodies, which bind to the hormone being measured during the assay incubation. This hormone–antibody interaction is measured by use of labelled hormone after separation of bound and free fractions *(Fig. 26.3)*.
FIGURE 26.3 Principles of measurement of hormone levels in plasma by immunoassay. (Precise details vary with different assays and manufacturers.) Immunoassays use two antibodies specific to the hormone being measured: one typically attached to a solid phase and one labelled antibody in the liquid phase. A. High hormone levels in plasma: a large amount of hormone binds to antibody in solid phase; a large amount of labelled antibody is linked to solid phase via molecules of the hormone. B. Low hormone levels in plasma: less hormone, and therefore less labelled antibody, is linked to the solid phase. Label (radioactive, chemiluminescent, enzymatic or fluorescent) can be measured in either solid or liquid phase after separation of phases; levels of label will be proportional to the amount of hormone in the sample.

Immunoassays are sensitive but have limitations. In particular, the immunological activity of a hormone, as used in developing the antibody, may not necessarily correspond to biological activity and there may be false positive and negative results. The patient's blood may also contain heterophile antibodies, which interact with the animal antibodies used in the assay and produce falsely low or high values. When there is a discrepancy between endocrine blood results and the clinical presentation, the clinician must question the validity of an endocrine result, and a close relationship with the relevant laboratory is essential. It may be necessary for the sample to be measured in a different laboratory using an alternative antibody, or to measure hormones in ways other than by immunoassay. Examples of alternative techniques that quantify and characterize hormone levels accurately include equilibrium dialysis, high-pressure liquid chromatography (HPLC) and, increasingly for the accurate measurement of steroid hormones, mass spectroscopy.

Hormone-binding proteins

Many hormones are transported in the bloodstream from the primary gland to their distant target organ attached to a specific binding protein (see p. 1178). It is more helpful to measure the free hormone rather than total bound hormone level, as this is the part that is biologically active. Some modern assays attempt to measure the free hormone level directly (e.g. free T₄) and are therefore a more accurate reflection of biological activity, although there are often technical problems with this approach and many assays still measure total hormone level.

Cortisol, which is bound to cortisol-binding globulin (CBG), and testosterone, which is
bound to sex-hormone-binding globulin (SHBG), are still usually measured in their total form and can be affected by alterations in binding protein levels. In women who are pregnant or on the combined oral contraceptive pill, high oestrogen levels may lead to an elevation in CBG, which can overestimate cortisol and give the false impression of hypercortisolaemia. In people with diabetes mellitus or other insulin-resistant states that may lower SHBG levels, low total testosterone levels may give the false impression of androgen deficiency. Conversely, hyperthyroidism or oestrogen excess can cause an elevation in SHBG, leading to apparently high total testosterone levels. As with all endocrine results, the data need to be interpreted in the clinical context.

**Patterns of hormonal secretion**

Hormone secretion can be continuous or intermittent, for example:

• **Continuous secretion** is shown by the thyroid hormones, with a half-life of 7–10 days for $T_4$ and 6–10 h for $T_3$, and with little variation in levels over the day, month and year.

• **Pulsatile secretion** is the normal pattern for the gonadotrophins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), with major pulses released every 1–2 h, depending on the phase of the menstrual cycle. Growth hormone (GH) is also secreted in a pulsatile fashion, with undetectable levels in between pulses. A single measurement is therefore not helpful to diagnose GH deficiency or excess.

**Biological rhythms**

*Circadian* means changes over the 24 hours of the day–night cycle and is best shown for the pituitary–adrenal axis. *Figure 26.4* shows plasma cortisol levels measured over 24 hours; levels are highest in the early morning and lowest overnight. Additionally, cortisol release is pulsatile, following the pulsatility of pituitary ACTH. Thus, ‘normal’ cortisol levels vary during the day and great variations can be seen in samples taken only 30 minutes apart.
The menstrual cycle is an example of a longer and more complex (28-day) biological rhythm (see pp. 1213–1214).

**Other regulatory factors**

- **Stress.** Physiological ‘stress’ and acute illness produce rapid increases in ACTH and cortisol, GH, prolactin, adrenaline (epinephrine) and noradrenaline (norepinephrine). These can occur within seconds or minutes.

- **Sleep.** Secretion of GH and prolactin is increased during sleep, especially the rapid eye movement (REM) phase.

- **Feeding and fasting.** Many hormones regulate the body's control of energy intake and expenditure, and are therefore profoundly influenced by feeding and fasting. Secretion of insulin is increased, whilst testosterone and GH are decreased after ingestion of food, and secretion of a number of hormones is altered during prolonged food deprivation.

**Investigation of endocrine function**

Endocrine function is assessed by measurement of hormone levels in blood (or, more precisely, in plasma or serum) and sometimes in other body fluids on samples obtained basally and in response to stimulation and suppression tests.

**Basal blood levels**

Assays for all clinically relevant pituitary and end-organ hormones are available.

The time, day and conditions of measurement make great differences to hormone levels, and the method and timing of samples therefore depend upon the characteristics of the endocrine system involved. There are also gender, pubertal and age differences.

Basal levels are especially useful for systems with long half-lives (e.g. \( T_4 \) and \( T_3 \), IGF-1, \( TSH \)).
androstenedione, SHBG). These vary little over the short term and random samples are therefore satisfactory.

Basal samples for many hormones need to be interpreted with respect to normal ranges for the time of day/month, diet or posture concerned. Hormones with a marked circadian rhythm (e.g. testosterone and cortisol) must be measured at an appropriate time of day. Testosterone should be measured before 11:00 hours in the fasting state; cortisol should be checked between 8:00 hours and 10:00 hours to exclude hypoadrenalism, but at midnight to demonstrate normal low levels (to exclude Cushing's). LH/FSH, oestrogen and progesterone vary with time of menstrual cycle, and renin/aldosterone may vary with sodium intake, posture and age. For these hormones, all relevant details must be recorded or the results may prove uninterpretable.

**Stress-related hormones**

Measurement of stress-related hormones may be problematic either because the patient is stressed by hospital attendance or venepuncture, leading to falsely high levels (e.g. catecholamines, prolactin; sampling via an indwelling needle may be required, some time after initial venepuncture), or because low levels in a non-stressed individual are unable to confirm an adequate reserve required for normal physiological stress (cortisol and GH).

**Urine collections**

Collections over 24 hours have the advantage of providing an ‘integrated mean’ of a day's secretion but, in practice, are often incomplete or wrongly timed. They also vary with sex and body size or age. Written instructions should be provided for the patient to ensure accurate collection. Examples of hormones measured in this way are catecholamines and urinary free cortisol levels.

**Saliva**

Saliva is sometimes used for steroid estimations, especially in children or for samples taken at home. Midnight salivary cortisol levels are increasingly used for the diagnosis of Cushing syndrome due to the practical difficulties in obtaining a midnight blood sample.

**Stimulation and suppression tests**

These tests are used when basal levels give equivocal information. In general, stimulation tests are used to confirm suspected deficiency of hormone secretion, and suppression tests to confirm suspected excess. These tests are valuable in many instances.

For example, where the secretory capacity of a gland is damaged, maximal stimulation by the trophic hormone will give a diminished output. Thus, in the short ACTH stimulation test for adrenal reserve (**Box 26.3, Fig. 26.5A**), the healthy subject shows a normal response while the subject with primary hypoadrenalism (Addison's disease) demonstrates an impaired cortisol response to tetracosactide (an ACTH analogue).
Short ACTH (tetracosactide) stimulation test

Indications

• Diagnosis of Addison's disease
• Screening test for ACTH deficiency

Procedure

• I.v. cannula for sampling
• Any time of day, but best at 09:00 hours; non-fasting
• Tetracosactide 250 µg, i.v. or i.m. at time 0
• Measure serum cortisol at time 0 and time +30 min

Normal response

• 30 min cortisol >600 nmol/L*
  – (400–600 nmol/L borderline and may indicate deficiency)

*Precise cortisol normal ranges are variable between laboratories and assays; appropriate local reference ranges must be used.
FIGURE 26.5 Short ACTH stimulation and dexamethasone suppression tests. A. The short ACTH stimulation test shows a normal response in a healthy subject and a decreased response in a patient with Addison's disease. B. Dexamethasone suppression tests in a normal subject and in a patient with Cushing's disease, showing inadequate suppression.

A patient with a hormone-producing tumour usually fails to show normal negative feedback. A patient with Cushing's disease (excess pituitary ACTH) will thus fail to suppress ACTH and cortisol production when given a dose of synthetic steroid, in contrast to normal subjects. Figure 26.5B shows the response of a normal subject given dexamethasone 1 mg at midnight; cortisol is suppressed the following morning. The subject with Cushing's disease shows inadequate suppression.

The detailed protocol for each test must be followed exactly, since differences in technique will produce variations in results.

The Pituitary Gland and Hypothalamus

Anatomy

Most peripheral hormone systems are controlled by the hypothalamus and pituitary. The
hypothalamus is sited at the base of the brain around the third ventricle and above the pituitary stalk, which leads down to the pituitary itself, carrying the hypophyseal–pituitary portal blood supply.

The anatomical relations of the hypothalamus and pituitary (Fig. 26.6) include the optic chiasm just above the pituitary fossa; any expanding lesion from the pituitary or hypothalamus can thus produce visual field defects by pressure on the chiasm. Such upward expansion of the gland through the diaphragma sellae is termed ‘suprasellar extension’. Lateral extension of pituitary lesions may involve the vascular and nervous structures in the cavernous sinus and may rarely reach the temporal lobe of the brain. The pituitary is itself encased in a bony box; therefore, any lateral, anterior or posterior expansion must cause bony erosion.

Embryologically, the anterior pituitary is formed from an upgrowth of Rathke's pouch (ectoderm); this meets an outpouching of the third ventricular floor, which becomes the posterior pituitary. This unique combination of primitive gut and neural tissue provides an essential link between the rapidly responsive central nervous system and the longer-acting endocrine system. Several transcription factors – LHX3, HESX1, PROP1, POU1F1 – are responsible for the differentiation and development of the pituitary cells. Mutation of these produces pituitary disease.

**Physiology**

**Hypothalamus**
This contains many vital centres for such functions as appetite, thirst, thermal regulation and sleeping/waking. It acts as an integrator of many neural and endocrine inputs to control the release of pituitary hormone-releasing factors. It plays a role in circadian rhythm, menstrual cyclicity, and responses to stress, exercise and mood.

Hypothalamic neurones secrete pituitary hormone-releasing and inhibiting factors and hormones (Box 26.4) into the portal system; these run down the stalk to the pituitary. As well as the classical hormones illustrated in Figure 26.7, the hypothalamus also contains large amounts of other neuropeptides and neurotransmitters such as neuropeptide Y, vasoactive intestinal peptide (VIP) and nitric oxide, which can also alter pituitary hormone secretion.

Synthetic hypothalamic hormones and their antagonists are available for the testing of many aspects of endocrine function and for treatment.
Anterior pituitary
The majority of anterior pituitary hormones are under predominantly positive control by the hypothalamic releasing hormones; the exception is prolactin, which is under tonic inhibition by dopamine. Pathological conditions interrupt the flow of hormones between the hypothalamus and pituitary gland, and therefore cause deficiency of most hormones but oversecretion of prolactin. There are five major anterior pituitary axes: the gonadotrophin axis, the growth axis, prolactin, the thyroid axis and the adrenal axis.

Posterior pituitary
The posterior pituitary is neuroanatomically connected to specific hypothalamic nuclei and acts merely as a storage organ. Antidiuretic hormone (ADH, also called vasopressin) and oxytocin, both nonapeptides, are synthesized in the supraoptic and paraventricular nuclei in the anterior hypothalamus. They are then transported along the axon and stored in the posterior pituitary (Fig. 26.7). This means that damage to the stalk or pituitary alone does not prevent synthesis and release of ADH and oxytocin. ADH is discussed on pages 1232–1235; oxytocin produces milk ejection and uterine myometrial contraction.

FIGURE 26.7 Hypothalamic releasing hormones and the pituitary trophic hormones. See the text for an explanation and for abbreviations.

Presentations of pituitary and hypothalamic disease
Diseases of the pituitary can cause under- or overactivity of each of the hypothalamic–pituitary–end-organ axes that are under the control of this gland. The clinical features of the syndromes associated with such altered pituitary function, such as Cushing syndrome, can be
the presenting symptom of pituitary disease or of end-organ disease and are discussed later. First, however, we look at the clinical features of pituitary disease that are common to all hormonal axes.

### Pituitary space-occupying lesions and tumours

Pituitary tumours (Box 26.5) are the most common cause of pituitary disease, and the great majority of these are benign pituitary adenomas, usually monoclonal in origin. Problems are caused by:

- local effects of a tumour
- excess hormone secretion
- the result of inadequate production of hormone by the remaining normal pituitary, i.e. hypopituitarism

**Investigations (for a possible or proven mass)**

**Is there a tumour?**

If there is, how big is it and what **local anatomical effects** is it exerting? Pituitary and hypothalamic space-occupying lesions, hormonally active or not, can cause symptoms by pressure on, or infiltration of:

- the visual pathways, with field defects and visual loss (most common)
• the cavernous sinus, with III, IV and VI cranial nerve lesions
• bony structures and the meninges surrounding the fossa, causing headache
• hypothalamic centres: altered appetite, obesity, thirst, somnolence/wakefulness or precocious puberty
• the ventricles, causing interruption of cerebrospinal fluid (CSF) flow and leading to hydrocephalus
• the sphenoid sinus with invasion, causing CSF rhinorrhoea.

**Investigations**

- **Magnetic resonance imaging (MRI) of the pituitary.** MRI is superior to computed tomography (CT) *(Fig. 26.8)* and will readily show any significant pituitary mass. Small lesions within the pituitary fossa, consistent with small pituitary microadenomas, are very common on MRI (10% of normal individuals in some studies). Such small lesions are sometimes detected during MRI of the head for other reasons – so-called ‘pituitary incidentalomas’.

![FIGURE 26.8](image-url)

- **Visual fields.** These should be plotted formally by automated computer perimetry or Goldmann perimetry, but clinical assessment by confrontation using a small red pin as the target is also sensitive and valuable. Common defects are upper temporal quadrantanopia and bitemporal hemianopia (see p. 804).

**Is there a hormonal excess?**

There are three major conditions that are usually caused by excess secretion from pituitary adenomas and which will show positive immunostaining for the relevant hormone:

• prolactin excess *(prolactinoma or hyperprolactinaemia)*: histologically, prolactinomas are ‘chromophobe’ adenomas (a description of their appearance on classical histological
staining)

- GH excess (acromegaly or gigantism): somatotroph adenomas, usually ‘acidophil’, and sometimes due to specific G-protein mutations (see p. 1184)
- excess ACTH secretion (Cushing's disease and Nelson syndrome): corticotroph adenomas, usually ‘basophil’.

Many tumours are able to synthesize several pituitary hormones, and occasionally more than one hormone is secreted in clinically significant excess (e.g. both GH and prolactin).

The clinical features of acromegaly, Cushing's disease or hyperprolactinaemia are usually (but not always) obvious, and are discussed on pages 1193–1194 and 1197–1199. Hyperprolactinaemia may be clinically ‘silent’. Tumours producing LH, FSH or TSH are well described but very rare.

Some common pituitary tumours, usually ‘chromophobe’ adenomas, cause no clinically apparent hormone excess and are referred to as ‘non-functioning’ tumours. Laboratory studies such as immunocytochemistry or in situ hybridization show that these tumours may often produce small amounts of LH and FSH or the α-subunit of LH, FSH and TSH, and occasionally ACTH.

Is there a deficiency of any hormone?

Clinical examination may give clues; thus, short stature in a child with a pituitary tumour is likely to be due to GH deficiency. A slow, lethargic adult with pale skin is likely to be deficient in TSH and/or ACTH. Milder deficiencies may not be obvious and require specific testing (see Box 26.8).

Management

Management depends on the type and size of tumour (Box 26.6). Decisions about pituitary tumour management are made in a multidisciplinary team (MDT) setting, which typically comprises an endocrinologist, a pituitary surgeon and a radiologist. In general, therapy has three aims: removal/control of the tumour, reduction of excess hormone secretion and replacement of hormone deficiencies.

Removal/control of tumour

This is only required if the tumour is large enough to cause, or is likely to cause, anatomical effects or if the tumour is secreting excess hormones. Small tumours producing no significant symptoms, pressure or endocrine effects may be observed with appropriate clinical, visual field, imaging and endocrine assessments.

- **Surgery** via the trans-sphenoidal route is usually the treatment of choice. Very large tumours are occasionally removed via the open transcranial (usually transfrontal) route.

- **Radiotherapy** – by conventional linear accelerator or newer stereotactic techniques – is usually employed when surgery is impracticable or incomplete, as it controls but rarely abolishes tumour mass. The conventional regimen involves a dose of 45 Gy, given as 20–25 fractions via three fields. Stereotactic techniques use either a linear accelerator or multiple cobalt sources (‘gamma-knife’).

- **Medical therapy** with somatostatin analogues and/or dopamine agonists sometimes causes shrinkage of specific types of tumour (see p. 1194) and, if successful, can be used as primary therapy, particularly in the case of prolactinomas.

Reduction of excess hormone secretion

Reduction is usually obtained by surgical removal but sometimes by medical treatment. Useful control can be achieved with dopamine agonists for prolactinomas or somatostatin analogues for acromegaly, but ACTH secretion usually cannot be controlled by medical means. GH antagonists are also available for acromegaly (see p. 1194).
Replacement of hormone deficiencies

Replacement of hormone deficiencies, i.e. hypopituitarism, is discussed below (see Box 26.10).

Differential diagnosis of pituitary or hypothalamic masses

Although pituitary adenomas are the most common mass lesion of the pituitary (90%), a variety of other conditions may also present as a pituitary or hypothalamic mass and form part of the differential diagnosis.

Other tumours

• **Craniopharyngioma** (1–2%), a usually cystic hypothalamic tumour that is often calcified and arises from Rathke's pouch, often mimics an intrinsic pituitary lesion. It is the most common pituitary tumour in children but may present at any age (Fig. 26.9).

![Fig. 26.9](image)

**FIGURE 26.9** Craniopharyngioma (arrowed): a partially cystic pituitary and suprasellar mass. A. Sagittal MRI. B. Coronal MRI.

• **Uncommon tumours** include meningiomas (Fig. 26.10), gliomas, chondromas, germinomas and pinealomas. Primary pituitary carcinomas are very rare, but occasionally prolactin- and ACTH-secreting tumours can present in an aggressive manner, which may require chemotherapy in addition to conventional treatment. Metastases occasionally present as apparent pituitary tumours, typically accompanied by headache and diabetes insipidus.
Hypophysitis and other inflammatory masses

A variety of inflammatory masses occur in the pituitary or hypothalamus. These include rare pituitary-specific conditions (e.g. autoimmune (lymphocytic) hypophysitis, giant cell hypophysitis, postpartum hypophysitis) or pituitary manifestations of more generalized disease processes (sarcoidosis, Langerhans' cell histiocytosis, granulomatosis with polyangiitis). These lesions may be associated with diabetes insipidus and/or an unusual pattern of hypopituitarism.

Other lesions

*Carotid artery aneurysms* may masquerade as pituitary tumours and must be diagnosed before surgery. Cystic lesions may also present as a pituitary mass, including arachnoid and Rathke cleft cysts.

### Hypopituitarism

#### Pathophysiology

Deficiency of hypothalamic releasing hormones or of pituitary trophic hormones can be selective or multiple. Thus isolated deficiencies of GH, LH/FSH, ACTH, TSH and vasopressin (ADH) are all seen, some cases of which are genetic and congenital, and others sporadic and autoimmune or idiopathic in nature.

Multiple deficiencies usually result from tumour growth or other destructive lesions. There is generally a progressive loss of anterior pituitary function. GH and gonadotrophins are usually first affected. Hyperprolactinaemia, rather than prolactin deficiency, occurs relatively early because of loss of tonic inhibitory control by dopamine. TSH and ACTH are usually last to be affected.

*Panhypopituitarism* refers to deficiency of all anterior pituitary hormones; it is most commonly caused by pituitary tumours, surgery or radiotherapy. Vasopressin (ADH) and oxytocin secretion will be significantly affected only if the hypothalamus is involved by a
hypothalamic tumour or major suprasellar extension of a pituitary lesion, or if there is an infiltrative/inflammatory process. Posterior pituitary deficiency with diabetes insipidus is rare in an uncomplicated pituitary adenoma.

**Genetics**

Specific genes are responsible for the development of the anterior pituitary, involving interaction between signalling molecules and transcription factors. For example, mutations in *PROP1* and *POU1F1* (previously PIT-1) prevent the differentiation of anterior pituitary cells (precursors to somatotroph, lactotroph, thyrotroph and gonadotroph cells), leading to deficiencies of GH, prolactin, TSH and gonadotrophin-releasing hormone (GnRH). In addition, novel mutations within GH and growth hormone-releasing hormone (GHRH) receptor genes have been identified, which may explain the pathogenesis of isolated GH deficiency in children. Despite these advances, most cases of hypopituitarism do not have specific identifiable genetic causes.

**Aetiology**

Disorders that cause hypopituitarism are listed in **Box 26.7**. Pituitary and hypothalamic tumours, and surgical or radiotherapy treatment, are the most common.

---

**Box 26.7**

**Causes of hypopituitarism**

**Congenital**

- Isolated deficiency of pituitary hormones (e.g. Kallmann syndrome)
- *POU1F1* (Pit-1), *Prop1*, *HESX1* mutations

**Infective**

- Basal meningitis (e.g. tuberculosis)
- Encephalitis
- Syphilis

**Vascular**

- Pituitary apoplexy
- Sheehan syndrome (postpartum necrosis)
- Carotid artery aneurysm

**Immunological**

- Autoimmune (lymphocytic) hypophysitis
Clinical features

Symptoms and signs depend upon the extent of hypothalamic and/or pituitary deficiencies, and mild deficiencies may not lead to any complaint on the part of the patient. In general, symptoms
of deficiency of a pituitary-stimulating hormone are the same as those of primary deficiency of the peripheral endocrine gland (e.g. TSH deficiency and primary hypothyroidism cause similar symptoms due to lack of thyroid hormone secretion).

- **Secondary hypothyroidism** and **adrenal failure** both lead to tiredness and general malaise.
- **Hypothyroidism** causes weight gain, slowness of thought and action, dry skin and cold intolerance.
- **Hypoadrenalism** causes mild hypotension, hyponatraemia and, ultimately, cardiovascular collapse during severe intercurrent stressful illness.
- **Gonadotrophin** and thus **gonadal deficiencies** lead to loss of libido, loss of secondary sexual hair, amenorrhoea and erectile dysfunction.
- **Hyperprolactinaemia** may cause galactorrhoea and hypogonadism, including amenorrhoea.
- **GH deficiency** causes growth failure in children and impaired wellbeing in some adults.
- **Weight may increase** (due to hypothyroidism; see above) or decrease in severe combined deficiency (pituitary cachexia).
- Longstanding **panhypopituitarism** gives the classic picture of pallor with hairlessness (‘alabaster skin’).

Particular syndromes related to hypopituitarism are described below.

**Kallmann syndrome**

This syndrome is isolated gonadotrophin (GnRH) deficiency (see p. 1217). It arises due to mutations in the *KAL1* gene, which is located on the short (p) arm of the X chromosome. Kallmann's is classically characterized by anosmia because the *KAL1* gene provides instructions to make anosmin, which has a role both in development of the olfactory system and in migration of GnRH-secreting neurones.

**Septo-optic dysplasia**

This is a rare congenital syndrome (associated with mutations in the *HESX1* gene), presenting in childhood with a clinical triad of midline forebrain abnormalities, optic nerve hypoplasia and hypopituitarism.

**Sheehan syndrome**

This is due to pituitary infarction following postpartum haemorrhage and is rare in developed countries.

**Pituitary apoplexy**

A pituitary tumour occasionally enlarges rapidly owing to infarction or haemorrhage. This may produce severe headache, double vision and sudden severe visual loss, sometimes followed by acute life-threatening hypopituitarism. Often, pituitary apoplexy can be managed conservatively with replacement of hormones and close monitoring of vision, although if there
is a rapid deterioration in visual acuity and fields, surgical decompression of the optic chiasm may be necessary (Fig. 26.11).

![Figure 26.11](image)

**FIGURE 26.11** Pituitary apoplexy. A bright area of haemorrhage at the top of a pituitary adenoma (arrowed) is shown. A. Sagittal MRI. B. Coronal MRI.

‘Empty sella’ syndrome

An ‘empty sella’ is sometimes reported on pituitary imaging. This is sometimes due to a defect in the diaphragma and extension of the subarachnoid space (cisternal herniation), or may follow spontaneous infarction or regression of a pituitary tumour. All or most of the sella turcica is devoid of apparent pituitary tissue but, despite this, pituitary function is usually normal, the pituitary being eccentrically placed and flattened against the floor or roof of the fossa.

### Investigations

Each axis of the hypothalamic–pituitary system requires separate investigation. However, the presence of normal gonadal function (ovulation/menstruation or normal libido/erections) suggests that multiple defects of anterior pituitary function are unlikely.

Investigations range from measurement of simple basal levels (e.g. free T₄ for the thyroid axis) to stimulatory tests for the pituitary and tests of feedback for the hypothalamus (Box 26.8). Assessment of the HPA axis is complex: basal 09:00 hours cortisol levels above 400 nmol/L usually indicate an adequate reserve, while levels below 100 nmol/L predict an inadequate stress response. In many cases, basal levels are equivocal and a dynamic test is essential. The insulin tolerance test (Box 26.9) is widely regarded as the ‘gold standard’ but the short ACTH stimulation test (see Box 26.3), though an indirect measure, is used by many as a routine test of HPA status. Occasionally, the difference between ACTH deficiency and normal HPA axis can be subtle, and the assessment of adrenal reserve is best left to an experienced endocrinologist.

⁺Releasing hormone tests were a traditional part of pituitary function testing but have been largely replaced by the advent of more reliable assays for basal hormones. They test only the ‘readily releasable pool’ of pituitary hormones, and normal responses may be seen in hypopituitarism.

ACTH, adrenocorticotrophic hormone; CRH, corticotrophin releasing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; IGF, insulin-like growth factor; LH, luteinizing hormone; LHRH, luteinizing hormone-releasing hormone; TRH, thyroid-releasing hormone; TSH, thyroid-stimulating hormone.

Box 26.9

Insulin tolerance test

**Indications**

- Diagnosis or exclusion of ACTH and GH deficiency

**Procedure**

- Test explained to patient and consent obtained
- Should only be performed in experienced, specialist units
- Exclude cardiovascular disease (ECG), epilepsy or unexplained blackouts; exclude severe untreated hypopituitarism (basal cortisol must be >100 nmol/L; normal free T₄)
• I.v. hydrocortisone and glucose available for emergency
• Overnight fast, begin at 08:00–09:00 hours
• Soluble insulin, 0.15 U/kg, i.v. at time 0
• Glucose, cortisol and GH levels at 0, 30, 45, 60, 90, 120 min

**Normal response**

• Cortisol rises above 550 nmol/L *
• GH rises above 7 ng/L (severe deficiency = <3 ng/L (<9 mU/L))
• Glucose must be <2.2 mmol/L to achieve adequate stress response

ACTH, adrenocorticotropic hormone; ECG, electrocardiogram; GH, growth hormone.

*Precise cortisol normal ranges are variable between laboratories and assays; appropriate local reference ranges must be used.

**Management**

• Steroid and thyroid hormones are essential for life. Both are given as oral replacement drugs, as in primary thyroid and adrenal deficiency, with the aim of restoring the patient to clinical and biochemical normality (**Box 26.10**); levels are monitored by routine hormone assays. **Note:** Thyroid replacement should not commence until normal glucocorticoid function has been demonstrated or replacement steroid therapy initiated, as an adrenal ‘crisis’ may otherwise be precipitated.

**Box 26.10**

Replacement therapy for hypopituitarism
<table>
<thead>
<tr>
<th>Axis</th>
<th>Usual replacement therapies</th>
</tr>
</thead>
<tbody>
<tr>
<td>Adrenal</td>
<td>Hydrocortisone 15–40 mg daily (starting dose 10 mg on rising/5 mg lunchtime/5 mg evening) (Normally no need for mineralocorticoid replacement)</td>

<td>Levothyroxine 100–150 µg daily</td>
</tr>
</tbody>
</table>
| Gonadal                  | Male: Testosterone intramuscularly, orally, transdermally or implant  
Female: Cyclical oestrogen/progestogen orally or as patch  
Fertility: HCG plus FSH (purified or recombinant) or pulsatile GnRH to produce testicular development, spermatogenesis or ovulation  |
| Growth                   | Recombinant human GH used routinely to achieve normal growth in children  
Also advocated for replacement therapy in adults, where GH has effects on muscle mass and wellbeing                                                                                                                                 |
| Thirst                   | Desmopressin 10–20 µg 1–3 times daily by nasal spray or orally 100–200 µg 3 times daily  
Carbamazepine, thiazides and chlorpropamide are very occasionally used in mild diabetes insipidus                                                                 |
| Breast (prolactin inhibition) | Dopamine agonist (e.g. cabergoline 500 µg weekly)                                                                                                                                                                           |

FSH, follicle-stimulating hormone; GH, growth hormone; HCG, human chorionic gonadotrophin.

• Sex hormones are replaced with androgens and oestrogens, both for symptomatic control and for prevention of long-term problems related to deficiency (e.g. osteoporosis).
• When fertility is desired, gonadal function is stimulated directly by human chorionic gonadotrophin (HCG, mainly acting as LH) or by purified or biosynthetic gonadotrophins, or indirectly by pulsatile gonadotrophin-releasing hormone (GnRH – also known as luteinizing hormone-releasing hormone, LHRH); all are expensive and time-consuming, and their use should be restricted to specialist units.
• GH therapy is given in the growing child, under the care of a paediatric endocrinologist. If the adolescent remains deficient at the achievement of adult height, GH therapy can be offered until patients reach their mid-twenties to support somatic development (increase in muscle and bone mass). In adult GH deficiency, GH therapy also produces improvements in body composition, work capacity and psychological wellbeing, together with reversal of lipid abnormalities associated with a high cardiovascular risk, and often results in significant symptomatic benefit. The National Institute for Health and Care Excellence (NICE) recommends GH replacement for children and adolescents with GH deficiency, and in adults with severe GH deficiency and significant quality of life impairment. It is expensive and in the UK costs £2500–6000 per annum.
• Glucocorticoid deficiency may mask impaired urine concentrating ability, diabetes insipidus only becoming apparent after steroid replacement because steroids are required for excretion of free water.

**Further reading**

Growth and abnormal stature

**Physiology**

Growth factor (GH) is the pituitary factor responsible for stimulation of body growth in humans. Its secretion is stimulated by GHRH, released into the portal system from the hypothalamus; it is also under inhibitory control exerted by somatostatin (Fig. 26.12). A separate GH-stimulating system involves a distinct receptor (GH secretogogue receptor), which interacts with ghrelin (see p. 390). It is not known how these two systems interact but, because ghrelin is synthesized in the stomach, a nutritional role is suggested for GH.

- **GH** acts by binding to a specific (single transmembrane) receptor located mainly in the liver (see Box 26.4). This induces an intracellular phosphorylation cascade involving the Janus kinase/signal transducing activators of transcription (JAK/STAT) pathway (see pp. 96–97). STAT proteins are translocated from the cytoplasm into the cell nucleus and cause GH-specific effects by binding to nuclear DNA.

- **Insulin-like growth factor-1 (IGF-1)**, a somatomedin, stimulates growth. Its hepatic secretion is stimulated by a tissue-specific effect of GH on the liver. There are multiple IGF-binding proteins (IGF-BP) in plasma; IGF-BP3 can be measured clinically to improve assessment of GH status, particularly in children.
The control of growth hormone (GH) and insulin-like growth factor-1 (IGF-1). Pituitary GH is secreted under dual control of growth hormone-releasing hormone (GHRH) and somatostatin, and stimulates release of IGF-1 in the liver and elsewhere. IGF-1 has peripheral actions, including bone growth, and exerts negative feedback to the hypothalamus and pituitary. REM, rapid eye movement.

The metabolic actions of the system are:

- increasing collagen and protein synthesis
- promoting retention of calcium, phosphorus and nitrogen, necessary substrates for anabolism
- opposing the action of insulin (a ‘counter-regulatory’ hormone effect).

GH release is intermittent and mainly nocturnal, especially during REM sleep. The frequency and size of GH pulses increase during the growth spurt of adolescence and decline thereafter. Acute stress and exercise both stimulate GH release, while, in the normal subject, hyperglycaemia suppresses it.

IGF-1 may, in addition, play a major role in maintaining neoplastic growth. A relationship has been shown between circulating IGF-1 concentrations and breast cancer in premenopausal women and prostate cancer in men.

Normal growth

There are factors other than GH that are involved in linear growth in the human:

- **Genetic factors.** Children of two short parents will probably be short and vice versa.
- **Nutritional factors.** Adequate nutrients must be available. Impaired growth can result from inadequate dietary intake or small bowel disease (e.g. coeliac disease).
• **General health.** Any serious systemic disease in childhood is likely to reduce growth (e.g. chronic kidney disease or chronic infection).

• **Intrauterine growth retardation.** These infants often grow poorly in the long term, while infants with simple prematurity usually catch up. There is some evidence that low birth weight may predispose to hypertension, diabetes and other health problems in later adult life (see p. 205).

• **Emotional deprivation and psychological factors.** These can impair growth by complex, poorly understood mechanisms, probably involving temporarily decreased GH secretion.

In general, there are three overlapping phases of growth: infantile (0–2 years), which appears to be largely dependent on substrates (food); childhood (age 2 years to puberty), which is largely GH-dependent; and the adolescent ‘growth spurt’, dependent on GH and sex hormones.

The relevant aspects of history and examination in the assessment of problems are shown in **Box 26.11**.

---

**Box 26.11**

**Assessment of problems of growth and development**

**History**

• Pregnancy records
• Rate of growth (home/school records, e.g. heights on kitchen door)
• Comparison with peers at school and siblings
• Change in appearance (old photographs)
• Change in shoe/glove/hat size or frequency of ‘growing out’ of these
• Age of appearance of pubic hair, breasts, menarche

**Physical signs**

• Evidence of systemic disease
• Body habitus, size, relative weight, proportions (span versus height)
• Skin thickness, interdental separation
• Facial features
• Spade hands/feet
• Grading of secondary sexual characteristics

**Assessment of growth**

Charts showing normal centiles of height and weight are essential to monitor growth; they are available for normal British children *(Fig. 26.13)* and many other national and ethnic groups.
Height must be measured, ideally at the same time of day on the same instrument by the same trained observer.

![Height Chart](image)

**FIGURE 26.13** A height chart for boys. *Child A* illustrates the course of a child with hypopituitarism, initially treated with cortisol and thyroxine, but showing growth only after growth hormone (GH) treatment. *Child B* shows the course of a child with constitutional growth delay without treatment.

Height velocity is more helpful than current height. It requires at least two measurements some months apart and, ideally, multiple serial measurements. Height velocity is the rate of current growth (centimetres per year), while the current attained height is largely dependent upon previous growth. Standard deviation scores (SDS) based on the degree of deviation from age–sex norms are widely used. Computer programs also allow calculation of many of these indices.

The approximate future height of a child (‘mid-parental height’) can be simply predicted from the parental heights. For a boy, this is:
(Maternal height +14 cm (5.5 inches) + Paternal height)/2

and for a girl:

(Paternal height – 14 cm (5.5 inches) + Maternal height)/2

Thus, with a father of 180 cm and mother of 154 cm, the predicted heights are 174 cm for a son and 160 cm for a daughter.

**Growth failure: short stature**

When children or their parents complain of short stature, particular attention should focus on:

- intrauterine growth retardation, and weight and gestation at birth
- possible systemic disorders – any system but especially small bowel disease
- evidence of skeletal, chromosomal or other congenital abnormalities
- endocrine status – particularly thyroid
- dietary intake and use of drugs, especially steroids for asthma
- emotional, psychological, family and school problems.

School, general practitioner, clinic and home records of height and weight should be obtained, if possible, to allow growth-velocity calculation. If unavailable, such data must be obtained prospectively.

A child with normal growth velocity is unlikely to have significant endocrine disease and the most common cause of short stature in this situation is pubertal or ‘constitutional’ delay. However, low growth velocity without an apparent systemic cause requires further investigation. Sudden cessation of growth suggests major physical disease; if no gastrointestinal, respiratory, renal or skeletal abnormality is apparent, then a cerebral tumour or hypothyroidism is most likely.

Consistently slow-growing children require full endocrine assessment. Features of the more common causes of growth failure are given in **Box 26.12**.

---

**Box 26.12**

**Clinical features of common causes of short stature**
<table>
<thead>
<tr>

</tr>
</tbody>
</table>

GH, growth hormone; TSH, thyroid-stimulating hormone.

Around the time of puberty, if constitutional delay is clearly shown and symptoms require intervention, then very-low-dose sex steroids in 3- to 6-month courses will usually induce acceleration of growth.

**Investigations**

Once systemic disease has been excluded, the following tests should be performed:

- **Thyroid function tests.** Serum TSH and free T₄ should be measured to exclude hypothyroidism.

- **GH status.** Basal levels are of little value. Validated dynamic tests include the GH response to insulin (the ‘gold standard’; see Box 26.9), arginine + GHRH and glucagon. Tests should only be performed in centres experienced in their use and interpretation. Normal responses depend on test and GH assay used.

- **Blood levels of IGF-1 and IGF-BP3.** These may provide evidence of GH undersecretion.

- **Assessment of bone age.** Non-dominant hand and wrist X-rays allow assessment of bone age by comparison with standard charts.

- **Karyotyping in females.** Turner syndrome (see p. 1220) is associated with short stature. It is thought that this is due to a defect in the short stature homeobox (SHOX) gene, which has a role in non-GH-mediated growth.

**Management**
Systemic illness should be treated and primary hypothyroidism managed with levothyroxine.

For GH insufficiency, recombinant GH (somatropin) is given as nightly injections in doses of 0.17–0.35 mg/kg per week, with dose adjustments made according to clinical response and IGF-1 levels. Treatment is expensive and should be supervised in expert centres.

GH treatment in so-called ‘short normal’ children has not been shown to produce any worthwhile increase in final height. In Turner syndrome (see p. 1220), large doses of GH are effective in increasing final height, especially in combination with appropriate very-low-dose oestrogen replacement. Familial cases of resistance to GH that is caused by an abnormal GH receptor (Laron-type dwarfism) are well described. They are very rare but may respond to therapy with synthetic IGF-1 (measermin).

### Tall stature

The most common causes are hereditary (two tall parents), idiopathic (constitutional) or early developmental factors (eventually resulting in short stature). Tall stature can occasionally be due to hyperthyroidism. Other causes include chromosomal abnormalities (e.g. Klinefelter syndrome, Marfan syndrome) or metabolic abnormalities. GH excess is a very rare cause and is usually clinically obvious.

**Further reading**

### Pituitary hypersecretion syndromes

#### Acromegaly and gigantism

Growth hormone stimulates skeletal and soft tissue growth. GH excess therefore produces gigantism in children (if acquired before epiphyseal fusion) and acromegaly in adults. Both are due to a GH-secreting pituitary tumour (somatotroph adenoma) in almost all cases. Hyperplasia due to ectopic GHRH excess is very rare. Overall incidence is approximately 3–4/million per year and the prevalence is 50–80/million worldwide. Acromegaly usually occurs sporadically, although gene mutations can rarely give rise to familial acromegaly: typically, the AIP gene in familial isolated pituitary adenoma. In familial acromegaly, there is an increased onset before puberty compared to sporadic cases, leading to a higher prevalence of gigantism.

**Clinical features**
Symptoms and signs of acromegaly are shown in Figure 26.14. One-third of patients present with changes in appearance, and one-quarter with visual field defects or headaches; in the remainder, the diagnosis is made by an alert observer in another clinic: for example, in general practice, or in the diabetes, hypertension, dental, dermatology departments. Sleep apnoea is common and requires investigation and treatment if there are suggestive symptoms (see pp. 1085–1086). Sweating, headaches and soft tissue swelling are particularly useful symptoms of persistent GH secretion. Headache is very common in acromegaly and may be severe, even with small tumours; it is often improved after surgical cure or with somatostatin analogues.

**FIGURE 26.14** Acromegaly: symptoms and signs. *Bold italic* type indicates signs of greater discriminant value.

</table>
• **GH levels** may exclude acromegaly if they are undetectable, but a detectable value is non-diagnostic taken alone. Normal adult levels are <0.5 µg/L for most of the day, except during stress or a ‘GH pulse’.

• **A glucose tolerance test** is diagnostic if there is no suppression of GH. Acromegalics fail to suppress GH below 0.3 µg/L and some show a paradoxical rise; about 25% of acromegalics have a positive diabetic glucose tolerance test.

• **IGF-1 levels** are almost always raised in acromegaly; a single plasma level of IGF-1 reflects mean 24-h GH levels and is useful in diagnosis. A normal IGF-1, together with random GH of <1 µg/L, may be taken to exclude acromegaly if the diagnosis is clinically unlikely.

• **Visual field examination** commonly reveals defects, such as bitemporal hemianopia.

• **MRI scan** of the pituitary is carried out if the above tests are abnormal. This will almost always reveal the pituitary adenoma. In cases where no clear lesion is present, or in postoperative cases where residual disease is being sought, there is increasing interest in the use of functional imaging such as positron emission tomography (PET).

• **Pituitary function** commonly demonstrates partial or complete anterior hypopituitarism.

• **Prolactin** levels show mild to moderate hyperprolactinaemia in 30% of patients (see Fig. 26.16). In some, the adenoma secretes both GH and prolactin.

---

### Management

Untreated acromegaly results in markedly reduced survival. Most deaths occur from heart failure, coronary artery disease and hypertension-related causes. In addition, there is an increase in deaths due to neoplasia, particularly large bowel tumours; guidance advocates regular colonoscopy to detect and remove colonic polyps in order to reduce the risk of colonic cancer, although the evidence is inconclusive. Treatment is therefore indicated in all except the elderly or those with minimal abnormalities. The aim of therapy is to achieve a mean GH level below 2.5 µg/L; this is not always ‘normal’ but has been shown to reduce mortality to normal levels and is therefore considered a ‘safe’ GH level. A normal IGF-1 is also a goal of therapy. Occasionally, there can be discordance between GH and IGF-1 levels, which can create management dilemmas.

When present, hypopituitarism should be corrected and concurrent diabetes and/or hypertension should be treated conventionally; both usually improve with treatment of the acromegaly.

The general advantages and disadvantages of surgery, radiotherapy and medical treatment are discussed on page 1190. Progress can be assessed by monitoring GH and IGF-1 levels.

### Surgery

Trans-sphenoidal surgery is the appropriate first-line therapy. It will result in clinical remission in a majority of cases (60–90%) with pituitary microadenoma, but in only 50% of those with macroadenoma. Very high preoperative GH and IGF-1 levels are also poor
prognostic markers of surgical cure. Surgical success rates are variable and highly dependent upon experience, and a specialist pituitary surgeon is essential. Transfrontal surgery is rarely required except for massive macroadenomas. There is a recurrence rate of approximately 10%.

**Pituitary radiotherapy**

External radiotherapy is normally used after pituitary surgery fails to normalize GH levels rather than as primary therapy. It is often combined with medium-term treatment using a somatostatin analogue, dopamine agonist or GH antagonist because of the slow biochemical response to radiotherapy, which may take 10 years or more; it is also often associated with hypopituitarism, which makes it unattractive in patients of reproductive age. Stereotactic (gamma-knife) radiotherapy is used in some centres, as it delivers a more concentrated field of radiation.

**Medical therapy**

There are three receptor targets for the treatment of acromegaly: pituitary somatostatin receptors and dopamine (D₂) receptors, and GH receptors in the periphery.

**Somatostatin receptor agonists**

*Octreotide* and *lanreotide* are synthetic analogues of somatostatin (see pp. 1190–1191), which act selectively on somatostatin receptor subtypes (SSTR2 and SSTR5) and are highly expressed in GH-secreting tumours. These drugs were used as a short-term treatment whilst other modalities become effective, but now are sometimes used as primary therapy. They reduce GH and IGF levels in most patients but not all achieve treatment targets. Both drugs are typically administered as monthly depot injections and are generally well tolerated; they are, however, associated with an increased incidence of gallstones and are expensive. Pasireotide (acting on SSTR 1, 2, 3 and 5) is a newer agent but its role in acromegaly is still being evaluated.

**Dopamine agonists**

Dopamine agonists act on D₂ receptors (see p. 1158) and can be given to shrink tumours prior to definitive therapy or to control symptoms and persisting GH secretion; they are probably most effective in mixed GH-producing (somatotroph) and prolactin-producing (mammatroph) tumours. Typical doses are bromocriptine 10–60 mg daily or cabergoline 0.5 mg daily (higher than for prolactinomas). Given alone, they reduce GH to ‘safe’ levels in only a minority of cases, but are useful for mild residual disease or in combination with somatostatin analogues. Drugs with combined somatostatin and dopamine receptor activity are under development.

**Growth hormone antagonists**

Pegvisomant (a genetically modified analogue of GH) is a GH receptor antagonist that exerts its effect by binding to and preventing dimerization of the GH receptor. It does not lower GH
levels or reduce tumour size but has been shown to normalize IGF-1 levels in 90% of patients. It is given by daily injection and its main role at the present time is treatment of patients in whom GH and IGF levels cannot be reduced to safe levels with somatostatin analogues alone, or by surgery or radiotherapy.

### Hyperprolactinaemia

The hypothalamic–pituitary control of prolactin secretion is illustrated in Figure 26.15. Prolactin is a large peptide secreted in the pituitary and acts via a transmembrane receptor stimulating JAK2 and other pathways (see Box 26.4).

![Figure 26.15](image)

**FIGURE 26.15** The control and actions of prolactin. Prolactin is mainly controlled by tonic inhibition by hypothalamic dopamine. Prolactin stimulates lactation but also inhibits both hypothalamic gonadotrophin-releasing hormone (GnRH) secretion and the gonadal actions of luteinizing hormone (LH). TRH, thyrotrophin-releasing hormone.

Prolactin is under tonic dopamine inhibition; factors known to increase prolactin secretion (e.g. TRH) are probably of less relevance unless the patient has primary hypothyroidism. Prolactin stimulates milk secretion (but not breast tissue development) but also inhibits gonadal activity. It decreases GnRH pulsatility at the hypothalamic level and, to a lesser extent,
blocks the action of LH on the ovary or testis, producing hypogonadism even when the pituitary gonadal axis itself is intact.

The role of prolactin outside pregnancy and lactation is not well defined, although there is some epidemiological evidence of a link between high prolactin levels and breast cancer, which has led to an interest in the development of prolactin receptor antagonists.

Physiological hyperprolactinaemia occurs in pregnancy, lactation and severe stress, as well as during sleep and coitus. The range of serum prolactin seen in common causes of hyperprolactinaemia is illustrated in Figure 26.16. Mildly increased prolactin levels (400–600 mU/L) may be physiological and asymptomatic but higher levels require a diagnosis. Levels above 5000 mU/L always imply a prolactin-secreting pituitary tumour.

![Figure 26.16 Range of serum prolactin seen in common causes of hyperprolactinaemia.](image)

### Aetiology

Hyperprolactinaemia has many causes:

- **Physiological.** These include pregnancy, lactation, stress, sleep, exercise and coitus.
- **Pathological.** These include prolactinoma, co-secretion of prolactin in tumours causing acromegaly, stalk compression due to pituitary adenomas and other pituitary masses, polycystic ovarian syndrome, primary hypothyroidism and idiopathic hyperprolactinaemia. Rarer causes include renal failure, liver failure, post-ictal state and chest wall injury (e.g. following herpes zoster).
- **Drug-induced.** Drug causes include oestrogens (e.g. contraceptive pill), dopamine
**antagonists** (e.g. antipsychotics such as phenothiazines), **antidepressants** (e.g. tricyclics, selective serotonin reuptake inhibitors (SSRIs)), and **others** (e.g. verapamil, cimetidine, methyldopa).

### Clinical features

Patients may present with features of hyperprolactinaemia or structural symptoms from a pituitary tumour with headaches and visual loss. This latter presentation is more common in males.

Hyperprolactinaemia stimulates milk production in the breast and inhibits GnRH and gonadotrophin secretion *per se*. It usually presents with:

- galactorrhoea, spontaneous or expressible (60% of cases)
- oligomenorrhoea or amenorrhoea
- decreased libido in both sexes
- decreased potency in men
- subfertility
- symptoms or signs of oestrogen or androgen deficiency – in the long term osteoporosis may result, especially in women
- delayed or arrested puberty in the peripubertal patient
- mild gynaecomastia – often seen in men due to the associated hypogonadism rather than being a direct effect of prolactin.

Additionally, headaches and/or visual field defects occur if there is a pituitary tumour (more common in men). Note that many people with galactorrhoea do not have hyperprolactinaemia – ‘normoprolactinaemic galactorrhoea’ – and the causes are poorly understood.

### Investigations

**Hyperprolactinaemia** should be confirmed by repeat measurement. If there are no clinical features of hyperprolactinaemia, the possibility of **macroprolactinaemia** should be considered. This is a higher-molecular-weight complex of prolactin bound to IgG, which is physiologically inactive but occurs in a small proportion of normal people and can therefore lead to unnecessary treatment. Macroprolactinaemia can be diagnosed in the laboratory by precipitation of immunoglobulin G (IgG) with polyethylene glycol, after which prolactin levels will be normal on testing; most laboratories will do this routinely. Hyperprolactinaemia should be excluded in all patients presenting with a pituitary mass.

Further tests are appropriate after physiological and drug causes have been excluded:

- **Visual fields** should be checked.
- **Primary hypothyroidism** must be excluded since this is a cause of hyperprolactinaemia.
- **Anterior pituitary function** should be assessed if there is any clinical evidence of
hypopituitarism or radiological evidence of a pituitary tumour (see Boxes 26.3, 26.8 and 26.9).

- **MRI of the pituitary** is necessary if there are any clinical features suggestive of a pituitary tumour, and desirable in all cases when prolactin is significantly elevated (>1000 mU/L).

  In the presence of a pituitary mass on MRI, the level of prolactin helps determine whether the mass is a prolactinoma or a non-functioning pituitary tumour causing stalk-disconnection hyperprolactinaemia: levels of above 5000 mU/L in the presence of a macroadenoma, or above 2000 mU/L in the presence of a microadenoma (or with no radiological abnormality), strongly suggest a prolactinoma (see p. 1186). Macroprolactinoma refers to tumours above 10 mm in diameter, microprolactinoma to smaller ones. Tumours that are approximately 10 mm are termed mesoadenomas.

  Occasionally, very large prolactinomas can be associated with such high serum prolactin levels that some assays give an artefactual falsely low result (known as the ‘hook effect’). If suspected, this can be excluded by serial dilutions of the serum sample.

### Management

Hyperprolactinaemia is usually treated to avoid the long-term effects of oestrogen deficiency (even if the patient would otherwise welcome the lack of periods!) or testosterone deficiency in the male. Exceptions include patients with minor elevations (400–1000 mU/L) and preservation of normal regular menstruation (or normal male testosterone levels), and postmenopausal women with microprolactinomas who are not taking oestrogen replacement.

#### Medical treatment

Hyperprolactinaemia is controlled with a dopamine agonist.

- **Cabergoline** (500 µg once or twice a week, judged on clinical response and prolactin levels) is the best-tolerated and longest-acting drug, and is the drug of choice.

- **Bromocriptine** is the longest-established therapy and is therefore preferred if pregnancy is planned; initial doses should be small (e.g. 1 mg), taken with food and gradually increased to 2.5 mg two or three times daily. Side-effects, which prevent effective therapy in a minority of cases, include nausea and vomiting, dizziness and syncope, constipation and cold peripheries.

- **Quinagolide** (75–150 µg once daily) is an alternative.

  Complications, seen when cabergoline is used in higher doses in Parkinson's disease, include pulmonary, retroperitoneal and pericardial fibrotic reactions, and cardiac valve lesions. Patients need monitoring, although studies suggest that adverse effects appear to be very rare in those on lower, ‘endocrine’, doses.

  In most cases, a dopamine agonist will be the first and only therapy, and can be used in the long term, although a trial of discontinuation can be considered in microprolactinomas after 2–3 years, as a significant percentage may not recur, or in females at the onset of the menopause who are not on oestrogen replacement therapy. Prolactinomas usually shrink in size on a
dopamine agonist, and in macroadenomas any pituitary mass effects commonly resolve (*Fig. 26.17*). Microprolactinomas may not recur after several years of dopamine agonist therapy in a minority of cases, but in the majority hyperprolactinaemia will return if treatment is stopped.

![Image](image_url)

**FIGURE 26.17** Macroprolactinoma (arrowed). A. Before treatment. B. After 2 years' treatment with the dopamine agonist cabergoline, showing marked adenoma shrinkage.

In patients planning *pregnancy*, it is useful to know the size of the pituitary lesion before starting dopamine agonist therapy. Rarely, tumours enlarge during pregnancy to produce headaches and visual field defects. Dopamine agonists, which are traditionally stopped after conception, particularly when used in the treatment of microprolactinomas, can be restarted if there are any signs of tumour growth during pregnancy.

**Trans-sphenoidal surgery**

Surgery may rarely be needed in patients who are intolerant of or unresponsive to dopamine agonists. Surgery may restore normoprolactinaemia in people with microadenoma, but is rarely completely successful in those with macroadenomas and risks damage to normal pituitary function. Therefore, most patients and physicians elect to continue medical therapy rather than proceed to surgery. Prolactin should therefore always be measured before surgery on any mass in the pituitary region. Some surgeons believe that long-term bromocriptine increases the hardness of the adenoma and makes resection more difficult, but others dissent from this view.

**Radiotherapy**

Also rarely needed, radiotherapy usually controls adenoma growth and is slowly effective in lowering prolactin, but causes progressive hypopituitarism. It may be advocated after medical tumour shrinkage or after surgery in larger tumours, especially where families are complete or if the drug treatment is poorly tolerated, but most workers simply advocate continuation of dopamine agonist therapy in responsive cases.
Cushing syndrome

Cushing syndrome is the term used to describe the clinical state of increased free circulating glucocorticoid. It occurs most often following the therapeutic administration of synthetic steroids or excess endogenous secretion of ACTH (see below).

Pathophysiology and aetiology

Spontaneous Cushing syndrome is rare, with an incidence of <5/million per year. Causes of Cushing syndrome are usually subdivided into two groups (Box 26.13):

1. Increased circulating ACTH from the pituitary (65% of cases), known as Cushing's disease, or from an ‘ectopic’, non-pituitary, ACTH-producing tumour elsewhere in the body (10%) with consequent glucocorticoid excess (‘ACTH-dependent’ Cushing's).
2. A primary excess of endogenous cortisol secretion (25%) by an adrenal tumour or, more rarely, by bilateral primary pigmented nodular hyperplasia (PPNH) with subsequent (physiological) suppression of ACTH (‘non-ACTH-dependent’ Cushing's). Rare cases are due to aberrant expression of receptors for other hormones (e.g. glucose-dependent insulinotropic peptide (GIP), LH or catecholamines) in adrenal cortical cells. Germline changes in protein kinase A (PKA) can also result in adrenal hyperplasia and adenomas.

Box 26.13

Causes of Cushing syndrome

**ACTH-dependent disease**
- Pituitary-dependent (Cushing's disease)
- Ectopic ACTH-producing tumours

**Non-ACTH-dependent disease**
- Adrenal adenomas
- Adrenal carcinomas
- Exogenous steroids
  - ACTH, adrenocorticotropic hormone.

Clinical features

The clinical features of Cushing syndrome are those of glucocorticoid excess and are illustrated in *Figure 26.18*.

- **Pigmentation** occurs only with ACTH-dependent causes (most frequently in ectopic ACTH syndrome).
• **A cushingoid appearance** can also be caused by excess alcohol consumption (pseudo-Cushing syndrome); the pathophysiology is poorly understood.

• **Impaired glucose tolerance** or frank diabetes is common, especially in the ectopic ACTH syndrome.

• **Hypokalaemia** due to the mineralocorticoid activity of cortisol is common with ectopic ACTH secretion.

• **Hypertension** is common in all causes of Cushing syndrome.

---

![Symptoms and Signs of Cushing Syndrome](image)

**FIGURE 26.18 Cushing syndrome: symptoms and signs. Bold italic type indicates signs of most value in discriminating Cushing syndrome from simple obesity and hirsutism.**

---

### Diagnosis

There are two phases to investigation.

### Confirmation

Most obese, hirsute, hypertensive patients do not have Cushing syndrome, and some cases of genuine Cushing's have relatively subtle clinical signs. Confirmation rests on demonstrating inappropriate cortisol secretion, not suppressed by exogenous glucocorticoids; difficulties occur with obesity and depression, where cortisol dynamics are often abnormal. Random cortisol measurements are of no value. Occasional patients are seen with so-called ‘cyclical Cushing’s’, in which the abnormalities come and go.

**Investigations** to confirm the diagnosis include:
• **48-h low-dose dexamethasone test (Box 26.14).** Normal individuals suppress plasma cortisol to <50 nmol/L. People with Cushing syndrome fail to show complete suppression of plasma cortisol levels (although levels may fall substantially in a few cases). This test is highly sensitive (>97%). The overnight dexamethasone test is slightly simpler but has a higher false-positive rate.

<td>2 mg 6-hourly Eight doses from 09:00 hours on day 0</td>
</tr>
</tbody>
</table>

*Plasma cortisol values are very dependent upon the assay used; local reference ranges must be consulted.*

• **24-h urinary free cortisol measurements.** This is simple but less reliable; repeatedly normal values render the diagnosis most unlikely, but some people with Cushing syndrome have normal values on some collections (approximately 10%).

• **Circadian rhythm.** After 48 h in hospital, cortisol samples are taken at 09:00 hours and 24:00 hours (without warning the patient and ideally when they are asleep). Normal subjects show a pronounced circadian variation (see Fig. 26.4); those with Cushing syndrome have high midnight cortisol levels (>100 nmol/L), though the 09:00 hours value may be normal.

• Midnight or late-night *salivary cortisol* collected at home can be used for the diagnosis and surveillance of Cushing's.

• **Other tests.** There are frequent exceptions to the classic responses to diagnostic tests in Cushing syndrome. If any clinical suspicion of Cushing's remains after preliminary tests, then specialist investigations are still indicated. These may include the insulin stress test, desmopressin stimulation test (see p. 1234) and corticotrophin-releasing hormone (CRH) tests.
Differential diagnosis of the cause

This can be extremely difficult since all causes can result in clinically identical Cushing syndrome. The classical ectopic ACTH syndrome is distinguished by a short history, pigmentation, weight loss, unprovoked hypokalaemia, clinical or chemical diabetes, and plasma ACTH levels above 200 ng/L, but many ectopic tumours are benign and mimic pituitary disease closely, both clinically and biochemically. Severe hirsutism/virilization suggests an adrenal tumour.

Biochemical and radiological procedures for diagnosis include:

- **Plasma ACTH levels.** Low or undetectable ACTH levels (<10 ng/L) on two or more occasions are a reliable indicator of non-ACTH-dependent disease.

- **Adrenal CT or MRI scan.** Adrenal adenomas and carcinomas causing Cushing syndrome are relatively large and always detectable by CT scan. Carcinomas are distinguished by their large size and irregular outline, and signs of infiltration or metastases. Bilateral adrenal hyperplasia may be seen in ACTH-dependent causes or in ACTH-independent nodular hyperplasia.

- **Pituitary MRI.** A pituitary adenoma may be seen but the adenoma is often small and not visible in a significant proportion of cases.

- **Plasma potassium levels.** Hypokalaemia is common with ectopic ACTH secretion. (All diuretics must be stopped.)

- **High-dose dexamethasone suppression test (Box 26.14).** Failure of significant plasma cortisol suppression suggests an ectopic source of ACTH or an adrenal tumour.

- **CRH test.** An exaggerated ACTH and cortisol response to exogenous CRH suggests pituitary-dependent Cushing's disease, as ectopic sources rarely respond.

- **Chest X-ray.** A carcinoma of the bronchus or a bronchial carcinoid is sought. Carcinoid lesions may be very small; if ectopic ACTH is suspected, whole-lung, mediastinal and abdominal CT scanning should be performed.

Further investigations may involve:

- **Selective catheterization** of the inferior petrosal sinus to measure ACTH for pituitary lesions, or blood samples taken throughout the body in a search for ectopic sources.

- **Radiolabelled octreotide** ($^{111}$In octreotide) is occasionally helpful in locating ectopic ACTH sites.

### Management

**Cushing syndrome**

Successful treatment with a normal biochemical profile should lead to reversal of the presenting clinical features. However, untreated Cushing syndrome has a very poor prognosis, with death from hypertension, myocardial infarction, infection and heart failure. Whatever the
underlying cause, cortisol hypersecretion should be controlled prior to surgery or radiotherapy. Considerable morbidity and mortality are otherwise associated with operating on unprepared patients, especially when abdominal surgery is required.

The usual drug is metyrapone, an 11β-hydroxylase blocker, which is given in doses of 750 mg to 4 g daily in 3–4 divided doses. Ketoconazole (200 mg three times daily) is also used and is synergistic with metyrapone. Plasma cortisol should be monitored, aiming to reduce the mean level during the day to 150–300 nmol/L, equivalent to normal production rates. Aminogluthethimide, trilostane (which reversibly inhibits 3-hydroxysteroid dehydrogenase/5–5,4 isomers) and etomidate infusion (in severe cases) are occasionally used.

Choice of further treatment depends upon the cause.

**Cushing's disease (pituitary-dependent hyperadrenalism)**

- **Trans-sphenoidal removal of the tumour** is the treatment of choice. Selective adenomectomy nearly always leaves the patient ACTH-deficient immediately postoperatively, and this is a good prognostic sign. Overall, pituitary surgery results in remission in 75–80% of cases, but results vary considerably and an experienced surgeon is essential.

- **External pituitary irradiation** alone is slow-acting, only effective in 50–60% even after prolonged follow-up, and mainly used after failed pituitary surgery. Children respond much better to radiotherapy, however, 80% being cured. Stereotactic radiotherapy can be useful in selected cases.

- **Medical therapy** to reduce ACTH (e.g. bromocriptine, cabergoline and cyproheptadine) is rarely effective. The somatostatin analogue pasireotide may provide medical control of Cushing's in some patients, but is associated with hyperglycaemia as a common side-effect. There is some evidence that aggressive corticotroph adenomas may respond to temozolomide chemotherapy.

- **Bilateral adrenalectomy** is an effective last resort if other measures fail to control the disease (see ‘Nelson syndrome’ below). This can be performed laparoscopically.

**Cushing syndrome due to other causes**

**Adrenal adenomas** should be resected laparoscopically after achievement of clinical remission with metyrapone or ketoconazole. Contralateral adrenal suppression may last for a year or more.

**Adrenal carcinomas** are highly aggressive and the prognosis is poor. In general, if there are no widespread metastases, tumour bulk should be reduced surgically. The adrenolytic drug mitotane may inhibit growth of the tumour and prolong survival, though it can cause nausea and ataxia. Some would also give radiotherapy to the tumour bed after surgery.

**Tumours secreting ACTH ectopically** should be removed if possible. Otherwise chemotherapy/radiotherapy may be used, depending on the tumour. Control of the Cushing syndrome with metyrapone or ketoconazole is beneficial for symptoms, and bilateral
adrenalectomy may be appropriate to give complete control of Cushing syndrome if prognosis from the tumour itself is reasonable.

If the source of ACTH is not clear, cortisol hypersecretion should be controlled with medical therapy until a diagnosis can be made.

Nelson syndrome

Nelson syndrome occurs in about 20% of cases after bilateral adrenalectomy for Cushing's disease and is characterized by increased pigmentation (because of high levels of ACTH), associated with an enlarging pituitary tumour. The syndrome is rare now that adrenalectomy is an uncommon primary treatment, and its incidence may be reduced by pituitary radiotherapy soon after adrenalectomy. The Nelson's adenoma may be treated by pituitary surgery and/or radiotherapy (unless given previously).

Hypersecretion of other pituitary hormones

Pituitary tumours may rarely secrete TSH (and cause thyrotoxicosis). Such ‘TSHomas’ lead to the unusual biochemical pattern of elevated fT₄ levels with normal or high circulating TSH levels. High fT₄ with non-elevated TSH should also make the physician think of thyroid hormone resistance or a laboratory assay problem (see p. 1181). FSH- and LH-secreting pituitary tumours may cause elevated sex steroids but are usually biologically inactive and seen incidentally on immunostaining after removal of apparent non-functioning pituitary adenomas.

Further reading

The Thyroid Axis

The metabolism of virtually all nucleated cells of many tissues is controlled by the thyroid hormones. Overactivity or underactivity of the gland is the most common of all endocrine
problems.

Anatomy

The thyroid gland consists of two lateral lobes connected by an isthmus. It is closely attached to the thyroid cartilage and to the upper end of the trachea, and thus moves on swallowing. It is often palpable in normal women.

Embryologically, it originates from the base of the tongue and descends to the middle of the neck. Remnants of thyroid tissue can sometimes be found at the base of the tongue (lingual thyroid) and along the line of descent. The gland has a rich blood supply from superior and inferior thyroid arteries.

The thyroid gland consists of follicles lined by cuboidal epithelioid cells. Inside is the colloid (the iodinated glycoprotein thyroglobulin), which is synthesized by the follicular cells. Each follicle is surrounded by basement membrane, and between them are parafollicular cells containing calcitonin-secreting C cells.

Physiology

Synthesis

The thyroid synthesizes two hormones:

- triiodothyronine ($T_3$), which acts at the cellular level
- L-thyroxine ($T_4$), which is the prohormone.

Inorganic iodide is trapped by the gland via an enzyme-dependent system, oxidized and incorporated into the glycoprotein thyroglobulin to form mono- and diiodotyrosine, and then $T_4$ and $T_3$ (Fig. 26.19).
More T₄ than T₃ is produced, but T₄ is converted in some peripheral tissues (liver, kidney and muscle) to the more active T₃ by 5'-monodeiodination; an alternative 3'-monodeiodination yields the inactive reverse T₃ (rT₃). The latter step occurs particularly in severe non-thyroidal illness (see below).

In plasma, more than 99% of all T₄ and T₃ is bound to hormone-binding proteins (thyroxine-binding globulin, TBG; thyroid-binding prealbumin, TBPA; and albumin). Only free hormone is available for action in the target tissues, where T₃ binds to specific nuclear receptors within target cells. Many drugs and other factors affect TBG; all may result in confusing total T₄ levels in blood, and most laboratories therefore now measure free T₄ levels.

Control of the hypothalamic–pituitary–thyroid axis
Thyrotrophin-releasing hormone (TRH), a peptide produced in the hypothalamus, stimulates the pituitary to secrete thyroid-stimulating hormone (TSH) (see Fig. 26.2). TSH, in turn, stimulates growth and activity of the thyroid follicular cells via the G-protein-coupled TSH membrane receptor (see Box 26.4). The T₃ and T₄ subsequently secreted into the circulation by follicular cells exert negative feedback on the hypothalamus, as described on page 1180.

Circulating T₄ is peripherally deiodinated to T₃, which binds to the thyroid hormone nuclear receptor (TR) on target organ cells to cause modified gene transcription. There are two TR
receptors (TR-α and TR-β) and the tissue-specific effects of T₃ are dependent upon the local expression of these TR receptors. TR-α knockout mice show poor growth, bradycardia and hypothermia, whilst TR-β knockout mice show thyroid hyperplasia and high T₄ levels in the presence of inappropriately normal circulating TSH, suggesting a role for the latter receptors in thyroid hormone resistance (see p. 1208).

Physiological effects of thyroid hormones

The physiological effects of thyroid hormones are summarized in Box 26.15.

Dietary iodine requirement

Globally, dietary iodine deficiency is a major cause of thyroid disease, as iodine is an essential requirement for thyroid hormone synthesis. The recommended daily intake of iodine should be at least 140 µg, and dietary supplementation of salt and bread has reduced the number of areas where ‘endemic goitre’ still occurs (see below).

Investigations: thyroid function tests

Immunoassays for free T₄, free T₃ and TSH are widely available. There are only minor circadian rhythms and measurements may be made at any time. Particular uses of the tests are summarized in Box 26.16, with typical findings in common disorders.

*The clinically most informative tests in each situation are shown in bold.

TSH, thyroid-stimulating hormone.

**TSH measurement**

In most circumstances, TSH levels can discriminate between hyperthyroidism, hypothyroidism and euthyroidism (normal thyroid gland function). Exceptions are hypopituitarism, and the ‘sick euthyroid’ syndrome where low levels (which normally imply hyperthyroidism) occur in the presence of low or normal T₄ and T₃ levels. As a single test of thyroid function, TSH measurement is the most sensitive in most circumstances, but accurate diagnosis requires at least two tests: for example, TSH plus free T₄ or free T₃ where hyperthyroidism is suspected; TSH plus serum free T₄ where hypothyroidism is likely.

**TRH test**

This has been rendered almost obsolete by modern sensitive TSH assays, except for investigation of hypothalamic–pituitary dysfunction. TRH (protirelin) is occasionally used to differentiate between thyroid hormone resistance and TSHoma in the context of raised fT₄ and TSH levels. Typically, after TRH administration, there is a rise in TSH in thyroid hormone resistance, whilst in TSHoma there is a flat response due to continued autonomous TSH secretion, which does not respond to TRH.

**Problems in interpretation of thyroid function tests**

There are three major areas of difficulty: serious acute or chronic illness, pregnancy and use of oral contraceptives, and certain drugs.

**Serious acute or chronic illness**

Thyroid function is affected in several ways:
• reduced concentration and affinity of binding proteins
• decreased peripheral conversion of T₄ to T₃ with more rT₃
• reduced hypothalamic–pituitary TSH production.

Systemically ill patients can therefore have an apparently low total and free T₄ and T₃ with a normal or low basal TSH (the ‘sick euthyroid’ syndrome). Levels are usually only mildly below normal and are thought to be mediated by interleukins IL-1 and IL-6; the tests should be repeated after resolution of the underlying illness.

**Pregnancy and oral contraceptives**

These lead to greatly increased TBG levels and thus to high or high-normal total T₄. Free T₄ is usually normal. Normal ranges for free T₄ and TSH alter with the normal physiological changes during pregnancy and TSH is often slightly suppressed in the first trimester, but this rarely causes clinical problems.

**Drugs**

Amiodarone decreases T₄ to T₃ conversion and free T₄ levels may therefore be above normal in a euthyroid patient; conversely, amiodarone may induce both hyper- and hypothyroidism – the TSH level is usually reliable.

Many drugs affect thyroid function tests by interfering with protein binding but this now rarely causes a problem with free T₄ assays.

**Antithyroid antibodies**

Serum antibodies to the thyroid are common.

- **Destructive antibodies** are directed against the microsomes or against thyroglobulin; the antigen for thyroid microsomal antibodies is the thyroid peroxidase (TPO) enzyme. TPO antibodies are found in up to 20% of the normal population, especially older women, but only 10–20% of these develop overt hypothyroidism.

- **TSH receptor IgG antibodies (TRAb)** typically stimulate, but occasionally block, the receptor. They are specific for Graves’ disease (see p. 1204).

**Hypothyroidism**

**Pathophysiology**

Underactivity of the thyroid is usually primary, caused by disease of the thyroid, but may be secondary to hypothalamic–pituitary disease (reduced TSH drive) (**Box 26.17**). Primary hypothyroidism is one of the most common endocrine conditions, with an overall UK prevalence of over 2% in women but under 0.1% in men; lifetime prevalence for an individual is higher – perhaps as high as 9% for women and 1% for men, with mean age at diagnosis
around 60 years. The worldwide prevalence of subclinical hypothyroidism varies from 1% to 10%.

Box 26.17
Causes of hypothyroidism

Primary disease of thyroid

Congenital
• Agenesis
• Ectopic thyroid remnants

Defects of hormone synthesis
• Iodine deficiency
• Dyshormonogenesis
• Antithyroid drugs
• Other drugs (e.g. lithium, amiodarone, interferon)

Autoimmune
• Atrophic thyroiditis
• Hashimoto’s thyroiditis
• Postpartum thyroiditis

Infective
• Post-subacute thyroiditis
  Post-surgery

Post-irradiation
• Radioactive iodine therapy
• External neck irradiation

Infiltration
• Tumour

Secondary (to hypothalamic–pituitary disease)

Hypopituitarism
• Isolated TSH deficiency

Peripheral resistance to thyroid hormone
TSH, thyroid-stimulating hormone.

Aetiology of primary hypothyroidism
See Box 26.17.

Autoimmune

Atrophic (autoimmune) hypothyroidism
This is the most common cause of hypothyroidism and is associated with antithyroid autoantibodies, leading to lymphoid infiltration of the gland and eventual atrophy and fibrosis. It is six times more common in females and the incidence increases with age. The condition is associated with other autoimmune disease, such as pernicious anaemia, vitiligo and other endocrine deficiencies (see p. 1177). Occasionally, intermittent hypothyroidism occurs with subsequent recovery; antibodies that block the TSH receptor may sometimes be involved in the aetiology.

Hashimoto's thyroiditis
This form of autoimmune thyroiditis, again more common in women and most common in late middle age, produces atrophic changes with regeneration, leading to goitre formation. The gland is usually firm and rubbery but may range from soft to hard. TPO antibodies are present, often in very high titres (>1000 IU/L). Patients may be hypothyroid or euthyroid, though they may go through an initial toxic phase, ‘Hashi-toxicity’. Levothyroxine therapy may shrink the goitre, even when the patient is not hypothyroid.

Postpartum thyroiditis
This is usually a transient phenomenon observed following pregnancy. It may cause hyperthyroidism, hypothyroidism or the two sequentially. It is believed to result from the modifications to the immune system necessary in pregnancy, and histologically is a lymphocytic thyroiditis. The process is normally self-limiting, but when conventional antibodies are found there is a high chance of this proceeding to permanent hypothyroidism. Postpartum thyroiditis may be misdiagnosed as postnatal depression, emphasizing the need for thyroid function tests in this situation.

Defects of hormone synthesis

Iodine deficiency
Dietary iodine deficiency still exists (see p. 203) as ‘endemic goitre’ in some areas where goitre, occasionally massive, is common. The patients may be euthyroid or hypothyroid, depending on the severity of iodine deficiency. The mechanism is thought to be borderline hypothyroidism leading to TSH stimulation and thyroid enlargement in the face of continuing iodine deficiency. Iodine deficiency is still a problem in the Netherlands, Western Pacific, India, South-east Asia, Russia and parts of Africa. Efforts to prevent deficiency by providing iodine in salt continue worldwide but often with incomplete success. Even in the late 20th century, of the 500 million with iodine deficiency in India, about 2 million had cretinism (see
Dyshormonogenesis
This rare condition is due to genetic defects in the synthesis of thyroid hormones; patients develop hypothyroidism with goitre. One particular familial form is associated with sensorineural deafness due to a deletion mutation in chromosome 7, causing a defect of the transporter pendrin (Pendred syndrome) (see Fig. 26.19).

Clinical features
Hypothyroidism produces many symptoms (Fig. 26.20). The alternative term ‘myxoedema’ refers to the accumulation of mucopolysaccharide in subcutaneous tissues. The classic picture of the slow, dry-haired, thick-skinned, deep-voiced patient with weight gain, cold intolerance, bradycardia and constipation makes the diagnosis easy. Milder symptoms are, however, more common and hard to distinguish from other causes of non-specific tiredness. Many cases are detected on biochemical screening.

Special difficulties in diagnosis may arise in certain circumstances:
• **Children with hypothyroidism** may not show classic features but often have a slow growth velocity, poor school performance and sometimes arrest of pubertal development.
• **Young women with hypothyroidism** may not show obvious signs. Hypothyroidism should be excluded in all people with oligomenorrhea/amenorrhea, menorrhagia, infertility or hyperprolactinaemia.
• The elderly show many clinical features that are difficult to differentiate from normal ageing. Hypothyroidism should be excluded in elderly patients with cognitive impairment.

Investigation of primary hypothyroidism

Serum TSH is the investigation of choice; a high TSH level confirms primary hypothyroidism. A low free T<sub>4</sub> level confirms the hypothyroid state (and is also essential to exclude TSH deficiency if clinical hypothyroidism is strongly suspected and TSH is normal or low).

Thyroid and other organ-specific antibodies may be present. Other abnormalities include the following:

• anaemia, which is usually normochromic and normocytic in type but may be macrocytic (sometimes this is due to associated pernicious anaemia) or microcytic (in women, due to menorrhagia or undiagnosed coeliac disease)
• increased serum aspartate transferase levels, from muscle and/or liver
• increased serum creatine kinase levels, with associated myopathy
• hypercholesterolaemia and hypertriglyceridaemia
• hyponatraemia due to an increase in ADH and impaired free water clearance.

Management

Replacement therapy

Replacement therapy with levothyroxine (thyroxine, i.e. T<sub>4</sub>) is given for life. The starting dose will depend upon the severity of the deficiency and on the age and fitness of the patient, especially their cardiac performance: 100 µg daily for the young and fit, 50 µg (increasing to 100 µg after 2–4 weeks) for the small, old or frail. People with ischaemic heart disease require even lower initial doses, especially if the hypothyroidism is severe and longstanding. Most physicians would then begin with 25 µg daily and perform serial electrocardiograms (ECGs), increasing the dose at 3- to 4-week intervals if angina does not occur or worsen, and the ECG does not deteriorate. Occasional patients develop ‘thyrotoxic’ (hyperthyroid) symptoms despite normal fT4 levels if the dose is increased too rapidly.

Monitoring

The aim is to restore T<sub>4</sub> and TSH to well within the normal range. Adequacy of replacement is assessed clinically and by thyroid function tests after at least 6 weeks on a steady dose. If serum TSH remains high, the dose of T<sub>4</sub> should be increased in increments of 25–50 µg, and the tests repeated at 6–8-week intervals until TSH becomes normal, ideally in the lower third of the normal range. Complete suppression of TSH should be avoided because of the risk of atrial fibrillation and osteoporosis. The usual maintenance dose is 100–150 µg given as a single daily dose. An annual thyroid function test is recommended – this is usually performed
in the primary care setting, often assisted and prompted by district ‘thyroid registers’.

Clinical improvement on T₄ may not begin for 2 weeks or more, and full resolution of symptoms may take 6 months. The necessity for lifelong therapy must be emphasized and the possibility of other autoimmune endocrine disease developing, especially Addison’s disease or pernicious anaemia, should be considered. During pregnancy, an increase in T₄ dosage of about 25–50 µg is often needed to maintain normal TSH levels, and the necessity for optimal replacement during pregnancy is emphasized by the finding of reductions in cognitive function in children of mothers with elevated TSH during pregnancy.

In cases where there is difficulty normalizing the TSH, compliance issues, concurrent medication that can interfere with thyroxine absorption (such as iron, calcium compounds and proton pump inhibitors), and undiagnosed coeliac disease should be considered.

A few people with primary hypothyroidism complain of incomplete symptomatic response to T₄ replacement. Combination T₄ and T₃ replacement has been advocated in this context, but randomized clinical trials show no consistent benefit in quality-of-life symptoms.

**Borderline hypothyroidism or ‘compensated euthyroidism’**

Patients are frequently seen with low-normal serum T₄ levels and slightly raised TSH levels. Sometimes this follows surgery or radioactive iodine therapy, when it can reasonably be seen as ‘compensatory’. Treatment with levothyroxine is normally recommended where the TSH is consistently above 10 mU/L, or when possible symptoms, high-titre thyroid antibodies, or lipid abnormalities are present. Where the TSH is only marginally raised, the tests should be repeated 3–6 months later, as a significant proportion will be normal on repeat testing. Conversion to overt hypothyroidism is more common in men or when TPO antibodies are present. In practice, vague symptoms in people with marginally elevated TSH (below 10 mU/L) rarely respond to treatment, but a ‘therapeutic trial’ of replacement may be needed to confirm that symptoms are unrelated to the thyroid. It is also considered best to normalize TSH during (and ideally before) pregnancy to avoid potential fetal adverse effects.

**Myxoedema coma**

Severe hypothyroidism, especially in the elderly, may present with confusion or even coma. Myxoedema coma is very rare; hypothermia is often present and the patient may have severe cardiac failure, pericardial effusions, hypoventilation, hypoglycaemia and hyponatraemia. The mortality was previously at least 50% and patients require full intensive care. Optimal treatment is controversial and data are lacking; most physicians would advise T₃ orally or intravenously in doses of 2.5–5 µg every 8 h, then increasing as above. Large intravenous doses should not be used. Additional measures, though unproven, should include:

- oxygen (by ventilation if necessary)
- monitoring of cardiac output and pressures
• gradual rewarming
• hydrocortisone 100 mg i.v. 8-hourly
• glucose infusion to prevent hypoglycaemia.

Myxoedema madness
Depression is common in hypothyroidism. Rarely, with severe hypothyroidism in the elderly, the patient may become frankly demented or psychotic, sometimes with striking delusions. This may occur shortly after starting $T_4$ replacement.

Screening for hypothyroidism
The incidence of congenital hypothyroidism is approximately 1 in 3500 births. Untreated, severe hypothyroidism produces permanent neurological and intellectual damage (‘cretinism’). Routine screening of the newborn using a blood spot, as in the Guthrie test, to detect a high TSH level as an indicator of primary hypothyroidism is efficient and cost-effective; cretinism is prevented if $T_4$ is started within the first few months of life.

Screening of elderly patients for thyroid dysfunction has a low pick-up rate and is controversial and not currently recommended. However, patients who have undergone thyroid surgery or received radioiodine should have regular thyroid function tests, as should those receiving lithium or amiodarone therapy.

Hyperthyroidism
Hyperthyroidism (thyroid overactivity, thyrotoxicosis) is common, affecting perhaps 2–5% of all females at some time and having a sex ratio of 5 : 1; it most often occurs between the ages of 20 and 40 years. Nearly all cases (>99%) are caused by intrinsic thyroid disease; a pituitary cause is extremely rare (Box 26.18).

<table>
<thead>
<tr>
<th>Box 26.18</th>
</tr>
</thead>
</table>

Causes of hyperthyroidism

Common
• Graves' disease (autoimmune)
• Toxic multinodular goitre
• Solitary toxic nodule/adenoma

Uncommon
• Acute thyroiditis
  – Viral (e.g. de Quervain's)
- Autoimmune
- Post-irradiation
- Postpartum
  - Gestational thyrotoxicosis (HCG-stimulated)
  - Neonatal thyrotoxicosis (maternal thyroid antibodies)
  - Exogenous iodine
  - Drugs – amiodarone
  - Thyrotoxicosis factitia (secret T₄ consumption)

**Rare**
- TSH-secreting pituitary tumours
- Metastatic differentiated thyroid carcinoma
- HCG-producing tumours
- Hyperfunctioning ovarian teratoma (struma ovariī)

HCG, human chorionic gonadotrophin; TSH, thyroid-stimulating hormone.

---

**Graves' disease**

This is the most common cause of hyperthyroidism and is due to an autoimmune process. Serum IgG antibodies bind to TSH receptors in the thyroid, stimulating thyroid hormone production; that is, they behave like TSH. These TSH receptor antibodies (TSHR-Ab) are specific for Graves' disease. Persistent high levels predict a relapse when drug treatment is stopped. There is an association with HLA-B8, DR3 and DR2; the concordance rate amongst monozygotic twins is 50% and that in dizygotic twins is 5%. There is an association with cytotoxic T lymphocyte-associated antigen 4 (CTLA-4), HLA-DRBP*08 and DRB3*0202 on chromosome 6. The mechanism of immune damage is illustrated in *Figure 8.15.*

_Yersinia enterocolitica, Escherichia coli* and other Gram-negative organisms contain TSH-binding sites. This raises the possibility that the initiating event in the pathogenesis may be an infection with possible ‘molecular mimicry’ in a genetically susceptible individual, but the precise initiating mechanisms remain unproven in most cases.

Thyroid eye disease is a feature of Graves' disease. It may accompany the hyperthyroidism in many cases but patients may also be euthyroid or hypothyroid. Other components of Graves' disease, such as Graves' dermopathy, are very uncommon. Rarely, lymphadenopathy and splenomegaly may occur. Graves' disease is also associated with other autoimmune disorders such as pernicious anaemia, vitiligo and myasthenia gravis.

The natural history is one of fluctuation, many patients showing a pattern of alternating relapse and remission; perhaps only 40% of subjects have a single episode. Many patients eventually become hypothyroid.
Other causes of hyperthyroidism/thyrotoxicosis

Solitary toxic adenoma/nodule
This is the cause of about 5% of cases of hyperthyroidism. While the hyperthyroidism will be controlled by the antithyroid drugs, it does not usually remit after a course of antithyroid drugs.

Toxic multinodular goitre
This commonly occurs in older women. Again, antithyroid drugs are rarely successful in inducing a remission, although they can control the hyperthyroidism.

De quervain's thyroiditis
This is transient hyperthyroidism from an acute inflammatory process, probably viral in origin. Apart from the toxicosis, there is usually fever, malaise and pain in the neck with tachycardia and local thyroid tenderness. Thyroid function tests show initial hyperthyroidism, the erythrocyte sedimentation rate (ESR) and plasma viscosity are raised, and thyroid uptake scans show suppression of uptake in the acute phase. Hypothyroidism, usually transient, may then follow after a few weeks. Treatment of the acute phase is with aspirin, using short-term prednisolone in severely symptomatic cases.

Postpartum thyroiditis
This is described on page 1307.

Amiodarone-induced thyrotoxicosis
Amiodarone, a class III antiarrhythmic drug (see pp. 978–979), causes two types of hyperthyroidism.

• **Type I amiodarone-induced thyrotoxicosis (AIT)** is associated with pre-existing Graves' disease or multinodular goitre. In this situation, hyperthyroidism is probably triggered by the high iodine content of amiodarone.

• **Type II AIT** is not associated with previous thyroid disease and is thought to be due to a direct effect of the drug on thyroid follicular cells, leading to a destructive thyroiditis with release of $T_4$ and $T_3$. Type II AIT may be associated with a hypothyroid phase several months after presentation. Because amiodarone inhibits the deiodination of $T_4$ to $T_3$, biochemical presentation of both types of AIT may be associated with higher $T_4;T_3$ ratios than usual.

Clinical features of hyperthyroidism
The symptoms and signs of hyperthyroidism affect many systems (Fig. 26.21).
Symptomatology and signs vary with age and with the underlying aetiology.

- **The eye signs – lid lag and ‘stare’** – may occur with hyperthyroidism of any cause but other features of thyroid eye disease (see below) occur only in Graves’ disease.

- **Graves’ dermopathy** is rare and can occur on any extensor surface. **Pretibial myxoedema** is the most commonly described and is an infiltration of the skin on the shin. **Thyroid acropachy** is very rare and consists of clubbing, swollen fingers and periosteal new bone formation.

- **In the elderly**, a frequent presentation is with atrial fibrillation, other tachycardias and/or heart failure, often with few other signs. Thyroid function tests are mandatory in any patient with atrial fibrillation.

- **Children** frequently present with excessive height or excessive growth rate, or with behavioural problems such as hyperactivity. They may also show weight gain rather than loss.

- **So-called ‘apathetic thyrotoxicosis’** in some elderly patients presents with a clinical picture more like that of hypothyroidism. There may be very few signs and a high degree of clinical suspicion is essential.

### Differential diagnosis

Hyperthyroidism is often clinically obvious but treatment should never be instituted without biochemical confirmation.
Differentiation of the mild case from anxiety states may be difficult; useful positive clinical markers are eye signs, a diffuse goitre, proximal myopathy and wasting. Weight loss, despite a normal or increased appetite, is a very useful clinical symptom of hyperthyroidism. The hyperdynamic circulation with warm peripheries seen with hyperthyroidism can be contrasted with the clammy hands of anxiety.

**Investigations**

- **Serum TSH** is suppressed in hyperthyroidism (<0.05 mU/L), except for the very rare instances of TSH hypersecretion.
- A raised free $T_4$ or $T_3$ confirms the diagnosis; $T_4$ is almost always raised but $T_3$ is more sensitive, as there are occasional cases of isolated ‘$T_3$ toxicosis’.
- **TSH receptor stimulating antibodies (TSHR-Ab)** are now measured routinely and the third-generation tests are 97–99% specific for Graves' disease.
- **Thyroid peroxidase (TPO)** and thyroglobulin antibodies are present in 80% of cases of Graves' disease, but are also found in normals.
- **Scintiscan $^{99}$Tm** is used when there is doubt as to the nature of the goitre.

**Management**

Three possibilities are available: antithyroid drugs, radioiodine and surgery. Practices and beliefs differ widely within and between countries.

**Antithyroid drugs**

*Carbimazole* is most often used in the UK, and propylthiouracil (PTU) is also an option. *Thiamazole* (methimazole), the active metabolite of carbimazole, is used in the USA. These drugs inhibit the formation of thyroid hormones and also have other minor actions; carbimazole/thiamazole is also an immunosuppressive agent. Initial doses and side-effects are detailed in **Box 26.19**.

Although thyroid hormone synthesis is reduced very quickly, the long half-life of T₄ (7 days) means that clinical benefit is not apparent for 10–20 days. As many of the manifestations of hyperthyroidism are mediated via the sympathetic system, beta-blockers are used to provide rapid partial symptomatic control; they also decrease peripheral conversion of T₄ to T₃. Preferred drugs are those without intrinsic sympathomimetic activity, e.g. propranolol (Box 26.19). They should not be used alone for hyperthyroidism except when the condition is self-limiting, as in subacute thyroiditis.

Subsequent management is either by gradual dose titration or by a ‘block and replace’ regimen. Neither regimen has been shown to be unequivocally superior. TSH often remains suppressed for many months after clinical improvement and normalization of T₄ and T₃.

**Dosage regimen**

**Gradual dose titration**

1. Start carbimazole 20–40 mg daily.
2. Review after 4–6 weeks and reduce the dose of carbimazole, depending on clinical state and fT₄/fT₃ levels. TSH levels may remain suppressed for several months and are unhelpful at this stage.
3. When the patient is clinically and biochemically euthyroid, stop beta-blockers.
4. Review thyroid function regularly during the planned course of treatment (typically 18 months – but some use courses between 6 and 24 months).
5. Reduce carbimazole if fT₄ falls below or TSH rises above normal, and when approaching the end of the planned course.
6. Increase carbimazole if fT₄ or fT₃ is above normal (and consider if TSH remains suppressed after several months with a normal fT₄).
7. Stop treatment at the end of the course if the patient is euthyroid on 5 mg daily carbimazole.

PTU is used in similar fashion (Box 26.19).
‘Block and replace’ regimen

With this policy, full doses of antithyroid drugs, usually carbimazole 40 mg daily, are given to suppress the thyroid completely while replacing thyroid activity with 100 µg of levothyroxine daily once euthyroidism has been achieved. This is continued usually for 18 months, the claimed advantages being the avoidance of over- or undertreatment and the better use of the immunosuppressive action of carbimazole. This regimen is contraindicated in pregnancy, as $T_4$ crosses the placenta less well than carbimazole.

Relapse

About 50% of patients will relapse after a course of carbimazole or PTU, mostly within the following 2 years but occasionally much later. Long-term antithyroid therapy is then used, or surgery or radiotherapy is considered (see below). Most patients (90%) with hyperthyroidism have a diffuse goitre but those with large single or multinodular goitres are unlikely to remit after a course of antithyroid drugs and will usually require definitive treatment. Severe biochemical hyperthyroidism is also less likely to remain in remission.

Toxicity

The major side-effect of drug therapy is agranulocytosis, which occurs in approximately 1 in 1000 patients, usually within 3 months of treatment. All patients must be warned to seek immediate medical attention for a white blood cell count if they develop unexplained fever or sore throat; written information is essential. Rashes are more frequent and usually require a change of drug. If toxicity occurs on carbimazole, PTU may be used, and vice versa; side-effects are only occasionally repeated on the other drug.

Radioactive iodine

Radioactive iodine (RAI) is given to patients of all ages, although it is contraindicated in pregnancy and while breast-feeding. RAI is the most common treatment modality in the USA, whereas antithyroid drugs tend to be favoured in Europe.

$^{131}$Iodine is given in an empirical dose (usually 400–550 MBq) because of variable uptake and radiosensitivity of the gland. It accumulates in the thyroid and destroys the gland by local radiation, although it takes several months to be fully effective.

Patients must be rendered euthyroid before treatment. They should stop antithyroid drugs at least 4 days before radioiodine, and not recommence until 3 days after radioiodine. Patients on PTU should stop antithyroid medication before RAI earlier than those on carbimazole because it has a radioprotective action. Many patients do not need to restart antithyroid medication after treatment.

Early discomfort in the neck and immediate worsening of hyperthyroidism are sometimes seen. If worsening occurs, the patient should receive propranolol (Box 26.19); if necessary, carbimazole can be restarted. Euthyroidism normally returns in 2–3 months. People with dysthyroid eye disease are more likely to show worsening of eye problems after radioiodine than after antithyroid drugs; this represents a partial contraindication to RAI, although
worsening can usually be prevented by steroid administration.

**Long-term surveillance**

Hypothyroidism affects the majority of subjects over the following 20 years. Some 75% of patients are rendered euthyroid in the short term, but a small proportion remain hyperthyroid and may require a second dose of radioiodine. Long-term surveillance of thyroid function is necessary, with frequent tests in the first year after therapy and at least annually thereafter.

There is no increased risk of malignancy after RAI.

**Surgery**

Thyroidectomy should be performed only in patients who have previously been rendered euthyroid. Conventional practice is to stop the antithyroid drug 10–14 days before operation and to give potassium iodide (60 mg three times daily), which reduces the vascularity of the gland.

The operation should be performed only by experienced surgeons to reduce the chance of complications:

* Early postoperative bleeding causing tracheal compression and asphyxia is a rare emergency that mandates immediate removal of all clips/sutures to allow escape of the blood/haematoma.
* Laryngeal nerve palsy occurs in 1%. Vocal cord movement should be checked preoperatively. Mild hoarseness is more common and thyroidectomy is best avoided in professional singers!
* Transient hypocalcaemia occurs in up to 10% but with permanent hypoparathyroidism in fewer than 1%.
* Ongoing thyroid function depends on the operation performed. With a single toxic nodule, excision of the lesion is curative. With Graves' disease or multinodular goitre, the traditional ‘subtotal’ thyroidectomy, aiming for euthyroidism on no treatment, results in recurrent hyperthyroidism in 1–3% within 1 year, then 1% per year and hypothyroidism in about 10% of patients within 1 year, and then increasing with time. ‘Near-total’ thyroidectomy is therefore now preferred, with inevitable hypothyroidism but a much reduced risk of recurrence.

Indications for either surgery or radioiodine are given in **Box 26.20**.

---

**Box 26.20**

Choice of surgery or radioiodine therapy for hyperthyroidism

**Indications for surgery or radioiodine**

- Patient choice
- Persistent drug side-effects
• Poor compliance with drug therapy
• Recurrent hyperthyroidism after drugs

**Indications for surgery**

• A large goitre, which is unlikely to remit after antithyroid medication

# Special situations in hyperthyroidism

**Thyroid crisis or ‘thyroid storm’**

This rare condition, with a mortality of 10%, is a rapid deterioration of hyperthyroidism with hyperpyrexia, severe tachycardia, extreme restlessness, cardiac failure and liver dysfunction. It is usually precipitated by stress, infection or surgery in an unprepared patient, or by radioiodine therapy. With careful management, it should no longer occur and most cases referred to as a ‘crisis’ are simply severe but uncomplicated thyrotoxicosis.

*Treatment is urgent.* Propranolol in full doses is started immediately together with potassium iodide, antithyroid drugs, corticosteroids (which suppress many of the manifestations of hyperthyroidism) and full supportive measures. Control of cardiac failure and tachycardia is also necessary.

Occasionally, hyperthyroidism can lead to a thyrotoxic cardiomyopathy, which causes ischaemic changes on a 12-lead ECG; these reverse after euthyroidism is achieved *(Fig. 26.22).*

![FIGURE 26.22 Thyrotoxic cardiomyopathies. ECG showing marked lateral T-wave inversion.](image)

**Hyperthyroidism in pregnancy and neonatal life**

Since hyperthyroidism typically affects young women, pregnancies, both planned and unplanned, inevitably occur during antithyroid treatment. PTU is usually the preferred antithyroid drug at conception and in the first trimester of pregnancy or in any woman planning
pregnancy, due to rare reports of congenital abnormalities with carbimazole, which have not been described with PTU (p. 1307). However, carbimazole is recommended in the second and third trimesters, as liver problems are more frequently described on PTU.

The high level of HCG found in normal pregnancy is a weak stimulator of the TSH receptor, commonly causing suppressed TSH with slightly elevated $fT_4/fT_3$ in the first trimester, which may be associated with hyperemesis gravidarum. True maternal hyperthyroidism occurring de novo during pregnancy is, however, uncommon and usually mild. Diagnosis can be difficult because of the overlap with symptoms of normal pregnancy and misleading thyroid function tests, although TSH is largely reliable. The pathogenesis is almost always Graves' disease.

Thyroid-stimulating immunoglobulin (TSI) crosses the placenta to stimulate the fetal thyroid. Carbimazole and PTU (see below) also cross the placenta but $T_4$ does so poorly, so a ‘block and replace’ regimen is contraindicated. The smallest dose necessary of PTU or carbimazole (see above) is used and the fetus must be monitored. If necessary (when high doses are needed, or there is poor patient compliance or drug side-effects), surgery can be performed, preferably in the second trimester. RAI is absolutely contraindicated.

**The fetus and maternal Graves' disease**

Any mother with a history of Graves' disease may have circulating TSI. Even if she is euthyroid after surgery or RAI, the immunoglobulin may still be present to stimulate the fetal thyroid, and the fetus can thus become hyperthyroid.

Any such patient should therefore be monitored during pregnancy. Fetal heart rate provides a direct biological assay of fetal thyroid status, and monitoring should be performed at least monthly. Rates above 160/minute are strongly suggestive of fetal hyperthyroidism, and maternal treatment with PTU and/or propranolol is used. Direct measurement of TSHR-Ab may be helpful to predict neonatal thyrotoxicosis in this situation. To prevent a euthyroid mother becoming hypothyroid, $T_4$ may be given, as this does not easily cross the placenta. Sympathomimetics, used to prevent premature labour, are contraindicated, as they may provoke fatal tachycardia in the fetus. The paediatrician should be informed and the infant checked immediately after birth, as overtreatment with PTU or carbimazole can cause fetal goitre. Breast-feeding while on the usual doses of carbimazole or PTU appears to be safe.

Hyperthyroidism may also develop in the neonatal period, as TSI has a half-life of approximately 3 weeks. Manifestations in the newborn include irritability, failure to thrive and persisting weight loss, diarrhoea and eye signs. Thyroid function tests are difficult to interpret, as neonatal normal ranges vary with age.

Untreated neonatal hyperthyroidism is probably associated with hyperactivity in later childhood.

**Thyroid hormone resistance**

Thyroid hormone resistance is an inherited condition, caused by an abnormality of the thyroid hormone receptor. Mutations to the receptor (TR $\beta$) result in the need for higher levels of thyroid hormones to achieve the same intracellular effect. As a result, the normal feedback
control mechanisms (see Fig. 26.2) result in high blood levels of T₄ with a normal TSH in order to maintain a euthyroid state. This has two consequences:

1. Thyroid function tests appear abnormal, even when the patient is euthyroid and requires no treatment. Specialist review is needed to differentiate this condition from hyperthyroidism due to inappropriate TSH secretion.

2. Different tissues contain different thyroid hormone receptors and, in some families, receptors in certain tissues may have normal activity. In this case, the level of thyroid hormones to maintain euthyroidism at pituitary and hypothalamic levels (which controls secretion of TSH) may be higher than that required in other tissues such as heart and bone, so that these tissues may exhibit ‘thyrotoxic’ effects in spite of a normal serum TSH. This ‘partial thyroid hormone resistance’ can be very difficult to manage effectively.

Thyroid hormone resistance is diagnosed on the basis of a raised T₄/T₃ in the context of a non-elevated TSH. The differential diagnosis of this pattern of blood results includes TSHoma and laboratory assay interference.

**Long-term consequences of hyperthyroidism**

Long-term follow-up studies of hyperthyroidism show a slight increase in overall mortality, which affects all age groups, is not fully explained and tends to occur in the first year after diagnosis. Thereafter, the only long-term risk of adequately treated hyperthyroidism appears to be an increased risk of osteoporosis. People with persistently suppressed TSH levels have an increased likelihood of developing atrial fibrillation, which may predispose to thromboembolic disease.

**Graves' orbitopathy (ophthalmopathy)**

**Pathophysiology**

Graves' orbitopathy is due to a specific immune response that causes retro-orbital inflammation (Fig. 26.23). Swelling and oedema of the extraocular muscles lead to limitation of movement and to proptosis, which is usually bilateral but can sometimes be unilateral. Ultimately, increased pressure on the optic nerve may cause optic atrophy. Histology of the extraocular muscles shows focal oedema and glycosaminoglycan deposition followed by fibrosis. The precise autoantigen that leads to the immune response remains to be identified, but it appears to be an antigen in retro-orbital tissue with similar immunoreactivity to the TSH receptor.
Eye disease is a manifestation of Graves' disease and can occur in patients who may be hyperthyroid, euthyroid or hypothyroid. Thyroid dysfunction and orbitopathy usually occur within 2 years of each other, although sometimes a gap of many years is seen. TSH receptor antibodies are almost invariably found in the serum but their role in the pathogenesis is becoming clearer (Fig. 26.23). Orbitopathy is more common and more severe in smokers.

Clinical features

The clinical appearances are characteristic (see Fig. 26.21) but thyroid eye disease demonstrates a wide range of severity. A high proportion of people with Graves' disease notice some soreness, painful watering or prominence of the eyes, and the ‘stare’ of lid retraction is relatively common. More severe proptosis occurs in a minority of cases, and limitation and discomfort of eye movement and visual impairment due to optic nerve compression are relatively uncommon. Proptosis and lid retraction may limit the ability to close the eyes completely so that corneal damage may occur. There is periorbital oedema, and conjunctival oedema and inflammation.

Eye manifestations do not parallel the degree of biochemical thyrotoxicosis or the need for antithyroid therapy, but exacerbation of eye disease is more common after radiiodine treatment (15% versus 3% on antithyroid drugs). Sight is threatened in only 5–10% of cases, but the discomfort and cosmetic problems cause great patient anxiety.

Investigations

If the appearance is characteristic, consideration is needed as to whether the patient requires
review by an ophthalmologist. Investigation would include:

- TSH, fT₃ and fT₄ measurement.
- MRI or CT of the orbits to exclude retro-orbital, space-occupying lesions. In Graves' orbitopathy, there may be enlarged muscles and oedema, with a taut optic nerve due to raised intra-orbital pressure.
- Assessment of vision, particularly optic nerve function.

**Management**

If the patient is thyrotoxic, this should be treated, but treatment will not directly result in an improvement of the ophthalmopathy; hypothyroidism must be avoided, as it may exacerbate the eye problem. Smoking should be stopped. Treatment of the eyes may be either local or systemic, and always requires close liaison between specialist endocrinologist and ophthalmologist:

- **Methylcellulose or hypromellose eyedrops** or ointment are given to aid lubrication and improve comfort.
- **Sleeping upright** affords some patients relief.
- **Taping the eyelids** ensures closure at night.
- **Systemic steroids** (prednisolone 30–120 mg daily) usually reduce inflammation if more severe symptoms are present. Pulse intravenous methylprednisolone may be used initially and is more rapidly effective in severe cases.
- **Surgical decompression of the orbit(s)** may be required, particularly if pressure of orbital contents on the optic nerve threatens vision (often called a ‘hot’ decompression), and at a later, stable stage for cosmetic reasons (‘cold’ decompression).
- **Lid surgery** will protect the cornea if lids cannot be closed, and can be useful later for cosmetic reasons.
- **Corrective eye muscle surgery** may improve diplopia due to muscle changes; it should be deferred until the situation has been stable for 6 months and should follow any orbital decompression.
- **Irradiation of the orbits** (20 Gy in divided doses) is used in some centres. This improves inflammation and ocular motility but has little effect on proptosis; its precise role is debated.
- **Immunomodulatory agents** may produce a response in some patients when conventional treatments fail, although clinical trial evidence is inconsistent.
- **Selenium** may have a beneficial effect on inflammatory thyroid ophthalmopathy in some patients.

**Goitre (thyroid enlargement)**

Goitre is more common in women than in men and may be either physiological or pathological.
Clinical features

Goitres are present on examination in up to 9% of the population. Most commonly, a goitre is noticed as a cosmetic defect by the patient or by friends or relatives. The majority are painless, but pain or discomfort can occur in acute varieties. Large goitres can produce dysphagia and difficulty in breathing, implying oesophageal or tracheal compression.

A small goitre may be more easily visible (on swallowing) than palpable. Clinical examination should record the size, shape, consistency and mobility of the gland, as well as whether its lower margin can be demarcated (thus implying the absence of retrosternal extension). A bruit may be present. Associated lymph nodes should be sought and the tracheal position determined if possible. Examination should never omit an assessment of the patient's clinical thyroid status.

Specific enquiry should be made about any medication, especially iodine-containing preparations, and possible exposure to radiation.

Particular points of note are as follows:

• Puberty and pregnancy may produce a diffuse increase in size of the thyroid.
• Pain in a goitre may be caused by thyroiditis, bleeding into a cyst or (rarely) a thyroid tumour.
• Excessive doses of carbimazole or PTU will induce goitre.
• Iodine deficiency and dyshormonogenesis (see above) can also cause goitre.

Diagnosis

There are four major aspects to any goitre: its pathological nature, whether it is causing any compressive symptoms, the patient's thyroid status and whether it is of cosmetic concern. The nature can often be judged clinically. Goitres (Box 26.21) are usually separable into diffuse and nodular types, the causes of which differ.

Box 26.21

Goitre: causes and types

Diffuse

• Simple:
  – Physiological (puberty, pregnancy)
• Autoimmune:
  – Graves' disease
  – Hashimoto's disease
• Thyroiditis:
  – Acute (de Quervain's thyroiditis)
• Iodine deficiency (endemic goitre)
• Dyshormonogenesis
• Goitrogens (e.g. sulphonylureas)

**Nodular**
• Multinodular goitre
• Solitary nodular
• Fibrotic (Riedel's thyroiditis)
• Cysts

**Tumours**
• Adenomas
• Carcinoma
• Lymphomas
**Miscellaneous**

- Sarcoidosis
- Tuberculosis

**Diffuse goitre**

**Simple goitre**

In this instance, no clear cause is found for enlargement of the thyroid, which is usually smooth and soft. It may be associated with thyroid growth-stimulating antibodies.

**Autoimmune thyroid disease**

Hashimoto's thyroiditis and thyrotoxicosis are both associated with firm diffuse goitre of variable size. A bruit is often present in thyrotoxicosis.

**Thyroiditis**

Acute tenderness in a diffuse swelling, sometimes with severe pain, is suggestive of an acute viral thyroiditis (de Quervain's). It may produce transient clinical hyperthyroidism with an increase in serum $T_4$ (see p. 1205).

**Nodular goitres**

**Multinodular goitre**

Most common is the multinodular goitre, especially in older patients. The patient is usually euthyroid but may be hyperthyroid or borderline with suppressed TSH levels but normal free $T_4$ and $T_3$. Multinodular goitre is the most common cause of tracheal and/or oesophageal compression and can lead to laryngeal nerve palsy. It may also extend retrosternally (*Fig. 26.24*).
The classical ‘multinodular goitre’ is usually readily apparent clinically, but it should be noted that modern, high-resolution ultrasound frequently reports multiple small nodules in glands, which are clinically diffusely enlarged and associated with autoimmune thyroid disease. These nodules are also found in up to 40% of the normal population.

### Solitary nodular goitre

Such a goitre presents a difficult problem of diagnosis. Malignancy should be of concern in any solitary nodule; however, the majority of such nodules are cystic or benign and, indeed, may simply be the largest nodule of a multinodular goitre. The diagnostic challenge is to differentiate the small minority of malignant nodules, which require surgery, from the majority of benign nodules, which do not. Sometimes a history of rapid enlargement, associated lymph nodes or pain may suggest an aggressive malignancy, but most thyroid cancers are painless and slow-growing so that investigations are paramount. Risk factors for malignancy include previous irradiation, longstanding iodine deficiency and occasional familial cases.

Solitary toxic nodules are quite uncommon and may be associated with T<sub>3</sub> toxicosis.

### Fibrotic goitre (Riedel's thyroiditis)

Fibrotic goitre is a rare condition, usually producing a ‘woody’ gland. It is associated with other midline fibrosis and is often difficult to distinguish from carcinoma, being irregular and hard. Clinical clues include systemic symptoms of inflammation and elevation in inflammatory markers; it has been shown to be an IgG<sub>4</sub>-related disease.

### Malignancy

In addition to thyroid carcinomas (see below), the thyroid is rarely the site of a metastatic deposit or the site of origin of a lymphoma.
Investigations

Clinical findings will dictate the appropriate initial tests:

- **Thyroid function tests** should include measurement of TSH plus free T<sub>4</sub> or T<sub>3</sub> (see Box 26.8).
- **Thyroid antibodies** are assessed to exclude an autoimmune aetiology.
- **Ultrasound** with high resolution is a sensitive method for delineating nodules and can demonstrate whether they are cystic or solid. In addition, a multinodular goitre may be demonstrated when only a single nodule is palpable. Unfortunately, even cystic lesions can be malignant and thyroid tumours may arise within a multinodular goitre; therefore fine-needle aspiration (see below) is often required and is performed under ultrasound control at the same time as the scan.
- **Chest and thoracic inlet X-rays or CT scan** may detect tracheal compression and large retrosternal extensions in people with a very large goitre or clinical symptoms.
- **Fine-needle aspiration (FNA)** should be performed in the outpatient clinic or during ultrasound if the appearance is suggestive of potential malignancy, based on defined ultrasound criteria, as in people with a solitary nodule or a dominant nodule in a multinodular goitre, there is a 5% chance of malignancy. Cytology in expert hands can usually differentiate the suspicious or definitely malignant nodule. FNA reduces the necessity for surgery but there is a 5% false-negative rate, which must be borne in mind (and the patient appropriately counselled). Continued observation is required when an isolated thyroid nodule is assumed to be benign without excision.

- **Thyroid scan** (99mTc) can be useful to distinguish between functioning (hot) or non-functioning (cold) nodules. A hot nodule is only rarely malignant; however, a cold nodule is malignant in only 10% of cases and FNA has largely replaced isotope scans in the diagnosis of thyroid nodules.

Management

Euthyroid goitre

Many goitres are small, cause no symptoms and can be observed (including self-monitoring by the patient in the long term). In particular, during puberty and pregnancy, a goitre associated with euthyroidism rarely requires intervention and the patient can be reassured that spontaneous resolution is likely. Indications for surgical intervention are:

- **The possibility of malignancy.** A positive or suspicious FNA makes surgery mandatory, and surgery may be necessary if doubt persists, even in the presence of a negative FNA (especially if the patient is concerned by the false-negative rate).
- **Pressure symptoms on the trachea or, more rarely, oesophagus.** The possibility of retrosternal extension should be excluded.
• **Cosmetic reasons.** A large goitre often causes considerable anxiety to the patient, even though it is functionally and anatomically benign.

RAI has also been advocated for the treatment of euthyroid goitre, particularly when surgery is an unattractive option.

**Toxic nodule**

This is initially treated with antithyroid drugs but surgery or radioiodine is often required.

**Thyroid carcinoma**

Types of thyroid carcinoma, with their characteristics and treatment, are listed in **Box 26.22**. While not common, these tumours are responsible for 400 deaths annually in the UK and there is an annual incidence of 30 000 cases in the USA. Over 75% occur in women. They present in 90% of cases as thyroid nodules (see above), but occasionally with cervical lymphadenopathy (about 5%), or with lung, cerebral, hepatic or bone metastases.

Carcinomas derived from thyroid epithelium may be papillary or follicular (differentiated), or anaplastic (undifferentiated). Medullary carcinomas (about 5% of all thyroid cancers) arise from the calcitonin-producing C cells. The pathogenesis of thyroid epithelial carcinomas is not understood, except for occasional familial papillary carcinoma, and those cases related to previous head and neck irradiation or ingestion of RAI (e.g. post-Chernobyl). These tumours are minimally active hormonally and are extremely rarely associated with hyperthyroidism; over 90%, however, secrete thyroglobulin, which can therefore act as a tumour marker after thyroid ablation.
**Papillary and follicular carcinomas**

The primary treatment is surgical: normally total or near-total thyroidectomy for local disease. Regional or more extensive neck dissection is needed where there is local nodal spread or involvement of local structures.

Most tumours will take up iodine, and UK and other guidelines currently recommend RAI ablation of residual thyroid tissue postoperatively for most people with differentiated thyroid cancer. After ablation of normal thyroid in this way, RAI may be used to localize residual disease (scanning using low doses) or to treat it (using high doses: 5.5–7.5 GBq). When disease does recur, local invasion and lymph node involvement is most common, and lungs and bone are the most common sites of distant metastases.

*To minimize risk of recurrence* patients are treated with suppressive doses of levothyroxine (sufficient to suppress TSH levels below the normal range). Patient progress is monitored, both clinically and biochemically, using serum thyroglobulin levels as a tumour marker. The measurement of thyroglobulin is most sensitive when TSH is high but this requires the withdrawal of levothyroxine therapy. Recombinant TSH (thyrotropin alpha, rhTSH) 900 µg (2 doses over 48 h) is used to stimulate thyroglobulin without stopping thyroxine therapy. Detectable thyroglobulin suggests recurrence, in which case whole-body $^{131}$I scanning is required. Unfortunately, the presence of anti-thyroglobulin antibodies can make the assay unreliable.

The *prognosis* is extremely good when differentiated thyroid cancer is excised while confined to the thyroid gland, and the specific therapies available lead to a relatively good prognosis even in the presence of metastases at diagnosis. Accepted markers of high risk include greater age (>40 years), larger primary tumour size (>4 cm) and macroscopic invasion of capsule and surrounding tissues. Recently, oral sorafenib has shown a good short-term response in locally advanced and metastatic differentiated thyroid cancers that were refractory to RAI.

**Medullary carcinoma**

Medullary thyroid carcinoma (MTC) is a neuroendocrine tumour of the calcitonin-producing C cells of the thyroid. This condition is often associated with MEN 2 (see pp. 1239–1240). Approximately 25% of patients diagnosed with MTC have a mutation of the *RET* proto-oncogene, although the other manifestations of MEN 2 may be absent; hence the importance of genetic counselling and family screening. People with MEN 2 mutations are advised to have a prophylactic thyroidectomy as early as 5 years of age to prevent the development of MTC.

Total thyroidectomy and wide lymph node clearance are usually indicated in MTC. Local invasion or metastasis is frequent, and the tumour responds poorly to treatment, although progression is often slow. Recent biological therapy with vandetanib and cabozantinib have shown benefit in advanced medullary thyroid carcinoma.
**Anaplastic carcinomas and lymphoma**

These do not respond to RAI, and external radiotherapy produces only a brief respite.

**Embryology**

Up to 8 weeks of gestation, the sexes share a common development, with a primitive genital tract including the Wolffian and Müllerian ducts. Additionally, there are a primitive perineum and primitive gonads.

- In the presence of a Y chromosome, the potential testis develops while the ovary regresses.
- In the absence of a Y chromosome, the potential ovary develops and related ducts form a uterus and the upper vagina.

Production of Müllerian inhibitory factor from the early ‘testis’ produces atrophy of the Müllerian duct, while, under the influence of testosterone and dihydrotestosterone, the Wolffian duct differentiates into an epididymis, vas deferens, seminal vesicles and prostate. Androgens induce transformation of the perineum to include a penis, penile urethra and scrotum containing the testes, which descend in response to androgenic stimulation. At birth, testicular volume is 0.5–1 mL. The number of oocytes in the ovaries of a female fetus has reached a maximum by the end of the second trimester of in utero development. At birth, the ovaries contain about 3 million oocytes, of which only 400 000 will remain by the time puberty occurs. With the onset of menarche, these oocytes will activate and grow, leading to ovulation and then menstruation.

**Physiology**

**The male**

An outline of the hypothalamic–pituitary–gonadal axis is shown in *Figure 26.25*.

1. Pulses of gonadotrophin-releasing hormone (GnRH) are released from the hypothalamus and stimulate luteinizing hormone (LH) and follicle-stimulating hormone (FSH) release from the pituitary. LH and FSH are composed of two glycoprotein chains (α and β
The α subunits are identical and are shared with TSH, whilst the β subunit confers specific biological activity.

2. LH stimulates testosterone production from Leydig cells of the testis.

3. Testosterone acts via nuclear androgen receptors, which interact with co-regulatory proteins to produce the appropriate tissue responses: male secondary sexual characteristics, anabolism and the maintenance of libido. It also acts locally within the testis to aid spermatogenesis. Testosterone circulates largely bound to sex hormone-binding globulin (SHBG) (see p. 1178). Testosterone feeds back on the hypothalamus/pituitary to inhibit GnRH secretion.

4. FSH stimulates the Sertoli cells in the seminiferous tubules to produce mature sperm and the inhibins A and B.

5. Inhibin feeds back to the pituitary to decrease FSH secretion. Activin, a related peptide, counteracts inhibin.

Secondary sexual characteristics
The secondary sexual characteristics of the male, for which testosterone is necessary, are the growth of pubic, axillary and facial hair, enlargement of the external genitalia, deepening of the voice, sebum secretion, muscle growth and frontal balding.

The female
Female physiology is more complex (Figs 26.25 and 26.26).

1. In the adult female, higher brain centres impose a menstrual cycle of 28 days upon the activity of hypothalamic GnRH.
2. Pulses of GnRH, at about 2-h intervals, stimulate release of pituitary LH and FSH.
3. LH stimulates ovarian androgen production by the ovarian theca cells.
4. FSH stimulates follicular development and activity of aromatase (an enzyme required to convert ovarian androgens to oestrogens) in the ovarian granulosa cells. FSH also stimulates release of inhibin from ovarian stromal cells, which inhibits FSH release. Activin counteracts inhibin (Fig. 26.25).
5. Although many follicles are ‘recruited’ for development in early folliculogenesis, by day 8–10 a ‘leading’ (or ‘dominant’) follicle is selected for development into a mature Graafian follicle.
6. Oestrogens have a double feedback action on the pituitary (Fig. 26.25). Initially, they inhibit gonadotrophin secretion (negative feedback) but, later, high-level exposure results in increased GnRH secretion and increased LH sensitivity to GnRH (positive feedback), which leads to the mid-cycle LH surge, inducing ovulation from the leading follicle (Fig. 26.26).
7. The follicle then differentiates into a corpus luteum, which secretes both progesterone and oestradiol during the second half of the cycle (luteal phase).
8. Oestrogen initially and then progesterone cause uterine endometrial proliferation in preparation for possible implantation; if implantation does not occur, the corpus luteum regresses and progesterone secretion and inhibin levels fall so that the endometrium is shed (menstruation), allowing increased GnRH and FSH secretion.
9. If implantation and pregnancy follow, human chorionic gonadotrophin (HCG) production from the trophoblast maintains corpus luteum function until 10–12 weeks of gestation, by which time the placenta will be making sufficient oestrogen and progesterone to support itself.
Secondary sexual characteristics

The secondary sexual characteristics of the female are induced by oestrogens, especially development of the breast and nipples, vaginal and vulval growth, and pubic hair development. Oestrogens also induce growth and maturation of the uterus and fallopian tubes. They circulate largely bound to SHBG.

Puberty

The mechanisms initiating puberty are thought to result from withdrawal of central inhibition of GnRH release and involve a complex interplay between hypothalamic peptides, as well as external factors. Environmental and physical factors (including body fat changes and physical exercise) are involved in the timing of puberty, as well as the genetic factors required for pubertal maturation. Kisspeptin is the endogenous ligand for kisspeptin receptor KISS1R, formerly known as GPR54 (a G protein-coupled receptor gene), and this peptide is believed to play a crucial role in the regulation of GnRH production and the timing of puberty.

LH and FSH are both low in the prepubertal child. In early puberty, FSH begins to rise first, initially in nocturnal pulses; this is followed by a rise in LH with a subsequent increase in testosterone/oestrogen levels. The milestones of puberty in the two sexes are shown in Figure 26.27.
In boys, pubertal changes begin with testes enlargement (>4 mL) at 10–14 years and are complete by 15–17 years. The testes enlarge, the genitalia develop and the area of pubic hair increases. Peak height velocity is reached between ages 12 and 17 years during stage 4 of testicular development. Full spermatogenesis occurs comparatively late.

In girls, events start a year earlier. Breast bud enlargement begins at age 9–13 years and continues to 12–18 years. Pubic hair growth commences at ages 9–14 years and is completed at 12–16 years. Menarche occurs relatively late (age 11–15 years) but peak height velocity is reached earlier (at age 10–13 years), and growth is completed much earlier than in boys.

Precocious puberty

Development of secondary sexual characteristics, or menarche in girls before the age of 8 and in boys before the age of 9 years, is premature. True precocious puberty can be divided into gonadotrophin-dependent and gonadotrophin-independent (secondary to exposure to either endogenous or sometimes exogenous sex steroids) types. Gonadotrophin-independent causes can also initiate gonadotrophin-dependent precocious puberty, as is the case in congenital adrenal hyperplasia. All cases require assessment by a paediatric endocrinologist.

True precocious puberty must be distinguished from normal variants:

• Premature thelarche. This is early breast development alone and is usually transient, at age 2–4 years. It may regress or persist until puberty. There is no evidence of follicular development.
• **Premature adrenarche.** This is early development of pubic hair without significant other changes, usually after the age of 5 years and more commonly in girls. It is also more common in obese children due to reduced SHBG levels, leading to higher free circulating androgens.

**Gonadotrophin-dependent precocious puberty**

• **Idiopathic precocity** is most common in girls and very rare in boys. This is a diagnosis of exclusion. With no apparent cause for premature breast or pubic hair development, and an early growth spurt, it may be normal and may run in families.

• **Cerebral precocity** is the mode of presentation of many causes of hypothalamic disease, especially tumours. In boys, these must be rigorously excluded. MRI scan is almost always indicated to exclude this diagnosis.

**Gonadotrophin-independent precocious puberty**

Causes include testicular or ovarian disorders, such as McCune–Albright syndrome (MAS; see also p. 1240). MAS usually occurs in girls, with precocity, polyostotic fibrous dysplasia and skin pigmentation (café-au-lait patches). HCG-secreting tumours, androgen- and oestrogen-secreting tumours, including teratomas, and congenital adrenal hyperplasia are also important causes of gonadotrophin-independent precocious puberty.

**Management**

Treatment depends on whether the cause is gonadotrophin-dependent or independent. If the cause is gonadotrophin-dependent, treatment with long-acting GnRH analogues (given by nasal spray, by subcutaneous injection or by implant) causes suppression of gonadotrophin release via downregulation of the receptor – and therefore reduced sex hormone production – and is moderately effective. If the cause is gonadotrophin-independent, inhibitors of steroidogenesis, antiandrogens, and aromatase inhibitors are also used.

**Delayed puberty**

Over 95% of children show signs of pubertal development by the age of 14 years. In its absence, investigation should begin by the age of 15 years. Causes of hypogonadism (see below) are clearly relevant but most cases represent constitutional delay.

In constitutional delay, pubertal development, bone age and stature are in parallel. A family history may confirm that other family members experienced the same delayed development, which is common in boys but very rare in girls.

**In boys,** a testicular volume >4 mL indicates the onset of puberty. A rising serum testosterone is an earlier clue.

**In girls,** the breast bud is the first sign. Ultrasound allows accurate assessment of ovarian and uterine development.

Elevated LH/FSH levels will identify a primary gonadal defect; in other cases, GnRH
(LHRH) tests can indicate the stage of early puberty.

If any progression into puberty is evident clinically, investigations are not required. When delay is great and problems are serious (e.g. severe teasing at school), low-dose, short-term sex hormone therapy is used to induce puberty.

### Clinical features of disorders of sex and reproduction

A detailed history and examination of all systems are required (Box 26.24). A man having regular satisfactory intercourse or a woman with regular ovulatory periods is most unlikely to have significant endocrine disease, assuming the history is accurate.

- Secondary sexual characteristics
- Extent/distribution of hair
- Genital size (testes, ovaries, uterus)
- Clitoromegaly
- Breast development, gynaecomastia
- Galactorrhoea

---

#### Investigation of gonadal function

Much can be deduced from basal measurements of the gonadotrophins, oestrogens/testosterone and prolactin:
- Low testosterone or oestradiol with high gonadotrophins indicates primary gonadal disease.
- Low levels of testosterone/oestradiol with low or normal LH/FSH imply hypothalamic—
pituitary disease.

- Demonstration of ovulation (by measurement of luteal phase serum progesterone and/or by serial ovarian ultrasound in the follicular phase) or a healthy sperm count (20–200 million/mL, >60% grade I motility and <20% abnormal forms) provides absolute confirmation of normal female or male reproductive endocrinology, but these tests are not always essential.

- Pregnancy provides complete demonstration of normal male and female function.

- Hyperprolactinaemia can be confirmed or excluded by direct measurement. Levels may increase with stress; if this is suspected, a cannula should be inserted and samples taken through it 30 min later.

  More detailed tests are indicated in Box 26.25.

### Disorders in the male

#### Hypogonadism
Clinical features

Male hypogonadism may be a presenting complaint or an incidental finding, such as one that emerges during investigation for subfertility. The testes may be small and soft, and there may be gynaecomastia. Except with subfertility, the symptoms are usually those of androgen deficiency: primarily, poor libido, erectile dysfunction and loss of secondary sexual hair (Box 26.26) rather than deficiency of semen production. Sperm makes up only a very small proportion of seminal fluid volume; most is prostatic fluid.

Causes of male hypogonadism are shown in Box 26.27.

### Box 26.27

**Causes of male hypogonadism**

- Reduced gonadotrophins (hypothalamic–pituitary disease):
  - Hypopituitarism
– Selective gonadotrophic deficiency, Kallmann syndrome, normosmic idiopathic hypogonadotropic hypogonadism
– Severe systemic illness
– Severe underweight
• Hyperprolactinaemia:
• Primary gonadal disease (congenital):
  – Anorchia/Leydig cell agenesis
  – Cryptorchidism (testicular maldescent)
  – Chromosome abnormality (e.g. Klinefelter syndrome)
  – Enzyme defects: 5α-reductase deficiency
• Primary gonadal disease (acquired):
  – Testicular torsion
  – Orchidectomy
  – Local testicular disease
  – Chemotherapy/radiation toxicity
  – Orchitis (e.g. mumps)
  – Chronic kidney disease
  – Cirrhosis/alcohol
  – Sickle cell disease
• Androgen receptor deficiency/abnormality

**Investigations**

Testicular disease may be immediately apparent but basal levels of testosterone, LH and FSH should be measured. These will allow the distinction to be made between primary gonadal (testicular) failure and hypothalamic–pituitary disease. Depending on the causes, semen analysis, chromosomal analysis (e.g. to exclude Klinefelter syndrome) and bone age estimation are required.

In clear-cut gonadotrophin deficiency, pituitary MRI scan, prolactin levels and other pituitary function tests are needed. However, equivocal lowering of serum testosterone (7–10 nmol/L) without elevation of gonadotrophins is a relatively common biochemical finding, and is a frequent cause of referral in men with poor libido or erectile dysfunction. Such test results are compatible with mild gonadotrophin deficiency, but may also be seen in acute illness of any cause and often simply represent the lower end of the normal range or the normal circadian rhythm of testosterone when bloods are checked in afternoon or evening surgeries, and in the non-fasting state. Regular use of opiate analgesia may lead to gonadotrophin deficiency and should be considered. ‘Anabolic’ steroid (i.e. androgen) abuse causes similar biochemical findings and is likely if the patient appears well virilized. People with obesity and diabetes mellitus commonly have low circulating SHBG levels associated with insulin resistance and therefore low total testosterone levels.
A therapeutic trial of testosterone replacement is often justified and forms part of the investigation in some patients; full pituitary evaluation may be required in such cases to exclude other pituitary disease.

**Management**

The cause of hypogonadism can rarely be reversed and testosterone replacement therapy should be commenced to control current symptoms and prevent osteoporosis in the long term. Replacement is usually given by transdermal gel or by intramuscular injection (Box 26.28). In gonadotrophin deficiency, LH and FSH (purified or synthetic) or pulsatile GnRH may be used when fertility is required.

Special instances of hypogonadism

**Cryptorchidism**

Cryptorchidism (or undescended testes) is usually treated by surgical exploration and orchidopexy in early childhood. After that age, the germinal epithelium is increasingly at risk, and lack of descent by puberty is associated with subfertility. A short trial of HCG occasionally induces descent; an HCG test with a testosterone response 72 h later excludes anorchia. Intra-abdominal testes have an increased risk of developing malignancy; if presentation is after puberty, orchidectomy is advised. Patients may present in adulthood with primary testicular failure (due to the testicular damage before or during surgery) or gonadotrophin deficiency (presumably the initial cause of maldescent).

**Klinefelter syndrome**

Klinefelter syndrome is a common congenital abnormality, affecting 1 in 1000 males. It is a
chromosomal disorder (47XXY and variants, e.g. 46XY/47XXY mosaicism, i.e. a male with an extra X chromosome). There is both a loss of Leydig cells and seminiferous tubular dysgenesis. Patients usually present in adolescence with poor sexual development, small or undescended testes, gynaecomastia or infertility. In 47XXY, there is long leg length with tall stature, as the androgen deficiency leads to lack of epiphyseal closure in puberty. Patients occasionally have behavioural problems and learning difficulties. There is also a predisposition to diabetes mellitus, breast cancer, emphysema and bronchiectasis; these are all unrelated to the testosterone deficiency.

Clinical examination shows a wide spectrum of features with small, pea-sized but firm testes, usually gynaecomastia and other signs of androgen deficiency. Some patients have a normal puberty and may present later with infertility. Confirmation is by chromosomal analysis.

Treatment is androgen replacement therapy unless testosterone levels are normal. No treatment is possible for the abnormal seminiferous tubules and infertility.

Kallmann syndrome
This is isolated GnRH deficiency. It is associated with decreased or absent sense of smell (anosmia), and sometimes with other bony (cleft palate), renal and cerebral abnormalities (e.g. colour blindness). It is often familial and is usually X-linked, resulting from a mutation in the KAL1 gene, which encodes anosmin-1 (producing loss of smell); one sex-linked form is due to an abnormality of a cell adhesion molecule. Management is that of secondary hypogonadism (see pp. 1216–1217). Fertility is possible.

Normosmic idiopathic hypogonadotropic hypogonadism
This refers to isolated GnRH deficiency in the absence of anosmia. Known mutations account for less than 15% of normosmic idiopathic hypogonadotropic hypogonadism (nIHH). Mutations include the KISS1 gene, which codes for kisspeptin, the protein that acts on the GPR54 receptor, and the FGFR1 gene.

Oligospermia and azoospermia
These may be secondary to gonadotrophin deficiency and can be corrected by gonadotrophin therapy. More often, they result from primary testicular diseases, in which case they are rarely treatable.

Azoospermia with normal testicular size and low FSH levels suggests a vas deferens block, which is sometimes reversible by surgical intervention.

Lack of libido and erectile dysfunction
Lack of libido is a loss of sexual desire; erectile dysfunction (ED) is inability to achieve or maintain erection; they may occur together or separately, and each can precipitate the other. Both are common symptoms in hypogonadism, but most people with either symptom have
normal hormones and many have no definable organic cause. ED may be psychological, neurogenic, vascular, endocrine or related to drugs, and often includes contributions from several causes. Vascular disease is a common aetiology, especially in smokers, and is often associated with vascular problems elsewhere. Autonomic neuropathy, most commonly from diabetes mellitus, is a common contributory cause (see pp. 1271–1272) and many drugs produce ED. The endocrine causes are those of hypogonadism (see above) and can be excluded by normal testosterone, gonadotrophin and prolactin levels. The presence of nocturnal emissions and frequent satisfactory morning erections make endocrine disease unlikely.

Psychogenic erectile dysfunction is frequently a diagnosis of exclusion, though complex tests of penile vasculature and function are available in some centres.

Management

Offending drugs should be stopped. Phosphodiesterase type-5 inhibitors (sildenafil, tadalafil, vardenafil), which increase penile blood flow (see pp. 1271–1272), are first choice for therapy. Other treatments include apomorphine, intracavernosal injections of alprostadil, papaverine or phentolamine, vacuum expanders and penile implants.

If no organic disease is found or if there is clear evidence of psychological problems, the couple should receive psychosexual counselling.

Further reading

Gynaecomastia

Gynaecomastia is development of breast tissue in the male. Causes are shown in Box 26.29. It is due to an imbalance between free oestrogen and free androgen effects on breast tissue.

Box 26.29

Causes of gynaecomastia

• Physiological
  – Neonatal
  – Pubertal
  – Old age
• Hyperthyroidism
• Hyperprolactinaemia
• Renal disease
• Liver disease
Hypogonadism (see Box 26.27)
- Oestrogen-producing tumours (testis, adrenal)
- HCG-producing tumours (testis, lung)
- Starvation/refeeding
- Carcinoma of breast
- Drugs
  - Oestrogenic: oestrogens, digoxin, cannabis, diamorphine
  - Antiandrogens: spironolactone, cimetidine, cyproterone
  - Others: gonadotrophins, cytotoxics

HCG, human chorionic gonadotrophin.

Pubertal gynaecomastia
This occurs in perhaps 50% of normal boys, often asymmetrically. It usually resolves spontaneously within 6–18 months, but after this duration may require surgical removal, as fibrous tissue will have been laid down. The cause is thought to be relative oestrogen excess, and the oestrogen antagonist tamoxifen is occasionally helpful.

Gynaecomastia in the older male
This requires a full assessment to exclude potentially serious underlying disease, such as bronchial carcinoma and testicular tumours (e.g. Leydig cell tumour). However, aromatase activity (see p. 1213) increases with age and may be the cause of gynaecomastia in this group. Aromatase is an enzyme of the cytochrome P450 family and converts androgens to produce oestrogens. Drug effects are common (especially digoxin and spironolactone), and once these and significant liver disease are excluded, most cases have no definable cause. Painful gynaecomastia may be treated with a 3–6-month trial of tamoxifen, and surgery is occasionally necessary if the symptoms or cosmetic appearance are unacceptable.

The ageing male
In the male, there is no sudden ‘change of life’. However, there is a progressive loss of sexual function with reduction in morning erections and frequency of intercourse.

The age of onset varies widely. Typically, overall testicular volume diminishes and SHBG and gonadotrophin levels gradually rise, but other men present with low or borderline testosterone without elevation of LH/FSH. Low testosterone certainly increases the risk of osteoporosis and, in some studies, is associated with increased cardiovascular risk. It remains unclear to what extent general symptoms of lack of energy, drive, muscle strength and general wellbeing may relate to these hormonal changes, but a recent trial of testosterone replacement showed no benefit in general symptoms although there was an improvement in sexual function. Loss of libido and erectile dysfunction are, however, common symptoms, even when hormones are normal, and long-term outcome studies of testosterone replacement are still awaited.
Therefore, the decision to offer testosterone replacement to an ageing male is currently based on full clinical and biochemical assessment and full discussion of potential risks (including prostate disease) as well as benefits. If testosterone is unequivocally low (<7 pmol/L) and there are symptoms specific to androgen deficiency (low libido, erectile dysfunction and loss of early morning erections), most authorities would recommend replacement. However, few would treat if testosterone is >12 pmol/L with normal LH/FSH. Clinically, a large proportion of cases are in the borderline range (7–12 pmol/L), which can lead to difficulties in reaching a firm diagnosis. There is an increasing move towards measuring fasting testosterone levels, as food intake may decrease testosterone, leading to an incorrect diagnosis of androgen deficiency.

Disorders in the female

Hypogonadism
Impaired ovarian function, whether primary or secondary, will lead to both oestrogen deficiency and abnormalities of the menstrual cycle. The latter is very sensitive to disruption, cycles becoming anovulatory and irregular before disappearing altogether. Symptoms will depend on the age at which failure develops. Thus, before puberty, primary amenorrhoea will occur, possibly with delayed puberty; after puberty, secondary amenorrhoea and hypogonadism will result.

Oestrogen deficiency
The physiological effects of oestrogens and symptoms/signs of deficiency are shown in Box 26.30.

## Amenorrhoea

Absence of periods or markedly irregular infrequent periods (oligomenorrhoea) is the most common presentation of female gonadal disease. The clinical assessment of such patients is shown in **Box 26.31**, and common causes are listed in **Box 26.32**. Causes can be divided into whether amenorrhoea is associated with oestrogen deficiency or not, whether it is associated with another condition, whether oestrogen deficiency is due to gonadotrophin deficiency or ovarian damage, and whether amenorrhoea is due to structural problems.

### Box 26.31

**Clinical assessment of amenorrhoea**

**History**

- ? Pregnant
- Date of onset
- Age of menarche, if any
- Sudden or gradual onset
- General health
- Weight – absolute and changes in recent past
- Stress (job, lifestyle, examinations, relationships)
- Excessive exercise
- Drugs
- Hirsutism, acne, virilization
- Headaches/visual symptoms
- Sense of smell
- Past history of pregnancies
- Past history of gynaecological surgery

**Examination**
- General health
- Body shape and skeletal abnormalities
- Weight and height
- Hirsutism and acne
- Evidence of virilization
- Maturity of secondary sexual characteristics
- Galactorrhoea
- Normality of vagina, cervix and uterus

|---|---|---|-----|-----|

Polycystic ovary syndrome is an example of amenorrhoea that is not associated with oestrogen deficiency. It is the most common cause of oligomenorrhoea and amenorrhoea (see below).

### Hypothalamic and weight-related amenorrhoea

Amenorrhoea with low oestrogen and gonadotrophins in the absence of organic pituitary disease is described as hypothalamic amenorrhoea. This may be related to ‘stress’; low body weight, excessive exercise or previous weight loss; stopping the contraceptive pill; or severe illness. However, some patients appear to have defective cycling mechanisms without apparent explanation.

A minimum body weight is necessary for regular menstruation. While anorexia nervosa is the extreme form of weight loss (see pp. 927–928), amenorrhoea is common and may be seen

---

*These conditions may present as primary amenorrhoea.

DHEAS, dehydroepiandrosterone sulphate; E2, oestradiol; EUA, examination under anaesthesia; FSH, follicle-stimulating hormone; HCG, human chorionic gonadotrophin; LH, luteinizing hormone; LHRRH, luteinizing hormone-releasing hormone; nIHH, normosmic idiopathic hypogonadotropic hypogonadism; PCOS, polycystic ovary syndrome; PRL, prolactin; SHBG, sex hormone-binding globulin; T, testosterone.
at weights within the ‘normal’ range. It is possible that alterations in leptin levels are responsible for the hypothalamic dysfunction seen in this situation. Restoration of body weight to above the 50th centile for height is usually effective in restoring menstruation, but in the many cases where this cannot be achieved then oestrogen replacement is necessary.

### Premature menopause and ovarian failure

The most common cause of premature menopause and, with it, amenorrhoea in women (before age 40) is ovarian failure. This may be autoimmune, and is rarely caused by identifiable genetic causes such as the fragile X pre-mutation or Turner syndrome; most commonly, however, it is of unknown aetiology, although often familial. Repeat measurements of LH/FSH levels are necessary before a diagnosis of premature menopause is given because of the psychological impact of this diagnosis and the possibility that a single elevation of LH/FSH might simply be the mid-cycle ovulatory surge. Bilateral oophorectomy and some chemotherapy regimens cause the same oestrogen deficiency state. In some scenarios, ovarian function can fluctuate; therefore, in younger women, consideration needs to be given as to whether contraception is required, and the combined oral contraceptive pill is the best option for hormone replacement therapy (HRT).

*Turner syndrome* (see p. 1224) is a cause of primary amenorrhoea. The phenotype is female with female external genitalia. There is gonadal dysgenesis with streak ovaries. Features include short stature, webbing of the neck (up to 40%), a wide carrying angle of the elbows, high-arched palate and low-set ears. These patients also have an increased incidence of autoimmune disease (2%), bicuspid aortic valves, aortic coarctation and dissection, coronary artery disease, hypertension, type 2 diabetes, horseshoe kidneys, lymphoedema, reduced bone density, hearing problems and inflammatory bowel disease (0.3%).

### Investigation of oligo-menorrhoea

Basal levels of FSH, LH, oestrogen and prolactin allow initial distinction between primary gonadal and hypothalamic–pituitary causes (*Box 26.32*). Elevation of LH and FSH to menopausal levels usually confirms the diagnosis. Subsequent investigations are also shown in *Box 26.32*.

### Management

Treatment is that of the cause wherever possible (e.g. hypothyroidism, low weight, stress, excessive exercise). Hyperprolactinaemia should be corrected (see below). Polycystic ovary syndrome is discussed in detail below.

When oestrogen deficiency is not reversed, HRT should almost always be given, as the risk of osteoporosis and other conditions related to oestrogen deficiency almost always outweighs the risks of HRT at this younger age. HRT may still also be actively recommended when normal menopause occurs relatively early (e.g. before the age of 50). In some women, in whom
ovarian function may recover or fluctuate, consideration should be given to using the combined oral contraceptive pill if fertility is not desired.

In cases of gonadotrophin deficiency, gonadotrophins can be given to achieve ovulation. Primary ovarian disease is rarely treatable except in the rare condition of ‘resistant’ ovary, where high-dose gonadotrophin therapy can occasionally lead to folliculogenesis.

Hirsutism

Normal hair versus hirsutism

The extent of normal hair growth varies between individuals, families and races, being more extensive in the Mediterranean and some Asian subcontinent populations. These normal variations in body hair, and the more extensive hair growth seen in patients complaining of hirsutism, represent a continuum from no visible hair to extensive cover with thick, dark hair. It is therefore impossible to draw an absolute dividing line between ‘normal’ and ‘abnormal’ degrees of facial and body hair in the female. Soft vellus hair is normally present all over the body; this type of hair on the face and elsewhere is ‘normal’ and is not sex hormone-dependent. Hair in the beard, moustache, breast, chest, axilla, abdominal midline, pubic and thigh areas is sex hormone-dependent. Any excess in the latter regions is thus a marker of increased ovarian or adrenal androgen production: most commonly, polycystic ovary syndrome (PCOS) but occasionally other rarer causes.

Aetiology

• **Idiopathic hirsutism.** People with hirsutism, no elevation of serum androgen levels and no other clinical features are sometimes labelled as having ‘idiopathic hirsutism’. However, studies suggest that most people with ‘idiopathic hirsutism’ have some radiological or biochemical evidence of PCOS on more detailed investigation, and several studies have demonstrated evidence of mild PCOS in up to 20% of the normal female population. Familial or idiopathic hirsutism does occur, but usually involves a distribution of hair growth that is not typically androgenic.

• **Ovarian hyperthecosis.** This is a non-malignant ovarian disorder characterized by luteinized thecal cells in the ovarian stroma, which secrete testosterone. The clinical features are similar to those of PCOS but tend to present in perimenopausal women, and serum testosterone levels are higher than typically seen in PCOS.

• **Iatrogenic hirsutism.** This occurs after treatment with androgens, or more weakly androgenic drugs such as progestogens or danazol.

• **Non-androgen-dependent hair growth (hypertrichosis).** This occurs with drugs such as phenytoin, diazoxide, minoxidil and ciclosporin.

• **Other causes.** Rarer and more serious endocrine causes of hirsutism and virilization include congenital adrenal hyperplasia (CAH; see pp. 1228–1229), Cushing syndrome (pp. 1197–
1199), and androgen-secreting (virilizing) tumours of the ovary and adrenal.

Management

See page 1222.

Polycystic ovary syndrome

Polycystic ovary syndrome (PCOS) is the most common cause of hirsutism in clinical practice, affecting about 1 in 5 women worldwide. It is characterized by multiple small cysts within the ovary (Fig. 26.28) (which represent arrested follicular development) and by excess androgen production from the ovaries (and to a lesser extent from the adrenals).

![Image of polycystic ovary syndrome](RT Ovary)

**FIGURE 26.28** Polycystic ovary syndrome. Ultrasound of the ovary, revealing multiple cysts with central ovarian stroma showing increased echo texture.

Measured levels of androgens in blood vary widely from patient to patient and may remain within the normal range, but SHBG levels are often low (due to high insulin levels), leading to high free androgen levels. In PCOS, there is thought to be an increased frequency of the GnRH pulse generator, causing an increase in LH pulses and androgen secretion. The response of the hair follicle to circulating androgens also seems to vary between individuals with otherwise identical clinical and biochemical features, and the reason for this variation in end-organ response remains poorly understood.

PCOS is frequently associated with:

• **hyperinsulinaemia and insulin resistance**, the prevalence of type 2 diabetes being 10 times higher than in normal women

• **hypertension, hyperlipidaemia and increased cardiovascular risk** (the metabolic syndrome; see p. 209), which is 2–3 times higher in PCOS, and studies suggest that PCOS per
se confers an absolute increase in cardiovascular end-points.

Obesity with PCOS is an additional risk factor for insulin resistance. The precise mechanisms that link the aetiology of polycystic ovaries, hyperandrogenism, anovulation and insulin resistance are still to be elucidated, and whether the basic defect is in the ovary, adrenal or pituitary, or is a more generalized metabolic defect, remains unknown. Frequently, there is a family history of either PCOS or type 2 diabetes, suggesting a genetic component.

In routine clinical practice, the majority of people with objective signs of androgen-dependent hirsutism will have PCOS, and investigation is mainly required to exclude rarer and more serious causes of virilization.

### Clinical features

Most patients with PCOS present with amenorrhoea/oligomenorrhoea and/or hirsutism and acne, shortly after menarche. Frequently, patients are also obese with evidence of insulin resistance. Clinical, biochemical and radiological features of PCOS merge imperceptibly into those of the normal populations.

- **Hirsutism.** This should be recorded objectively, ideally using a scoring system, both to document the problem and to monitor treatment. The method and frequency of physical removal (e.g. shaving, plucking) should also be recorded. The development of hirsutism commonly provokes severe distress in young women and may lead to avoidance of normal social activities. Most patients who complain of hirsutism will have an objective excess of hair on examination, but occasionally very little will be found (and appropriate counselling is then indicated).

- **Age and speed of onset.** Hirsutism related to PCOS usually begins around the time of the menarche and increases slowly and steadily in the teens and twenties. Rapid progression and prepubertal or late onset suggest a more serious cause.

- **Accompanying virilization.** Hirsutism due to PCOS may be severe and affect all androgen-dependent areas on the face and body. However, more severe virilization (clitoromegaly, recent-onset frontal balding, male phenotype) implies substantial androgen excess, and usually indicates a rarer cause rather than PCOS. Thinning of head hair in a male pattern – androgenic alopecia – occurs in a proportion of women with uncomplicated PCOS, typically with a familial tendency for premature androgen-related hair loss in both sexes.

- **Menstruation.** Most people with PCOS will have some disturbance of menstruation, typically oligo-/amenorrhea, although more frequent erratic bleeding can also occur. However, PCOS can present as hirsutism with regular periods or as irregular periods, with no evidence of hirsutism or acne.

- **Weight.** Many people with PCOS are also overweight or obese. The obesity worsens the underlying androgen excess and insulin resistance, and inhibits the response to treatment; it is an indication for appropriate advice on diet and exercise. In severe cases, the insulin resistance may have a visible manifestation as acanthosis nigricans on the neck and in the
In addition to worsening the symptoms of PCOS, central obesity in PCOS significantly increases the likelihood of developing diabetes and cardiovascular disease.

**Investigations and differential diagnosis**

- **Serum total testosterone.** This is often elevated in PCOS and is invariably substantially raised in virilizing tumours (usually >5 nmol/L). People with hirsutism and normal testosterone levels frequently have low levels of SHBG, leading to high free androgen levels. The *free androgen index* ([(testosterone/SHBG] *100) is often used and is high; free testosterone is difficult to measure directly.

- **Other androgens.** Androstenedione and dehydroepiandrosterone sulphate are frequently elevated in PCOS, and even higher in congenital adrenal hyperplasia (CAH) and virilizing tumours.

- **17α-Hydroxyprogesterone.** This is elevated in classical CAH, but may be apparent in late-onset CAH only after stimulation tests.

- **Gonadotrophin levels.** LH hypersecretion is a frequent feature of PCOS, but the pulsatile nature of secretion of this hormone means that a ‘classic’ increased LH/FSH ratio is not always observed on a random sample.

- **Oestrogen levels.** Oestradiol is usually normal in PCOS, but oestrone levels (which are rarely measured) are elevated because of peripheral conversion. Levels are variable in other causes.

- **Ovarian ultrasound.** This is a useful investigation *(Fig. 26.28)*. Typical features are those of a thickened capsule, multiple 3–5 mm cysts and a hyperechogenic stroma. Prolonged hyperandrogenization from any cause may lead to polycystic changes in the ovary. Ultrasound may also reveal virilizing ovarian tumours, although these are often small.

- **Serum prolactin.** Mild hyperprolactinaemia is common in PCOS but rarely exceeds 1500 mU/L.

  If an androgen-secreting tumour is suspected clinically or after investigation, then more complex investigations include dexamethasone suppression tests, CT or MRI of adrenals, and selective venous sampling.

**Diagnosis**

Most patients presenting with a combination of hirsutism and menstrual disturbance will be shown to have PCOS, but the rarer alternative diagnoses should be excluded; the latter include late-onset CAH (early onset, raised serum 17α-hydroxyprogesterone), Cushing syndrome (look for other clinical features), and virilizing tumours of the ovary or adrenals (severe virilization, markedly elevated serum testosterone).

The consensus *(Rotterdam) criteria 2003* for diagnosis of PCOS are at least two of the following:
Management

Local therapy for hirsutism

Regular plucking, bleaching, use of depilatory cream, waxing or shaving is used. Such removal neither worsens nor improves the underlying severity of hirsutism. More ‘permanent’ solutions include electrolysis and a variety of ‘laser’ hair removal systems; all appear effective but have not been evaluated in long-term studies, are expensive, and still often require repeated long-term treatment. **Eflornithine cream** (an antiprotzoal) inhibits hair growth by inhibiting ornithine decarboxylase, but is effective in only a minority of cases and should be discontinued if there is no improvement after 4 months.

Systemic therapy for hirsutism

This always requires a year or more of treatment for maximal benefit, and long-term therapy is frequently required as the problem tends to recur when treatment is stopped. The patient must therefore always be an active participant in the decision to use systemic therapy and must understand the rare risks as well as the benefits. Weight loss should also be encouraged, as many patients have improvement in symptoms.

- **Oestrogens** (e.g. oral contraceptives) suppress ovarian androgen production and reduce free androgens by increasing SHBG levels. Combined hormone pills, which contain ethinylestradiol and a non-androgenic progestogen – e.g. desogestrel drospirenone, or cyproterone acetate plus ethinylestradiol (co-cyprindiol) – will produce a slow improvement in hirsutism in a majority of cases and should normally be used first unless there is a contraindication, such as a history of thrombosis. The risk of venous thrombosis appears to be 2–4-fold higher than with other low-dose oral contraceptive pills. After the menopause, HRT preparations that contain medroxyprogesterone (rather than more androgenic progestogens) may be helpful.

- **Cyproterone acetate** (50–100 mg daily) is an antiandrogen but is also a progestogen, teratogen and a weak glucocorticoid. Given continuously, it produces amenorrhea, and so is normally given for days 1–14 of each cycle. In women of childbearing age, contraception is essential.

- **Spironolactone** (200 mg daily) also has antiandrogen activity and can cause useful improvements in hirsutism. In women of childbearing age, contraception is essential.

- **Finasteride** (5 mg daily), a 5α-reductase inhibitor that prevents the formation of dihydrotestosterone in the skin, has also been shown to be effective but long-term experience is limited. In women of childbearing age, contraception is essential.
• **Flutamide**, another antiandrogen, is less commonly used owing to the high incidence of hepatic side-effects. In women of childbearing age, contraception is essential.

**Treatment of menstrual disturbance**

• **Cyclical oestrogen/progestogen** administration will regulate the menstrual cycle and remove the symptom of oligo- or amenorrhoea. This is most frequently an additional benefit of the treatment of hirsutism, but may also be used when menstrual disturbance is the only symptom.

• **Metformin** (500 mg three times daily) is commonly used in this condition because of the recognised association between PCOS and insulin resistance. It may improve menstrual cyclicity and ovulation; some patients also report improvement in hirsutism and ease of weight loss, but gastrointestinal upset may limit use.

**Treatment for fertility in PCOS**

• **Clomifene** 50–100 mg is given daily on days 2–6 of the cycle and is effective in 75% of women in achieving ovulation. It can occasionally cause the **ovarian hyperstimulation syndrome**, an iatrogenic complication of ovulation induction therapy, consisting of ovarian enlargement, oedema, hypovolaemia, acute kidney injury and possibly shock; specialist supervision is essential. It is recommended that clomifene should not normally be used for more than six cycles (owing to a possible increased risk of ovarian cancer in patients treated for longer than recommended).

• **Low-dose FSH** is used for non-responders to clomifene.

• **Metformin** alone may improve ovulation and achieve conception.

  Wedge resection of the ovary was a traditional therapy but is now rarely required, although laparoscopic ovarian electrodiathermy may be helpful.

**Subfertility**

Subfertility, or ‘infertility’, is defined as the inability of a couple to conceive after 1 year of unprotected intercourse. Investigation requires the combined skills of gynaecologist, endocrinologist and, ideally, andrologist. Both partners must be involved and every aspect of the physiology critically examined.

**Aetiology**

A significant proportion of couples have both male and female contributing factors (*Fig. 26.29*).
Inadequate intercourse, hostile cervical mucus and vaginal factors are uncommon (5%). Some 15% of cases appear to be idiopathic, and natural fertility decreases with increasing age. Conception over 40 years of age for both males and females is reduced to below 30%.

**Male factors**

About 30–40% of couples have a major identifiable male factor. There is some evidence that male sperm counts are declining in many populations. Untreated male hypogonadism of any cause (see Box 26.27) is likely to be associated with subfertility.

**Female factors**

Female tubal problems due to pathologies such as pelvic inflammatory disease and endometriosis account for perhaps 20%; a similar proportion have ovulatory disorders. Any cause of oligomenorrhea or amenorrhoea (see Box 26.32) is likely to be associated with suboptimal ovulation or anovulation.

---

**Clinical features**

Both partners should be seen and the following factors checked:

- **The man.** Look for previous testicular damage (orchitis, trauma), undescended testes,
urethral symptoms and evidence of sexually transmitted infection, local surgery, and use of alcohol and drugs. A semen analysis early in the investigations is essential.

• **The woman.** Look for previous pelvic infection, regularity of periods, previous surgery, alcohol intake, smoking and body weight (see p. 1219).

• **Together.** Check the frequency and adequacy of intercourse, and the use of lubricants, which may damage sperm and affect their ability to travel to the uterus.

**Investigations**

See *Figure 26.29.*

**Management**

Counselling of both partners is essential. Any defect(s) found should be treated if possible. Ovulation can usually be induced by exogenous hormones if simpler measures fail, while *in vitro* fertilization (IVF) and similar techniques are widely used, especially where there is tubal blockage, oligospermia or ‘idiopathic subfertility’. Intracytoplasmic sperm injection (ICSI) appears particularly effective for severe oligospermia and poor sperm function.

**Disorders of sexual differentiation**

Disorders of sexual differentiation are rare but may affect chromosomal, gonadal, endocrine and phenotypic development (*Box 26.33*). Such cases always require extensive, multidisciplinary clinical management. An individual’s sex can be defined in several ways:

• **Chromosomal sex.** The normal female is 46XX, the normal male 46XY. The Y chromosome confers male sex; if it is not present, development follows female lines.

• **Gonadal sex.** This is determined predominantly by chromosomal sex but requires normal embryological development.

• **Phenotypic sex.** This describes the normal physical appearance and characteristics of male and female body shape. This, in turn, is a manifestation of gonadal sex and subsequent sex hormone production.

• **Social sex (gender).** This is heavily dependent on phenotypic sex and normally assigned on appearance of the external genitalia at birth.

• **Sexual orientation** – heterosexual, homosexual or bisexual.

**The Adrenal Axis**
Anatomy and function of the adrenal gland

The human adrenals (see Box 26.4) together weigh 8–10 g and comprise an outer cortex and inner medulla. The cortex has three zones: the zona glomerulosa, which secretes aldosterone under the control of the renin–angiotensin system, and the zona reticularis and zona fasciculata, which produce cortisol and androgens under feedback control of the hypothalamic–pituitary–adrenal (HPA) axis. The inner medulla synthesizes, stores and secretes catecholamines (see below and Fig. 26.30).

![FIGURE 26.30](The adrenal gland and its hormones.)

The adrenal cortex

The steroids produced by the adrenal cortex are grouped into three classes, based on their predominant physiological effects: glucocorticoids, mineralocorticoids and androgens.

Glucocorticoids

These are so named after their effects on carbohydrate metabolism. Major actions are listed in Box 26.34. They act on intracellular corticosteroid receptors and combine with coactivating proteins to bind the ‘glucocorticoid response element’ (GRE) in specific regions of DNA to cause gene transcription. Glucocorticoid action is modified locally by the action of 11β-hydroxysteroid dehydrogenase (11βHSD). 11βHSD type 1 converts inactive cortisone into active cortisol, hence amplifying the hormone signal, whilst 11βHSD type 2 does the opposite.

### Box 26.34

The major actions of glucocorticoids

**Increased or stimulated**

- Gluconeogenesis
- Glycogen deposition
- Protein catabolism

---

**Mineralocorticoids**

The predominant effect of mineralocorticoids is on the extracellular balance of sodium and potassium in the distal tubule of the kidney. Aldosterone, produced solely in the zona glomerulosa, is the predominant mineralocorticoid in humans (about 50%); corticosterone makes a small contribution to overall mineralocorticoid activity. Mineralocorticoids act on type 1 corticosteroid receptors, whilst glucocorticoids act on type 2 receptors, both having a very similar structure. The mineralocorticoid activity of cortisol is weak but cortisol is present in considerable excess. The mineralocorticoid receptor in the kidney is largely protected from
this excess by the intrarenal conversion (‘shuttle’) of cortisol to cortisone by 11βHSD type 2.

**Androgens**

Although secreted in considerable quantities, most androgens have only relatively weak intrinsic androgenic activity until metabolized peripherally to testosterone or dihydrotestosterone. Dihydrotestosterone is metabolized from testosterone by 5α-reductase and is a potent androgen receptor agonist. The androgen receptor has been well characterized and mutations within this gene may cause androgen insensitivity syndromes.

### Biochemistry

All steroids have the same basic skeleton ([Fig. 26.31B](#)) and the chemical differences between them are slight. The major biosynthetic pathways are shown in [Figure 26.31A](#).

**Physiology**

*Glucocorticoid* production by the adrenal is under hypothalamic–pituitary control ([Fig. 26.32](#)).
Corticotrophin-releasing hormone (CRH) is secreted in the hypothalamus in response to circadian rhythm, stress and other stimuli. CRH travels down the portal system to stimulate adrenocorticotropic hormone (ACTH) release from the anterior pituitary. Hypothalamic vasopressin (antidiuretic hormone, ADH) also stimulates ACTH secretion and acts synergistically. ACTH is derived from the prohormone pro-opiomelanocortin (POMC), which undergoes complex processing within the pituitary to produce ACTH and a number of other peptides, including beta-lipotrophin and beta-endorphin. Many of these peptides, including ACTH, contain melanocyte-stimulating hormone (MSH)-like sequences, which cause pigmentation when levels of ACTH are markedly raised.

Circulating ACTH stimulates cortisol production in the adrenal. The secreted cortisol (or any other synthetic corticosteroid administered to the patient) causes negative feedback on the hypothalamus and pituitary to inhibit further CRH/ACTH release. The set-point of this system clearly varies through the day according to the circadian rhythm, and is usually overridden by severe stress. Unlike cortisol, mineralocorticoids and sex steroids do not cause negative feedback on the CRH/ACTH axis.

Following adrenalectomy or other adrenal damage (e.g. Addison's disease), cortisol secretion will be absent or reduced; ACTH levels will therefore rise.

Mineralocorticoid secretion is mainly controlled by the renin–angiotensin system (see pp.
Investigation of glucocorticoid abnormalities

Basal levels
ACTH and cortisol are released episodically and in response to stress. When taking a blood sample, remember:

• Sampling time should be recorded. Basal levels should be taken between 08:00 hours and 09:00 hours, near the peak of the circadian variation.
• Stress should be minimized.
• Appropriate reference ranges (for time and assay method) should be used.
  Suppression tests are used if excess cortisol is suspected, and stimulation tests are used if cortisol deficiency is suspected.

Dexamethasone suppression tests
Administration of a synthetic glucocorticoid (dexamethasone) to a normal subject produces prompt feedback suppression of CRH and ACTH levels, and thus of endogenous cortisol secretion (dexamethasone is not measured by most cortisol assays). Three forms of the test, used in the diagnosis and differential diagnosis of Cushing syndrome, are available (see Box 26.14).

ACTH stimulation tests
Synthetic ACTH (tetracosactide, which consists of the first 24 amino acids of human ACTH) is given to stimulate adrenal cortisol production. Details are given in Box 26.3 and Figure 26.5 (see p. 1183).

Addison's disease: primary hypoadrenalism

Pathophysiology and aetiology
In this condition, there is destruction of the entire adrenal cortex. Glucocorticoid, mineralocorticoid and sex steroid production are therefore all reduced. (This differs from hypothalamic–pituitary disease, in which mineralocorticoid secretion remains largely intact, being predominantly stimulated by angiotensin II. Adrenal sex steroid production is also largely independent of pituitary action.) In Addison's disease, reduced cortisol levels lead, through feedback, to increased CRH and ACTH production, the latter being directly responsible for the hyperpigmentation.

Addison's disease is rare, with an incidence of 3–4/million per year and prevalence of 40–60/million. Primary hypoadrenalism shows a marked female preponderance and is most
often caused by autoimmune disease (>90% in the UK), but in countries with a high prevalence of HIV/AIDS, tuberculosis is an increasing cause. Autoimmune adrenalitis results from the destruction of the adrenal cortex by organ-specific autoantibodies, with 21-hydroxylase as the common antigen. There are associations with other autoimmune conditions in the polyglandular autoimmune syndromes types I and II (e.g. type 1 diabetes mellitus, pernicious anaemia, thyroiditis, hypoparathyroidism, premature ovarian failure; see p. 1239).

All other causes are rare (Box 26.36). In patients with degenerative neurological symptoms, a diagnosis of adrenoleukodystrophy should be excluded.

**Box 26.36**

**Causes of primary hypoadrenalism**

- Autoimmune disease
- Tuberculosis (<10% in UK)
- Surgical removal
- Haemorrhage/infarction:
  - Meningococcal septicaemia
  - Venography
- Infiltration:
  - Malignant destruction
  - Amyloid
- Schilder's disease (adrenal leukodystrophy)

**Clinical features**

These are shown in Figure 26.33. The symptomatology of Addison's disease is often vague and non-specific. These symptoms may be the prelude to an addisonian crisis with severe hypotension and dehydration precipitated by intercurrent illness, accident or operation.
Pigmentation (dull, slaty, grey–brown) is the predominant sign in over 90% of cases. Postural systolic hypotension, due to hypovolaemia and sodium loss, is present in 80–90% of cases, even if supine blood pressure is normal. Mineralocorticoid deficiency is the cause of the hypotension.

**Investigations**

Once Addison's disease is suspected, investigation is urgent. If the patient is seriously ill or hypotensive, hydrocortisone 100 mg should be given intravenously or intramuscularly, together with intravenous 0.9% saline. Ideally, this should be done immediately after a blood sample is taken for later measurement of plasma cortisol. Alternatively, an ACTH stimulation test can be performed immediately. Full investigation should be delayed until emergency treatment (see below) has improved the patient's condition. Otherwise, tests are as follows:

- **Single cortisol measurements** are of little value, although a random cortisol below 100 nmol/L during the day is highly suggestive, and a random cortisol >550 nmol/L makes the diagnosis unlikely.

- **The short ACTH stimulation test** should be performed (see Box 26.3 and Fig. 26.5). Note that an absent or impaired cortisol response confirms the presence of hypoadrenalism but does not differentiate Addison's disease from ACTH deficiency or iatrogenic suppression by steroid medication. The long ACTH test is no longer used because of the availability of accurate ACTH assays.

- **A 09:00 hours plasma ACTH level** is measured, a high level (>80 ng/L) with low or low-normal cortisol confirming primary hypoadrenalism.

- **Electrolytes and urea** classically show hyponatraemia, hyperkalaemia and a high urea, but they can be normal.

- **Blood glucose** may be low, with hypoglycaemia.
• **Adrenal antibodies** are present in approximately 90% of cases of autoimmune adrenalitis.

• **Chest and abdominal X-rays** or cross-sectional imaging of the abdomen (CT or MRI) may show evidence of tuberculosis and/or calcified adrenals *(Fig. 26.34).*

![CT scan showing bilateral adrenal calcification.](image)

**FIGURE 26.34** CT scan showing bilateral adrenal calcification.

• **Plasma renin activity** is high due to low *serum aldosterone*.

• **Hypercalcaemia and anaemia** (after rehydration) are sometimes seen.

---

### Management

Acute hypoadrenalism needs urgent treatment *(Box 26.37).*

---

**Box 26.37**

**Management of acute hypoadrenalism**

**Clinical context**

Hypotension, hyponatraemia, hyperkalaemia, hypoglycaemia, dehydration, pigmentation often with precipitating infection, infarction, trauma or operation. The major deficiencies are of salt, steroid and glucose.

**Requirements**

Assuming normal cardiovascular function, the following are required:

- 1 L of 0.9% saline should be given over 30–60 min with 100 mg of i.v. bolus hydrocortisone

- Subsequent requirements are several litres of saline within 24 h (assessing with central
venous pressure line if necessary) plus hydrocortisone, 100 mg i.m., 6-hourly, until the patient is clinically stable
• Glucose should be infused if there is hypoglycaemia
• Oral replacement medication is then started, unless the patient is unable to take oral medication: initially, hydrocortisone 20 mg, 8-hourly, reducing to 20–30 mg in divided doses over a few days (see Box 26.38)
• Fludrocortisone is unnecessary acutely, as the high cortisol doses provide sufficient mineralocorticoid activity – it should be introduced later

Long-term treatment is with replacement glucocorticoid and mineralocorticoid; tuberculosis must be treated if present or suspected. Replacement dosage details are shown in Box 26.38. A recent dual-release, oral, once-daily hydrocortisone preparation is now on the market. Dehydroepiandrosterone (DHEA) replacement has also been advocated; some studies suggest that this may cause symptomatic improvements, although others show no clear benefit and acne and hirsutism occur.

**Box 26.38**

**Average replacement steroid dosages for adults with primary hypoadrenalism**

</tbody>
</table>

Adequacy of glucocorticoid dose is judged by:
• clinical wellbeing and restoration of normal, but not excessive, weight
• normal cortisol levels during the day while on replacement hydrocortisone (cortisol levels cannot be used for synthetic steroids).

Adequacy of fludrocortisone replacement is assessed by:
• restoration of serum electrolytes to normal
• blood pressure response to posture (it should not fall >10 mmHg systolic after 2 minutes'
standing)

• suppression of plasma renin activity to normal.

Patient advice
All patients requiring replacement steroids should:

• know how to increase steroid replacement by doubling the dose for intercurrent illness
• carry a ‘steroid card’
• wear a Medic-Alert bracelet (or similar), which gives details of their condition so that emergency replacement therapy can be given if found unconscious
• keep an (up-to-date) ampoule of hydrocortisone at home in case oral therapy is impossible, for administration by self, family or doctor.
Secondary hypoadrenalism

This may arise from:

• hypothalamic–pituitary disease (inadequate ACTH production) or
• long-term steroid therapy leading to hypothalamic–pituitary–adrenal suppression.

Most people with hypothalamic–pituitary disease have panhypopituitarism (see p. 1188) and need T₄ replacement, as well as cortisol; in this case, hydrocortisone must be started before T₄.

Long-term corticosteroid medication for non-endocrine disease is the most common cause of secondary hypoadrenalism. The hypothalamic–pituitary axis and the adrenal may both be suppressed and the patient may have vague symptoms of feeling unwell. ACTH levels are low in secondary hypoadrenalism. Weaning off steroids is often a long and difficult process.

Congenital adrenal hyperplasia

Pathophysiology

Congenital adrenal hyperplasia (CAH) results from an autosomal recessive deficiency of an enzyme in the cortisol synthetic pathways. There are six major types; most common is 21-hydroxylase deficiency (CYP21A2), which occurs in about 1 in 15 000 births and has been shown to be due to defects on chromosome 6 near the HLA region, affecting one of the cytochrome p450 enzymes (p450C21).

As a result, cortisol secretion is reduced and feedback leads to increased ACTH secretion to maintain adequate cortisol, causing adrenal hyperplasia. Diversion of the steroid precursors into the androgenic steroid pathways occurs (see Fig. 26.31A). Thus, 17-hydroxyprogesterone, androstenedione and testosterone levels are increased, leading to virilization. Aldosterone synthesis may be impaired with resultant salt wasting.

The other forms affect 11β-hydroxylase, 17α-hydroxylase, 3β-hydroxysteroid dehydrogenase and a cholesterol side-chain cleavage enzyme (p450scc) (see Fig. 26.31A).

Clinical features

Classical CAH presents at birth with:

• Sexual ambiguity (in the female, clitoral hypertrophy, urogenital abnormalities and labioscrotal fusion are common) or
• Adrenal failure (collapse, hypotension, hypoglycaemia), sometimes with a salt-losing state (hypotension, hyponatraemia). The syndrome may be unrecognized in the male until a salt-losing crisis occurs, usually within 10 days of birth.
• Non-classified disease presents later as precocious puberty with hirsutism; rare, milder cases only present in adult life, usually accompanied by primary amenorrhoea. Hirsutism
developing before puberty is suggestive of CAH.

**Investigations**

Expert advice is essential in the confirmation and differential diagnosis of 21-hydroxylase deficiency; with ambiguous genitalia, such advice must be sought urgently before any assignment of gender is made.

A profile of adrenocortical hormones is drawn up before and 1 hour after ACTH administration.

- 17-Hydroxyprogesterone levels are increased.
- Urinary pregnanetriol excretion is increased.
- Androstenedione levels are raised.
- Basal ACTH levels are raised.

**Management**

Glucocorticoid activity must be replaced, as must mineralocorticoid activity if deficient. The practice in CAH of giving the larger dose of glucocorticoid at night to suppress the morning ACTH peak, with a smaller dose in the morning, is largely outdated. Correct dosage is often difficult to establish in the *child* but should ensure normal androstenedione and 17-hydroxyprogesterone levels while allowing normal growth; excessive replacement leads to stunting of growth. In *adults*, clinical features and biochemistry (plasma renin, androstenedione and 17-hydroxyprogesterone) are used to modify treatment. The use of modified-release hydrocortisone may have a role in the management of CAH.

**Prenatal diagnosis**

Genetic counselling and antenatal diagnosis is useful (see pp. 116–117). There is a 1:4 chance of recurrence in a family. Dexamethasone given to the mother of a female fetus with a 21-hydroxylase deficiency can prevent virilization by suppressing ACTH levels. There are, however, concerns about the potential adverse consequences of this practice.

**Problems of therapeutic steroid therapy**

Apart from their use as therapeutic replacement for endocrine deficiency states, synthetic glucocorticoids are widely used for many non-endocrine conditions. Short-term use (e.g. for acute asthma) carries only small risks of significant side-effects, except for the simultaneous suppression of immune responses. The danger lies in their continuance, often through medical oversight or patient default. In general, therapy for 3 weeks or less, or a dose of prednisolone of less than 5 mg per day, will not result in significant long-term suppression of the normal adrenal axis.

Long-term therapy with synthetic or natural steroids will, in most respects, mimic
endogenous Cushing syndrome. Exceptions are the relative absence of hirsutism, acne, hypertension and severe sodium retention, as the common synthetic steroids have low androgenic and mineralocorticoid activity.

Excessive doses of steroids may also be absorbed from skin when strong dermatological preparations are used but inhaled steroids rarely cause Cushing syndrome; they commonly cause adrenal suppression, however.

The major hazards are detailed in Box 26.39. In the long term, many are of such severity that the clinical need for high-dose steroids should be continually and critically assessed. Steroid-sparing agents should always be considered, and screening and prophylactic therapy for osteoporosis introduced (see pp. 712–713). New targeted biological therapies for inflammatory conditions may reduce the incidence of steroid-induced adrenal suppression.

---

**Box 26.39**

**Major adverse effects of corticosteroid therapy**

**Physiological**
- Adrenal and/or pituitary suppression

**Pathological**

**Cardiovascular**
- Increased blood pressure

**Gastrointestinal**
- Pancreatitis

**Renal**
- Polyuria
- Nocturia

**Central nervous**
- Depression
- Euphoria
- Psychosis
- Insomnia

**Endocrine**
- Weight gain
- Glycosuria/hyperglycaemia/diabetes
- Impaired growth
- Amenorrhoea

**Bone and muscle**
• Osteoporosis
• Proximal myopathy and wasting
• Aseptic necrosis of the hip
• Pathological fractures

**Skin**
• Thinning
• Easy bruising

**Eyes**
• Cataracts (including inhaled drug)

**Increased susceptibility to infection**
(Signs and fever are frequently masked)
• Septicaemia
• Fungal infections
• Reactivation of tuberculosis
• Skin (e.g. fungi)

**Supervision of steroid therapy**

All patients receiving steroids should carry a ‘steroid card’. They should be made aware of the following points:

• Long-term steroid therapy must never be stopped suddenly.
• Doses should be reduced very gradually, with most being given in the morning at the time of withdrawal; this minimizes adrenal suppression. Many authorities believe that ‘alternate-day therapy’ produces less suppression.
• Doses need to be increased at times of serious intercurrent illness (defined as presence of a fever), accident and stress. Double doses should be taken during these periods.
• Other physicians, anaesthetists and dentists must be told about steroid therapy.

Patients should also be informed of potential side-effects, and all this information should be documented in the clinical record. If prophylactic use of bisphosphonate therapy is required to prevent the development of osteoporosis (National Institute for Health and Care Excellence (NICE) guidance), patients should be informed of the rationale.

**Steroids and surgery**

Any patient receiving steroids, or who has recently received them (within the last 12 months) and may still have adrenal suppression, requires special control of steroid medication around the time of surgery. Details are shown in Box 26.40.

*A useful summary of surgical steroid guidelines can be found at: [http://www.addisons.org.uk/](http://www.addisons.org.uk/).

### Incidental adrenal tumours (‘incidentalomas’)

With the advent of abdominal CT, MRI and high-resolution ultrasound scanning, unsuspected adrenal masses have been discovered in 3–10% of scans (increasing with age). The two issues of concern with an incidental adrenal mass are:

- whether the lesion is functional or non-functional
- whether it is benign or malignant.

Most incidentalomas are asymptomatic and benign, but direct questioning may reveal symptoms of endocrine hypersecretion such as cushingoid features, catecholamine excess, virilization in women, or evidence of endocrine hypertension (see Box 23.56). Even in the absence of symptoms, functional tests to exclude secretory activity should be performed, as adrenal adenomas often secrete cortisol at a low level – ‘subclinical Cushing syndrome’, which may confer increased cardiovascular risk. If no endocrine activity is found, then most authorities recommend removal only of large adrenal tumours (>4–5 cm) because of the risk of malignancy. Smaller, hormonally inactive lesions are usually observed, as long as there are no worrying radiological features.

Phaeochromocytoma must be excluded before surgery due to the risk of perioperative hypertensive or hypotensive crises (see p. 1231).

### Primary hyperaldosteronism
Increased mineralocorticoid secretion from the adrenal cortex, termed primary hyperaldosteronism, is thought to account for 5–10% of all hypertension. Other endocrine causes of hypertension should also be considered if there is clinical suspicion (Box 26.41). It is impracticable and unnecessary to screen all hypertensive patients for secondary endocrine causes. The highest chances of detecting such causes are in patients:

• under 35 years, especially those without a family history of hypertension
• with accelerated (malignant) hypertension
• with hypokalaemia before diuretic therapy
• resistant to conventional antihypertensive therapy (e.g. more than three drugs) or
• with unusual symptoms (e.g. sweating attacks or weakness).

### Box 26.41

**Endocrine causes of hypertension**

**Excessive renin, and thus angiotensin II, production**

• Renal artery stenosis
• Other local renal disease
• Renin-secreting tumours

**Excessive production of catecholamines**

• Phaeochromocytoma

**Excessive growth hormone (GH) production**

• Acromegaly

**Excessive aldosterone production**

• Adrenal adenoma (Conn syndrome)
• Idiopathic adrenal hyperplasia
• Dexamethasone-suppressible hyperaldosteronism

**Excessive production of other mineralocorticoids**

• Cushing syndrome (massive excess of cortisol, a weak mineralocorticoid)
• Congenital adrenal hyperplasia (in rare cases)
• Tumours producing other mineralocorticoids, e.g. corticosterone

**Exogenous ‘mineralocorticoids’ or enzyme inhibitors**

• Liquorice ingestion (inhibits 11β-hydroxylase)
• Misuse of mineralocorticoid preparations
Pathophysiology

Primary hyperaldosteronism is a disorder of the adrenal cortex characterized by excess aldosterone production leading to sodium retention, potassium loss and the combination of hypokalaemia and hypertension. This must be distinguished from secondary hyperaldosteronism, which arises when there is excess renin (and hence angiotensin II) stimulation of the zona glomerulosa. Common causes of secondary hyperaldosteronism are accelerated hypertension and renal artery stenosis, when the patient will also be hypertensive. Causes associated with normotension include congestive cardiac failure and cirrhosis, where excess aldosterone production contributes to sodium retention.

Aetiology

Adrenal adenomas (Conn syndrome; see Box 26.41) originally accounted for 60% of cases of primary hyperaldosteronism but represented a rare cause of hypertension. The use of the aldosterone:renin ratio in the routine investigation of hypertension now suggests that hyperaldosteronism due to bilateral adrenal hyperplasia (idiopathic hyperaldosteronism) is much more common than the classical Conn's adenoma. Some claim that idiopathic hyperaldosteronism is the cause of up to 10% of cases of ‘essential’ hypertension.

Clinical features

The usual presentation is simply hypertension; hypokalaemia (<3.5 mmol/L) is frequently not present. The few symptoms are non-specific; rarely, muscle weakness, nocturia and tetany are seen. The hypertension may be severe and associated with renal, cardiac and retinal damage.

Adenomas, often very small, are more common in young females, while bilateral hyperplasia rarely occurs before the age of 40 years and is more common in males.

Investigations

Beta-blockers and other drugs may interfere with renin activity, and spironolactone, angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor antagonists will all affect results; all should be discontinued, if possible. The characteristic features of investigation are as follows:

- **Plasma aldosterone:renin ratio (ARR)** is now most frequently used as a screening test for the condition, but raised ARR alone does not confirm the diagnosis (if the renin is low enough, ARR will always be high). Note that normal ranges are highly assay-dependent.
- **Elevated plasma aldosterone levels** are not suppressed with 0.9% saline infusion (2 L over 4 h) or fludrocortisone administration. Between 30% and 50% of people with a raised ARR on screening will suppress normally, excluding the diagnosis.
- **Suppressed plasma renin activity** or immunoreactivity is seen.
• **Hypokalaemia** is often present but a normal serum potassium does not exclude the diagnosis.

• **Urinary potassium loss** of >30 mmol daily during hypokalaemia is inappropriate.

Once a diagnosis of hyperaldosteronism is established, differentiation of adenoma from hyperplasia involves adrenal CT or MRI, but small adenomas may be missed and non-functioning incidentalomas also occur. Further information is obtained from diurnal/postural changes in plasma aldosterone levels (which tend to rise with adenomas between 09:00 hours supine and 13:00 hours erect samples; in contrast, they fall with hyperplasia), measurement of 18-OH cortisol levels (raised in adenoma), and venous catheterization for aldosterone levels. All of these tests have their pitfalls and exceptions.

### Management

An adenoma can be removed surgically, usually laparoscopically; blood pressure falls in 70% of patients. Those with hyperplasia should be treated with the aldosterone antagonist, spironolactone (100–400 mg daily); frequent side-effects include nausea, rashes and gynaecomastia. The pure aldosterone receptor antagonist, eplerenone, can be a useful alternative if side-effects preclude the use of spironolactone (see p. 158) Spironolactone metabolites have been linked with tumour development in animals but this has not been described in humans. Amiloride and calcium-channel blockers are moderately effective in controlling the hypertension but do not correct the hyperaldosteronism.

### Glucocorticoid (or dexamethasone)-suppressible hyperaldosteronism

This rare condition is caused by a chimeric gene on chromosome 8. A fusion gene resulting from an unusual crossover at meiosis between the genes encoding aldosterone synthase and adrenal 11β-hydroxylase produces aldosterone, which is under ACTH control. Treatment with glucocorticoid resolves the problem.

### Syndrome of apparent mineralocorticoid excess

This causes the clinical syndrome of primary hyperaldosteronism but with low renin and aldosterone levels. Reduced activity of the enzyme 11β-hydroxysteroid dehydrogenase type 2 (11βHSD2) prevents the normal conversion in the kidney of cortisol (which is active at the mineralocorticoid receptor) to cortisone (which is not), and therefore ‘exposes’ the mineralocorticoid receptor in the kidney to the usual molar excess of cortisol over aldosterone in the blood. While the inherited syndrome is rare, the same clinical syndrome can occur with excessive ingestion of liquorice, which inhibits the 11βHSD2 enzyme.

### The adrenal medulla
The adrenal medulla is the innermost part of the adrenal gland, consisting of cells that secrete the major catecholamines, noradrenaline (norepinephrine) and adrenaline (epinephrine), which produce the sympathetic nervous response. The catecholamines are interconverted in the adrenal medulla, and an increase in levels of their metabolites in the urine is a marker of abnormal hypersecretion (Fig. 26.35).

**Phaeochromocytoma and paraganglioma**

These are very rare tumours of the sympathetic nervous system (less than 1 in 1000 cases of hypertension) that secrete catecholamines, noradrenaline (norepinephrine), adrenaline (epinephrine) and their metabolites (Fig. 26.35):

- 90% arise in the adrenal medulla (*phaeochromocytomas*)
- 10% occur elsewhere in the sympathetic chain (*paragangliomas*).

Some are associated with MEN 2 syndromes (see below) and the von Hippel–Lindau (VHL) syndrome (see p. 881). Most tumours release both noradrenaline (norepinephrine) and adrenaline (epinephrine), but large tumours and extra-adrenal tumours produce almost entirely noradrenaline.

Paragangliomas typically occur in the head and neck but are also found in the thorax, pelvis...
and bladder. They are more closely associated with other genetic associations than is phaeochromocytoma. The association of paraganglioma, bilateral adrenal phaeochromocytomas, positive family history or young age at presentation is seen in multiple endocrine neoplasms (see pp. 1239–1240). Mutations in the succinate dehydrogenase (SDHD) gene have been shown to be strongly associated with the development of paraganglioma.

**Pathology**

Oval groups of cells occur in clusters and stain for chromogranin A. Some 25% are multiple and 10% malignant, the latter being more frequent in the extra-adrenal tumours. Malignancy cannot be determined on simple histological examination alone.

**Clinical features**

The clinical features are those of catecholamine excess and are frequently, but not necessarily, intermittent (Box 26.42). All people with suspected phaeochromocytomas must be investigated because phaeochromocytomas may cause acute cardiovascular compromise during routine medical procedures, and can also present with sudden death if the diagnosis is missed.

---

**Box 26.42**

**Symptoms and signs of phaeochromocytoma**

**Symptoms**

- Anxiety or panic attacks
- Palpitations
- Tremor
- Sweating
- Headache
- Flushing
- Nausea and/or vomiting
- Weight loss
- Constipation or diarrhoea
- Raynaud's phenomenon
- Chest pain
- Polyuria/nocturia

**Signs**

- Hypertension
- Tachycardia/arrhythmias
- Bradycardia
- Orthostatic hypotension
- Pallor or flushing
- Glycosuria
- Fever
- (Signs of hypertensive damage)

**Investigations**

Specific tests are:

- **Measurement of urinary catecholamines and metabolites** (metanephrines are most sensitive and specific; *Fig. 26.35*) is a useful screening test; normal levels on three 24-h collections of metanephrines virtually exclude the diagnosis. Many drugs, e.g. tricyclics, and dietary vanilla interfere with these tests.

- **Resting plasma metanephrines** are raised.

- **Plasma chromogranin A** (a storage vesicle protein) is raised.

- **Clonidine suppression test** may be appropriate but should only be performed in specialist centres.

- **CT/MRI scans**, initially of the abdomen, are helpful to localize the tumours, which are often large (*Fig. 26.36*).
• **Scanning with** $^{131}$I-meta-iodobenzylguanidine (MIBG) **produces** **specific uptake** in sites of sympathetic activity with about 90% success. It is particularly useful with extra-adrenal tumours. $^{18}$F-deoxyglucose positron emission tomography (PET) is also used by some centres in the localization of phaeochromocytomas (**Fig. 26.37**).

![FIGURE 26.37 MIBG scan showing a solitary area of increased uptake in the liver consistent with metastasis from a phaeochromocytoma.]

• **Genetic testing** for MEN2, VHL, SDHB and SDHD mutations should be performed in all people with confirmed phaeochromocytoma or paraganglioma.

**Management**

Tumours should be removed if this is possible; 5-year survival is about 95% for non-malignant tumours. Medical preoperative and perioperative treatment is vital and includes complete alpha- and beta-blockade with phenoxybenzamine (20–80 mg daily initially in divided doses), then propranolol (120–240 mg daily), plus intravenous hydration to re-expand the contracted plasma volume. The alpha-blockade must precede the beta-blockade, as worsened hypertension may otherwise result. Labetalol is not recommended. Surgery in the unprepared patient is fraught with dangers of both hypertension and hypotension; expert anaesthesia and an experienced surgeon are both vital, and sodium nitroprusside and phentolamine (a rapid-acting α-blocker) should be available in case sudden severe hypertension develops.

When operation is not possible, combined alpha- and beta-blockade can be used long-term. Radionucleotide treatment with MIBG has been employed but has had limited success in malignant phaeochromocytoma.
Patients should be kept under clinical and biochemical review after tumour resection, as over 10% of tumours recur or a further tumour develops. Catecholamine excretion measurements should be performed at least annually.

**Further reading**

**The Thirst Axis**

Thirst and water regulation are largely controlled by vasopressin, also known as antidiuretic hormone (ADH), which is synthesized in the hypothalamus (see p. 1183) and then migrates in neurosecretory granules along axonal pathways to the posterior pituitary. Pituitary disease alone without hypothalamic involvement therefore does not lead to ADH deficiency, as the hormone can still ‘leak’ from the damaged end of the intact axon.

At normal concentrations, the kidney is the predominant site of action of vasopressin. Vasopressin stimulation of the V$_2$ receptors (see **Box 26.4** ) allows the collecting ducts to become permeable to water via the migration of aquaporin-2 water channels, thus permitting reabsorption of hypotonic luminal fluid (see pp. 153–154). Vasopressin therefore reduces diuresis and results in overall retention of water. At high concentrations, vasopressin also causes vasoconstriction via the V$_1$ receptors in vascular tissue.

Changes in plasma osmolality are sensed by osmoreceptors in the anterior hypothalamus. Vasopressin secretion is suppressed at levels below 280 mOsm/kg, thus allowing maximal water diuresis. Above this level, plasma vasopressin increases in direct proportion to plasma osmolality. At the upper limit of normal (295 mOsm/kg), maximum antidiuresis is achieved and thirst is experienced at about 298 mOsm/kg (**Fig. 26.38**).
OTHER factors affecting vasopressin release are shown in **Box 26.43**.

**Box 26.43**

**Factors affecting vasopressin (ADH) release**

**Increased by**
- Increased osmolality
- Hypovolaemia
- Hypotension
- Nausea
- Hypothyroidism
- Angiotensin II
- Adrenaline (epinephrine)
- Cortisol
- Nicotine
- Antidepressants

**Decreased by**
- Decreased osmolality
- Hypervolaemia
- Hypertension
- Ethanol
- α-Adrenergic stimulation

Disorders of vasopressin secretion or activity include:
cranial diabetes insipidus with deficiency as a result of hypothalamic disease

‘nephrogenic’ diabetes insipidus – a rare condition in which the renal tubules are insensitive to vasopressin, and an example of a receptor abnormality

inappropriate excess of the hormone.

While all these are uncommon, they need to be distinguished from the occasional patient with ‘primary polydipsia’ and those whose renal tubular function has been impaired by electrolyte abnormalities, such as hypokalaemia or hypercalcaemia.

Diabetes insipidus

Clinical features

Deficiency of vasopressin (ADH) or insensitivity to its action leads to excess excretion of dilute urine with a compensatory increase in thirst (polydipsia). Daily urine output may reach as much as 10–15 L, leading to dehydration that may be very severe if the thirst mechanism or consciousness is impaired or the patient is denied fluid.

Diabetes insipidus (DI) may be masked by simultaneous cortisol deficiency; cortisol replacement allows a water diuresis and DI then becomes apparent.

Aetiology

Causes of DI are listed in Box 26.44. The most common is hypothalamic–pituitary surgery, following which transient DI is common, frequently remitting after a few days or weeks. Typically, inflammatory lesions of the pituitary stalk are associated with DI (Fig. 26.39).

Box 26.44

Causes of diabetes insipidus

Cranial diabetes insipidus

• Familial (e.g. DIDMOAD)
• Idiopathic (often autoimmune)
• Tumours:
  – Craniopharyngioma
  – Hypothalamic tumour, e.g. glioma, germinoma
  – Metastases, especially breast
  – Lymphoma/leukaemia
  – Pituitary with suprasellar extension (rare)
• Infections:
- Tuberculosis
- Meningitis
- Cerebral abscess

- Infiltrations:
  - Sarcoidosis
  - Langerhans' cell histiocytosis

- Inflammatory:
  - Hypophysitis

- Post-surgical:
  - Transfrontal
  - Trans-sphenoidal

- Post-radiotherapy (cranial)

- Vascular:
  - Haemorrhage/thrombosis
  - Sheehan syndrome
  - Aneurysm

- Trauma (e.g. head injury)

**Nephrogenic diabetes insipidus**

- Familial (e.g. vasopressin receptor gene, aquaporin-2 gene defect)
- Idiopathic
- Renal disease (e.g. renal tubular acidosis)
- Hypokalaemia
- Hypercalcaemia
- Drugs (e.g. lithium, demeclocycline, glibenclamide)
- Sickle cell disease
- Prolonged polyuria due to any cause, including cranial DI and primary polydipsia – can cause mild temporary nephrogenic DI

  DIDMOAD, diabetes insipidus, diabetes mellitus, optic atrophy and deafness.
Familial isolated vasopressin deficiency causes DI from early childhood and is dominantly inherited, caused by a mutation in the AVP-NPII gene. DIDMOAD (Wolfram) syndrome is a rare autosomal recessive disorder comprising diabetes insipidus, diabetes mellitus, optic atrophy and deafness, and is caused by mutations in the WFS1 gene on chromosome 4. MRI may show an absent or poorly developed posterior pituitary.

Biochemistry

- High or high-normal plasma osmolality with low urine osmolality (in primary polydipsia, plasma osmolality tends to be low).
- Resultant high or high-normal plasma sodium (hypernatraemia).
- High 24-h urine volumes (<2 L excludes the need for further investigation).
- Failure of urinary concentration with fluid deprivation.
- Restoration of urinary concentration with vasopressin or an analogue.

The latter two points are studied with a formal water deprivation test (Box 26.45). In normal subjects, plasma osmolality remains normal while urine osmolality rises above 600 mOsm/kg. In DI, plasma osmolality rises while the urine remains dilute, only concentrating after exogenous vasopressin is given (in ‘cranial’ DI), or not concentrating after vasopressin if nephrogenic DI is present. An alternative is measurement of plasma vasopressin during hypertonic saline infusion, but these measurements are not widely available.

Box 26.45

Water deprivation test

Indications
• Diagnosis or exclusion of diabetes insipidus.

**Procedure**

• Fasting and no fluids from 07:30 h (or overnight if only mild DI is expected and polyuria is only modest).
• Monitor serum and urine osmolality, urine volume and weight hourly for up to 8 h.
• Abandon fluid deprivation if weight loss >3% occurs.
• If serum osmolality is >300 mOsm/kg and/or urine osmolality <600 mOsm/kg, give desmopressin 2 µg i.m. at end of test. Allow free fluid but measure urine osmolality for 2–4 h.

**Interpretation**

• Normal response – serum osmolality remains within normal range (275–295 mOsm/kg). Urine osmolality rises to >600 mOsm/kg.
• Diabetes insipidus (DI) – serum osmolality rises above normal without adequate concentration of urine osmolality (i.e. serum osmolality >300 mOsm/kg; urine osmolality <600 mOsm/kg).
• Nephrogenic DI – if desmopressin does not concentrate urine.
• Cranial DI – if urine osmolality rises by >50% after desmopressin.

**Management**

The synthetic vasopressin (ADH) analogue, desmopressin, is the treatment of choice in cranial DI. It has a longer duration of action than vasopressin and has no vasoconstrictive effects. It can be given intranasally as a spray 10–40 µg once or twice daily, and orally as 100–200 µg three times daily, or intramuscularly 2–4 µg daily. Response is variable and must be monitored carefully with enquiry about fluid input/output and plasma osmolality measurements. The main problem is avoiding water overload and consequent hyponatraemia (see p. 163). Where there is a reversible underlying cause (e.g. a hypothalamic tumour), this should be investigated and treated.

Alternative agents in mild DI, probably working by sensitizing the renal tubules to endogenous vasopressin, include thiazide diuretics, carbamazepine (200–400 mg daily) or chlorpropamide (200–350 mg daily) but these are rarely used.

**Nephrogenic diabetes insipidus**

In this condition, renal tubules are resistant to normal or high levels of plasma vasopressin (ADH). Nephrogenic diabetes insipidus may be inherited as a rare sex-linked recessive, with an abnormality in the vasopressin-2 receptor, or as an autosomal post-receptor defect in an ADH-sensitive water channel, aquaporin-2. More commonly, it can be acquired as a result of
renal disease, sickle cell disease, drug ingestion (e.g. lithium), hypercalcaemia or hypokalaemia. Wherever possible, the cause should be reversed (see Box 26.44). Polyuria is helped by thiazide diuretics.

### Other causes of polyuria and polydipsia

Diabetes mellitus, hypokalaemia and hypercalcaemia should be excluded. In the case of diabetes mellitus, the cause is an osmotic diuresis secondary to glycosuria, which leads to dehydration and an increased perception of thirst owing to hypertonicity of the extracellular fluid.

#### Primary polydipsia

This is a relatively common cause of thirst and polyuria. It is a psychiatric disturbance characterized by the excessive intake of water. Plasma sodium and osmolality fall as a result and the urine produced is appropriately dilute. Vasopressin levels become virtually undetectable. Prolonged primary polydipsia may lead to the phenomenon of ‘renal medullary washout’, with a fall in the concentrating ability of the kidney. Characteristically, the diagnosis is made by a water deprivation test. A low plasma osmolality is usual at the start of the test, and since vasopressin secretion and action can be stimulated, the patient's urine becomes concentrated (although ‘maximum’ concentrating ability may be impaired); the initially low urine osmolality gradually increases with the duration of the water deprivation.

#### Syndrome of inappropriate antidiuretic hormone secretion

##### Clinical features

Inappropriate secretion of antidiuretic hormone (ADH, also called vasopressin) leads to retention of water and hyponatraemia. The presentation of the syndrome of inappropriate antidiuretic hormone secretion (SIADH) is usually vague, with confusion, nausea, irritability and, later, fits and coma. There is no oedema. Mild symptoms usually occur with plasma sodium levels below 125 mmol/L and serious manifestations are likely below 115 mmol/L. The elderly may show symptoms with milder abnormalities.

The syndrome must be distinguished from dilutional hyponatraemia due to excess infusion of glucose/water solutions or diuretic administration (thiazides or amiloride; see p. 164).

##### Diagnosis

The usual features are:

- dilutional hyponatraemia due to excessive water retention
- euvolaemia (in contrast to hypovolaemia of sodium and water depletion states)
• low plasma osmolality with ‘inappropriate’ urine osmolality >100 mOsm/kg (and typically higher than plasma osmolality)
• continued urinary sodium excretion >30 mmol/l (lower levels suggest sodium depletion and should respond to 0.9% saline infusion)
• absence of hypokalaemia (or hypotension)
• normal renal and adrenal and thyroid function.

The causes are listed in *Box 26.46*. 

---

**Box 26.46**

**Common causes of the syndrome of inappropriate antidiuretic hormone secretion (SIADH)**

**Tumours**

• Small-cell carcinoma of lung
• Prostate
• Thymus
• Pancreas
• Lymphomas

**Pulmonary lesions**

• Pneumonia
• Tuberculosis
• Lung abscess

**Central nervous system causes**

• Meningitis
• Tumours
• Head injury
• Subdural haematoma
• Cerebral abscess
• Systemic lupus erythematosus
• Vasculitis

**Metabolic causes**

• Alcohol withdrawal
• Porphyria

**Drugs**
Hyponatraemia is very common during illness in frail elderly patients and it may sometimes be clinically difficult to distinguish SIADH from salt and water depletion, particularly when mixed clinical features are present. Under these circumstances, a trial infusion of 1–2 L 0.9% saline is given. SIADH will not respond (but will excrete the sodium and water load effectively); sodium depletion will respond. ACTH deficiency can give a very similar biochemical picture to SIADH; therefore it is necessary to ensure that the hypothalamic–pituitary–adrenal axis is intact, particularly in neurosurgical patients, in whom ACTH deficiency may be relatively common.

**Management**

The underlying cause should be corrected where possible. Symptomatic relief can be obtained by the following measures:

- **Fluid intake** should be restricted to 500–1000 mL daily. If tolerated and complied with, this will correct the biochemical abnormalities in almost every case.
- **Frequent measurement** of plasma osmolality, serum sodium and body weight is needed.
- **Demeclocycline** (600–1200 mg daily) is given if water restriction is poorly tolerated or ineffective; this inhibits the action of vasopressin on the kidney, causing a reversible form of nephrogenic diabetes insipidus. It often causes photosensitive rashes, however.
- **Hypertonic saline** may be indicated when the syndrome is very severe (i.e. acute and symptomatic), but this is potentially dangerous and should only be used with extreme caution (see pp. 162–163).
- **Vasopressin V₂ antagonists**, e.g. tolvaptan 15 mg daily, are being used with good results.

**Further reading**

**Disorders of Calcium Metabolism**

Serum calcium levels are mainly controlled by parathyroid hormone (PTH) and vitamin D. Hypercalcaemia is much more common than hypocalcaemia and is frequently detected incidentally with multichannel biochemical analysers. Mild asymptomatic hypercalcaemia
occurs in about 1 in 1000 of the population, with an incidence of 25–30 per 100 000 population. It occurs mainly in elderly females and is usually due to primary hyperparathyroidism.

Parathyroid hormone

There are normally four parathyroid glands, which are situated posterior to the thyroid; occasionally, additional glands exist or they may be found elsewhere in the neck or mediastinum. PTH, an 84-amino-acid hormone derived from a 115-residue pre-prohormone, is secreted from the chief cells of the parathyroid glands. PTH levels rise as serum ionized calcium falls. The latter is detected by specific G-protein-coupled, calcium-sensing receptors on the plasma membrane of the parathyroid cells. PTH has several major actions, all serving to increase plasma calcium by:

• increasing osteoclastic resorption of bone (occurring rapidly)
• increasing intestinal absorption of calcium (a slow response)
• increasing synthesis of 1,25-dihydroxyvitamin D₃
• increasing renal tubular reabsorption of calcium
• increasing excretion of phosphate.

PTH effects are mediated at specific membrane receptors on the target cells, resulting in an increase of adenyl cyclase messenger activity.

Vitamin D metabolism is discussed on page 708.

PTH measurements use two-site immunometric assays that measure only the intact PTH molecule; interpretation requires a simultaneous calcium measurement in order to differentiate most causes of hyper- and hypocalcaemia.

### Hypercalcaemia

#### Pathophysiology and aetiology

The major causes of hypercalcaemia are listed in Box 26.47; primary hyperparathyroidism and malignancies are by far the most common (>90% of cases). Hyperparathyroidism itself may be primary, secondary or tertiary. Primary hyperparathyroidism is caused by single (>80%) parathyroid adenomas or by diffuse hyperplasia of all the glands (15–20%); multiple parathyroid adenomas are rare. Involvement of multiple parathyroid glands may be part of a familial syndrome (e.g. MEN type 1 or 2a). Parathyroid carcinoma is rare (<1%), though it usually produces severe and intractable hypercalcaemia. Hyperparathyroidism–jaw tumour syndrome is a rare familial cause of hyperparathyroidism that may be associated with parathyroid carcinoma and maxillary or mandibular tumours.
Box 26.47

Causes of hypercalcaemia

Excessive parathyroid hormone (PTH) secretion

• Primary hyperparathyroidism (most common by far), adenoma (common), hyperplasia or carcinoma (rare)
• Tertiary hyperparathyroidism
• Ectopic PTH secretion (very rare indeed)

Malignant disease – low PTH levels (second most common cause)

• Myeloma
• Secondary deposits in bone
• Production of osteoclastic factors by tumours
• PTH-related protein secretion

Excess action of vitamin d

• Iatrogenic or self-administered excess
• Granulomatous diseases, e.g. sarcoidosis, tuberculosis
• Lymphoma

Excessive calcium intake

• ‘Milk-alkali’ syndrome

Other endocrine disease (mild hypercalcaemia only)

• Thyrotoxicosis
• Addison's disease

Drugs

• Thiazide diuretics
• Vitamin D analogues
• Lithium administration (chronic)
• Vitamin A

Miscellaneous

• Long-term immobility
• Familial hypocalciuric hypercalcaemia

Primary hyperparathyroidism
Primary hyperparathyroidism is of unknown cause, though it appears that adenomas are monoclonal. Hyperplasia may also be monoclonal. Chromosomal rearrangements in the 5’ regulatory region of the parathyroid hormone gene have been identified, and inactivation of some tumour suppressor genes at a variety of sites may also be involved.

**Secondary hyperparathyroidism**

Secondary hyperparathyroidism (see p. 779) is physiological compensatory hypertrophy of all parathyroids because of hypocalcaemia, such as occurs in chronic kidney disease or vitamin D deficiency. PTH levels are raised but calcium levels are low or normal, and PTH falls to normal after correction of the cause of hypocalcaemia where this is possible.

**Tertiary hyperparathyroidism**

Tertiary hyperparathyroidism is the development of apparently autonomous parathyroid hyperplasia after longstanding secondary hyperparathyroidism, most often in renal failure. Plasma calcium and phosphate are both raised, the latter often grossly so. Parathyroidectomy is necessary at this stage.

### Clinical features

#### Mild hypercalcaemia

Mild hypercalcaemia (e.g. adjusted calcium <3 mmol/L) is frequently asymptomatic, but more severe hypercalcaemia can produce a number of symptoms:

- **General.** There may be tiredness, malaise, dehydration and depression.
- **Renal.** Renal colic occurs from stones, polyuria or nocturia, haematuria and hypertension. The polyuria results from the effect of hypercalcaemia on renal tubules, reducing their concentrating ability – a form of mild nephrogenic diabetes insipidus. Primary hyperparathyroidism is present in about 5% of patients who present with renal calculi.
- **Bones.** There may be bone pain. Hyperparathyroidism mainly affects cortical bone, and bone cysts and locally destructive ‘brown tumours’ occur but only in advanced disease. Only 5–10% of all cases have definite bony lesions even when sought. Bone disease may be more apparent when there is coexisting vitamin D deficiency.
- **Abdomen.** There may be abdominal pain.
- **Chondrocalcinosis** and ectopic calcification. These are occasional features.
- **Corneal calcification.** This is a marker of longstanding hypercalcaemia but causes no symptoms.

There may also be symptoms from the underlying cause. Malignant disease is usually advanced by the time hypercalcaemia occurs, typically with bony metastases. The common primary tumours are bronchus, breast, myeloma, oesophagus, thyroid, prostate, lymphoma and renal cell carcinoma. True ‘ectopic PTH secretion’ by the tumour is very rare, and most cases
are associated with raised levels of PTH-related protein. This is a 144-amino-acid polypeptide, the initial sequence of which shows an approximate homology with the biologically active part of PTH, which is necessary in fetal development but does not have a clearly defined role in the adult. Bone-resorbing cytokines and prostaglandins may be involved locally where there are metastatic skeletal lesions, leading to local mobilization of calcium by osteolysis with subsequent hypercalcaemia.

**Severe hypercalcaemia**

Severe hypercalcaemia (>3 mmol/L) is usually associated with malignant disease, hyperparathyroidism, chronic kidney disease or vitamin D therapy.

**Investigations and differential diagnosis**

**Biochemistry**

Several fasting serum calcium and phosphate samples should be taken.

- **Serum PTH.** The hallmark of primary hyperparathyroidism is hypercalcaemia and hypophosphataemia with detectable or elevated intact PTH levels during hypercalcaemia. When this combination is present in an asymptomatic patient, then further investigation is usually unnecessary. However, an undetectable PTH level in the context of hypercalcaemia always requires further investigation to exclude malignancy or other pathology (*Box 26.47*).

- **Hyperchloraemic acidosis.** This is often mild.

- **Renal function.** This is usually normal but should be measured as a baseline.

- **24-h urinary calcium** or single calcium creatinine ratio. This should be measured in a young patient with modest elevation in calcium and PTH to exclude familial hypocalciuric hypercalcaemia (see p. 1238).

- **Elevated serum alkaline phosphatase.** This is found in severe parathyroid bone disease, but otherwise it suggests an alternative cause for hypercalcaemia.

  Where PTH is undetectable or equivocal, a number of other tests may lead to the diagnosis:

  - Protein electrophoresis/immunofixation: to exclude myeloma.
  - Serum TSH: to exclude hyperthyroidism.
  - 09:00 hours cortisol and/or ACTH test: to exclude Addison's disease.
  - Serum ACE: helpful in the diagnosis of sarcoidosis.
  - Hydrocortisone suppression test: hydrocortisone 40 mg three times daily for 10 days leads to suppression of plasma calcium in sarcoidosis, vitamin D-mediated hypercalcaemia and some malignancies.

**Imaging**

The success of parathyroid imaging is highly operator-dependent and choice therefore depends
on local skills and experience. Imaging is frequently far less accurate than parathyroid exploration by an expert surgeon, where the success rate is at least 90%. Methods include:

- Radioisotope scanning using $^{99m}$Tc-sestamibi, which is approximately 90% sensitive in detecting adenomas; it is enhanced with single-photon emission computed tomography (SPECT).
- Ultrasound, which is simple and safe, although insensitive for small tumours.
- High-resolution CT scan or MRI (more sensitive).

  Dual energy X-ray absorptiometry (DXA) bone density scanning is useful to detect bone effects in asymptomatic people with hyperparathyroidism in whom conservative management is planned.

  Abdominal X-rays may show renal calculi or nephrocalcinosis. High-definition hand X-rays can show subperiosteal erosions in the middle or terminal phalanges. Neither is required as part of diagnosis unless symptoms of renal calculi are present or there is evidence of renal failure.

### Management of hypercalcaemia

Details of emergency treatment for severe hypercalcaemia are given in Box 26.48. This should be followed by oral therapy unless the underlying disease can be treated.

---

**Box 26.48**

**Management of acute severe hypercalcaemia**

Acute hypercalcaemia often presents with dehydration, nausea and vomiting, nocturia and polyuria, drowsiness and altered consciousness. The serum Ca$^{2+}$ is $>$3 mmol/L and sometimes as high as 5 mmol/L. While investigation of the cause is under way, immediate treatment is mandatory if the patient is seriously ill or if the Ca$^{2+}$ is $>$3.5 mmol/L.

- **Rehydrate** using at least 4–6 L of 0.9% saline on day 1, and 3–4 L for several days thereafter. Central venous pressure (CVP) may need to be monitored to control the hydration rate.

- **Intravenous bisphosphonates** are the treatment of choice for the hypercalcaemia of malignancy or of undiagnosed cause. Pamidronate is preferred (60–90 mg as an intravenous infusion in 0.9% saline or glucose over 2–4 h or, if less urgent, over 2–4 days). Levels fall after 24–72 h, lasting for approximately 2 weeks. Zoledronate is an alternative.

- **Prednisolone** (30–60 mg daily) is effective in some instances (e.g. in myeloma, sarcoidosis and vitamin D excess) but in most cases is ineffective.

- **Calcitonin** (200 units i.v. 6-hourly) has a short-lived action and is little used.

- **Oral phosphate** (sodium cellulose phosphate 5 g three times daily) produces diarrhoea.
Management of primary hyperparathyroidism

Medical management

There are no effective medical therapies at present for primary hyperparathyroidism, but a high fluid intake should be maintained and replacement of vitamin D in those that are deficient appears to have no detrimental effect on calcium levels. New therapeutic agents that target the calcium-sensing receptors (e.g. cinacalcet) are of proven value in parathyroid carcinoma and in dialysis patients (see p. 780), and are used in primary hyperparathyroidism where surgical intervention is contraindicated.

Surgery

There is agreement that surgery is indicated in primary hyperparathyroidism for:

- people with renal stones or impaired renal function
- bone involvement or marked reduction in cortical bone density
- unequivocal marked hypercalcaemia (UK guidelines advocate consideration of surgery if calcium is >2.85 mmol/L, although many endocrinologists will use a figure of >3.0 mmol/L; USA guidelines state >1 mg/dL above the reference range)
- the uncommon younger patient, below the age of 50 years
- a previous episode of severe acute hypercalcaemia.

The situation where plasma calcium is mildly raised (2.65–3.00 mmol/L) is more controversial. Most authorities feel that young patients should be operated on, as should those who have reduced cortical bone density or significant hypercalciuria, as this is associated with stone formation.

In older patients without these problems, or in those unfit for or unwilling to have surgery, conservative management is indicated. Regular measurement of serum calcium and of renal function is necessary. Bone density of cortical bone should be monitored if conservative management is used. Hyperparathyroidism can cause non-specific symptoms of weakness, fatigue and depression, and it can be difficult to determine whether these symptoms are related to hypercalcaemia or coincidental.

Surgical technique and complications

Parathyroid surgery should be performed only by experienced surgeons, as the minute glands may be very difficult to define, and it is difficult to distinguish between an adenoma and normal parathyroid. In expert centres, over 90% of operations are successful, involving removal of the adenoma or removal of all four hyperplastic parathyroids. Minimal access surgery is used, and some centres measure PTH levels intraoperatively to ensure that the adenoma has been removed.

Other than postoperative hypocalcaemia (see below), the other rare complications are those of thyroid surgery: bleeding and recurrent laryngeal nerve palsies (<1%). Vocal cord function
should be checked preoperatively.

If initial exploration is unsuccessful, a full work-up, including venous catheterization and scanning, is essential, remembering that parathyroid tissue can be ectopic.

**Postoperative care**

The major danger after operation is hypocalcaemia, which is more common in patients who have significant bone disease and/or vitamin D deficiency – the ‘hungry bone’ syndrome. Some authorities pre-treat such patients with alfacalcidol 2 µg daily from 2 days preoperatively for 10–14 days, and routine vitamin D replacement (preferably without calcium) is always indicated if deficiency is diagnosed. Chvostek’s and Trousseau’s signs (see below) are monitored, as well as biochemistry. Plasma calcium measurements are performed at least daily until stable, with or without replacement; a mild transient hypoparathyroidism often continues for 1–2 weeks. Depending on its severity, oral or intravenous calcium should be given temporarily, as only a few patients (<1%) will develop longstanding surgical hypoparathyroidism.

**Familial hypocalciuric hypercalcaemia**

This uncommon autosomal dominant, and usually asymptomatic, condition demonstrates increased renal reabsorption of calcium despite hypercalcaemia. PTH levels are normal or slightly raised and urinary calcium is low. Familial hypocalciuric hypercalcaemia is caused by loss-of-function mutations in the gene on the long arm of chromosome 3 encoding for the calcium-ion-sensing G-protein-coupled receptor in the kidney and parathyroid gland. Family members are often affected and this is detected by genetic analysis. Parathyroid surgery is not indicated, as the course appears benign. This diagnosis can be differentiated from hyperparathyroidism in an isolated case by the calcium:creatinine ratio in blood and urine.

**Hypocalcaemia and hypoparathyroidism**

**Pathophysiology**

Hypocalcaemia may be due to deficiencies of calcium homeostatic mechanisms, or secondary to high phosphate levels or other causes of hypocalcaemia (*Box 26.49*). All forms of hypoparathyroidism, except transient surgical effects, are uncommon.

---

*Box 26.49*

**Causes of hypocalcaemia**

**Increased phosphate levels**
• Chronic kidney disease (common)
• Phosphate therapy

**Hypoparathyroidism**

• Surgical – after neck exploration (thyroidectomy, parathyroidectomy – common)
• Congenital deficiency (DiGeorge syndrome)
• Idiopathic hypoparathyroidism (rare)
• Severe hypomagnesaemia

**Vitamin D deficiency**

• Osteomalacia/rickets
• Vitamin D resistance

**Resistance to PTH**

• Pseudohypoparathyroidism

**Drugs**

• Calcitonin
• Bisphosphonates

**Other**

• Acute pancreatitis (quite common)
• Citrated blood in massive transfusion (not uncommon)
• Low plasma albumin, e.g. malnutrition, chronic liver disease
• Malabsorption, e.g. coeliac disease

PTH, parathyroid hormone.

---

**Aetiology**

*Chronic kidney disease* is the most common cause of hypocalcaemia.

*Severe vitamin D deficiency* may cause mild, and occasionally severe, hypocalcaemia.

*Hypocalcaemia after thyroid or parathyroid surgery* is common but usually transient; fewer than 1% of thyroidectomies leave permanent damage (see above).

*Idiopathic hypoparathyroidism* is one of the rarer autoimmune disorders, and is often accompanied by vitiligo, cutaneous candidiasis and other autoimmune disease.

*DiGeorge syndrome* (see p. 140) is a familial condition in which the hypoparathyroidism is associated with intellectual impairment, cataracts and calcified basal ganglia, and occasionally with specific autoimmune disease.

*Pseudohypoparathyroidism* is a syndrome of end-organ resistance to PTH owing to a
mutation in the G\textsubscript{S}α-protein (GNAS1), which is coupled to the PTH receptor. It is associated with short stature, short metacarpals, subcutaneous calcification and sometimes intellectual impairment. Variable degrees of resistance involving other G protein-linked hormone receptors may also be seen (TSH, LH, FSH).

Pseudo-pseudohypoparathyroidism describes the phenotypic defects but without any abnormalities of calcium metabolism. Individuals with this condition may share the same gene defect as those with pseudohypoparathyroidism and be members of the same families.

### Clinical features

Hypoparathyroidism presents as neuromuscular irritability and neuropsychiatric manifestations. Paraesthesiae, circumoral numbness, cramps, anxiety and tetany (**Box 26.50**) are followed by convulsions, laryngeal stridor, dystonia and psychosis. Two signs of hypocalcaemia are Chvostek's sign (gentle tapping over the facial nerve causes twitching of the ipsilateral facial muscles) and Trousseau's sign (inflation of the sphygmomanometer cuff above systolic pressure for 3 min induces tetanic spasm of the fingers and wrist). Severe hypocalcaemia may cause papilloedema and, frequently, a prolonged QT interval on the ECG.

**Box 26.50**

**Causes of tetany**

#### In the presence of alkalosis

- Hyperventilation
- Excess antacid therapy
- Persistent vomiting
- Hypochloraaemic alkalosis, e.g. primary hyperaldosteronism

#### In the presence of hypocalcaemia

- See **Box 26.49**

### Investigations

The clinical history and picture is usually diagnostic and is confirmed by a low serum calcium (after correction for any albumin abnormality). Additional tests include:

- **Serum and urine creatinine.** These test for renal disease.
- **PTH levels** in the serum. These are absent or inappropriately low in hypoparathyroidism, high in other causes of hypocalcaemia.
- **Parathyroid antibodies.** These are present in idiopathic hypoparathyroidism.
• **25-hydroxyvitamin D serum level.** This is low in vitamin D deficiency.

• **Magnesium level.** Severe hypomagnesaemia results in functional hypoparathyroidism, which is reversed by magnesium replacement.

• **X-rays of metacarpals.** Short fourth metacarpals occur in pseudohypoparathyroidism.

### Management

In vitamin D deficiency, colecalciferol is the most appropriate treatment (see p. 717). In other cases, alpha-hydroxylated derivatives of vitamin D are preferred for their shorter half-life, and especially in renal disease, as the others require renal hydroxylation. Usual daily maintenance doses are 0.25–2 µg for alfalcacidol (1α-OH-D₃). During treatment, plasma calcium must be monitored frequently to detect hypercalcaemia. Oral calcium supplements may be used in the early stages of treatment, and severe hypocalcaemia presenting as an emergency may occasionally require replacement with intravenous calcium gluconate. In hypoparathyroidism, PTH therapy is being used.

### Further reading

### Other Endocrine Disorders

#### Diseases of many glands

### Polyglandular autoimmune syndromes

Primary endocrine gland failure is commonly caused by autoantibodies (see *Box 26.2*) and there may be multiple gland deficiencies. Most common are the associations of primary hypothyroidism and type 1 diabetes, and either of these with Addison's disease or pernicious anaemia.

**Autoimmune polyendocrinopathy type 1**

Autoimmune polyendocrinopathy type 1 (APS-1) is an autosomal recessive disorder and is
caused by \textit{AIRE} gene mutations. This condition is also associated with non-endocrine manifestations. The \textit{AIRE} gene is present in the epithelium of the thymus and is involved in the presentation of self-antigens to thymocytes. Mutations will allow persistence of thymic lymphocytes, which react against self antigens and cause development of autoimmune disorders. Mucocutaneous candidiasis often develops before the onset of endocrine deficiencies, such as hypothyroidism, Addison's disease, type 1 diabetes, hypoparathyroidism, primary hypogonadism, nail dystrophy, vitiligo and dental enamel hypoplasia.

\textbf{Autoimmune polyendocrinopathy type 2}

Autoimmune polyendocrinopathy type 2 (APS-2) is not associated with candidiasis and is also known as Schmidt syndrome, typically when hypothyroidism, Addison's disease, type 1 diabetes, myasthenia gravis and primary hypogonadism are present in combination; coeliac disease is also an association.

\textbf{Multiple endocrine neoplasias}

Multiple endocrine neoplasia (MEN) is the name given to the simultaneous or metachronous occurrence of tumours involving a number of endocrine glands (\textit{Box 26.51}). The condition is inherited in an autosomal dominant manner and arises from the expression of recessive oncogenic mutations, most of which have been isolated. Affected persons may pass on the mutation to their offspring in the germ cell, but for the disease to become evident, a somatic mutation must also occur, such as deletion or loss of a normal homologous chromosome.

|                |           | Type 2a with marfanoid phenotype and intestinal and visceral ganglioneuromas but not hyperparathyroidism. Neuromas also present around lips and tongue |

ACTH, adrenocorticotrophic hormone; GH, growth hormone; VIP, vasoactive intestinal peptide.

**MEN 1**

The defect in MEN 1 is in a novel gene (*menin*) on the long arm of chromosome 11, which encodes for a 610-amino-acid protein. *Menin* represses a transcription factor (*JunD*), and lack of *JunD* suppression leads to decreased apoptosis and oncogenesis. People with the *MEN1* gene carry one mutant gene and a wild-type gene (i.e. are heterozygous). When the wild-type gene undergoes a random somatic mutation during life, this leads to loss of heterozygosity and explains the late onset of tumours at any stage (the ‘two hit’ hypothesis). MEN 1 is classically associated with pancreatic, parathyroid and pituitary tumours, although other glands may be affected (*Box 26.51, Fig. 26.40*).
MEN 2a and 2b

MEN 2a and 2b are caused by mutations of the RET proto-oncogene on chromosome 10 (see medullary thyroid cancer, p. 1212). This gene encodes for a transmembrane glycoprotein receptor. For MEN 2a, the mutation is in the extracellular domain; for 2b, it is in the intracellular domain. MEN 2 is classically associated with parathyroid tumours, phaeochromocytoma and medullary thyroid carcinoma (Box 26.51). Unlike MEN 2a, MEN 2b is associated with a marfanoid phenotype and intestinal and visceral ganglioneuromas, as well as neuromas around the lips and tongue.

Management

Management of established tumours in MEN is largely the same as treatment for similar tumours occurring sporadically. In MEN 1, four-gland parathyroidectomy is usually recommended when surgery is needed since all glands are typically involved. However, the essence of management in MEN is annual screening to detect tumours at an early, treatable stage.

Screening

A careful family history is essential. If the precise gene mutation has been identified in a particular family, then family members at risk can be offered genetic screening for the presence of the mutation, ideally in childhood. In affected individuals, biochemical screening and periodic imaging are then required.

Screening for MEN 1

Hyperparathyroidism is usually the first manifestation, and serum calcium is the simplest screening test in families with no identified mutation. In an established case (or gene-positive family member), other screening bloods include prolactin, GH/IGF-1 and ‘gut hormones’ (see p. 377). Periodic imaging of pancreas, adrenals and pituitary is usually performed. People with MEN 1 can develop metastases to the liver from non-functional pancreatic tumours that are clinically silent; this emphasizes the need for regular screening imaging.
Screening for MEN 2

Serum calcium levels will easily detect hyperparathyroidism.

• **Medullary carcinoma of thyroid (MCT).** With the known presence of the gene defect, total thyroidectomy is recommended in early childhood or as soon as the gene defect is identified. Calcitonin is a useful tumour marker.

• **Phaeochromocytoma.** Metanephrine or catecholamine estimations are required.

### McCune–Albright syndrome

This condition is associated with autonomous hypersecretion of a number of endocrine glands at a young age. Gonadotrophin-independent puberty occurs, with Leydig cell hyperplasia in males and ovarian oestrogen production in girls. Pituitary hypersecretion may lead to hyperprolactinaemia, acromegaly or gigantism. Cushing syndrome due to nodular hyperplasia of the adrenal cortex is observed, as well as autonomous functioning thyroid nodules. Non-endocrine manifestations include café-au-lait patches and increased bone deformity and fractures due to polyostotic fibrous dysplasia. The pathological basis is a point mutation of the **GNAS1** gene that inhibits GTPase activity, leading to persistent activation of cAMP-mediated endocrine secretion.

### Ectopic hormone secretion

This term refers to hormone synthesis, and normally secretion, from a neoplastic non-endocrine cell, most usually seen in tumours that have some degree of embryological resemblance to specialist endocrine cells. The clinical effects are those of the hormone produced, with or without manifestations of systemic malignancy. The most common situations seen are the following:

• **Hypercalcaemia of malignant disease,** often from squamous cell tumours of lung and breast, often with bone metastases. Where metastases are not present, most cases are mediated by secretion of PTH-related protein (PTHrP), which has considerable sequence homology to PTH; a variety of other factors may sometimes be involved but very rarely PTH itself (see p. 1236). Treatment is discussed on page 1237.

• **SIADH** (see pp. 1234–1235). Again, this is most commonly caused by a primary lung tumour.

• **Ectopic ACTH syndrome** (see p. 1198). Small-cell carcinoma of the lung, carcinoid tumours and medullary thyroid carcinomas are the most common causes, though many other tumours rarely cause it.

• **Production of insulin-like activity.** This may result in hypoglycaemia (see p. 1276).

### Endocrine treatment of other malignancies

(From Miller MD 2011 Presentation, Imaging and Treatment of Common Musculoskeletal Conditions, Saunders, with permission.)
Introduction

Diabetes mellitus (DM) is a syndrome of chronic hyperglycaemia due to relative insulin deficiency, resistance or both. The International Diabetes Federation (IDF) estimated that 382 million people (8.3% of the global population) had diabetes in 2013, and estimates an increase
to 592 million (10.1%) in 2035. Diabetes is generally irreversible and, although patients can lead a reasonably normal lifestyle, its late complications result in reduced life expectancy and major health costs. These include macrovascular disease, leading to an increased prevalence of coronary artery disease, peripheral vascular disease and stroke, and microvascular damage causing diabetic retinopathy and nephropathy. Neuropathy is another major complication.

**Hyperglycaemia, insulin and insulin action**

**Insulin structure and secretion**

Insulin is the key hormone involved in the storage and controlled release within the body of the chemical energy available from food. It is coded for on chromosome 11 and synthesized in the β cells of the pancreatic islets (*Fig. 27.1*). The synthesis, intracellular processing and secretion of insulin by the β cell is typical of the way that the body produces and manipulates many peptide hormones. *Figure 27.2* illustrates the cellular events triggering the release of insulin-containing granules. After secretion, insulin enters the portal circulation and is carried to the liver, its prime target organ. About 50% of secreted insulin is extracted and degraded in the liver; the residue is broken down by the kidneys. C-peptide is only partially extracted by the liver (and hence provides a useful index of the rate of insulin secretion) but is mainly degraded by the kidneys.
FIGURE 27.1 Part of a β cell. The ribosomes manufacture pre-proinsulin from insulin messenger RNA (mRNA). The hydrophobic ‘pre’ portion of pre-proinsulin allows it to transfer to the Golgi apparatus, and is subsequently enzymatically cleaved off. Proinsulin is parcellated into secretory granules in the Golgi apparatus. These mature and pass towards the cell membrane, where they are stored before release. The proinsulin molecule folds back on itself and is stabilized by disulphide bonds. The biochemically inert peptide fragment known as connecting (C-)peptide splits off from proinsulin in the secretory process, leaving insulin as a complex of two linked peptide chains. Equimolar quantities of insulin and C-peptide are released into the circulation via the ‘regulated pathway’. A small amount of insulin is secreted by the β cell directly via the ‘constitutive pathway’, which bypasses the secretory granules.
**An outline of glucose metabolism**

Blood glucose levels are closely regulated in health and rarely stray outside the range of 3.5–8.0 mmol/L (63–144 mg/dL), despite the varying demands of food, fasting and exercise. The principal organ of glucose homeostasis is the liver, which absorbs and stores glucose (as glycogen) in the post-absorptive state and releases it into the circulation between meals to match the rate of glucose utilization by peripheral tissues. The liver also combines three-carbon molecules derived from breakdown of fat (glycerol), muscle glycogen (lactate) and protein (e.g. alanine) into the six-carbon glucose molecule by the process of gluconeogenesis.

**Glucose production**

About 200 g of glucose is produced and utilized each day. More than 90% is derived from liver glycogen and hepatic gluconeogenesis, and the remainder from renal gluconeogenesis.

**Glucose utilization**

The brain is the major consumer of glucose and its function depends on an uninterrupted supply of this substrate. Its requirement is 1 mg/kg body weight per minute, or 100 g daily in a 70 kg person. Glucose uptake by the brain is obligatory and is not dependent on insulin, and the glucose used is oxidized to carbon dioxide and water. Tissues such as muscle and fat have insulin-responsive glucose transporters and absorb glucose in response to postprandial peaks in glucose and insulin. At other times, energy requirements are largely met by fatty-acid oxidation. Glucose taken up by muscle is stored as glycogen or metabolized to lactate or carbon dioxide and water. Fat uses glucose as a substrate for triglyceride synthesis; lipolysis...
releases fatty acids from triglyceride together with glycerol, a substrate for hepatic gluconeogenesis.

**Hormonal regulation**

Insulin is a major regulator of intermediary metabolism, although its actions are modified in many respects by other hormones. Its actions in the fasting and postprandial states differ (**Fig. 27.3**). In the fasting state, its main action is to regulate glucose release by the liver, and in the postprandial state it additionally promotes glucose uptake by fat and muscle. The effect of counter-regulatory hormones (glucagon, adrenaline (epinephrine), cortisol and growth hormone) is to increase glucose production by the liver and reduce its utilization in fat and muscle for a given level of insulin.

![Fasting and postprandial effects of insulin](image)

**FIGURE 27.3** Fasting and postprandial effects of insulin. In the **fasting state**, insulin concentrations are low and it acts mainly as a hepatic hormone, modulating glucose production (via glycogenolysis and gluconeogenesis) from the liver. Hepatic glucose production rises as insulin levels fall. In the **postprandial state**, insulin concentrations are high and it then suppresses glucose production from the liver and promotes the entry of glucose into peripheral tissues (increased glucose utilization).

**Glucose transport**

Cell membranes are not inherently permeable to glucose. A family of specialized glucose-transporter (GLUT) proteins carry glucose through the membrane into cells.

- **GLUT-1** enables basal non-insulin-stimulated glucose uptake into many cells (see **Fig. 13.30**).
- **GLUT-2** transports glucose into the β cell, a prerequisite for glucose sensing, and is also present in the renal tubules and hepatocytes.
- **GLUT-3** enables non-insulin-mediated glucose uptake into brain neurones and placenta.
• **GLUT-4** mediates much of the peripheral action of insulin. It is the channel through which glucose is taken up into muscle and adipose tissue cells following stimulation of the insulin receptor *(Fig. 27.4).*

![Figure 27.4](image)

**FIGURE 27.4** Insulin signalling in peripheral cells (e.g. muscle and adipose tissue). The insulin receptor consists of α- and β-subunits linked by disulphide bridges (top right). The β-subunits straddle the cell membrane. The transporter protein GLUT-4 (bottom left) is stored in intracellular vesicles. The binding of insulin to its receptor initiates many intracellular actions, including translocation of these vesicles to the cell membrane, carrying GLUT-4 with them; this allows glucose transport into the cell.

**The insulin receptor**

This is a glycoprotein (400 kDa), coded for on the short arm of chromosome 19, which straddles the cell membrane of many cells *(Fig. 27.4).* It consists of a dimer with two α-subunits, which include the binding sites for insulin, and two β-subunits, which traverse the cell membrane. When insulin binds to the α-subunits, it induces a conformational change in the β-subunits, resulting in activation of tyrosine kinase and initiation of a cascade response involving a host of other intracellular substrates. One consequence of this is migration of the GLUT-4 glucose transporter to the cell surface and increased transport of glucose into the cell. The insulin-receptor complex is then internalized by the cell, insulin is degraded, and the receptor is recycled to the cell surface.

**Classification of Diabetes**

Diabetes may be primary (idiopathic) or secondary *(Box 27.1).* Primary diabetes is classified into:

• **type 1 diabetes**, which has an immune pathogenesis and is characterized by severe insulin
deficiency
• **type 2 diabetes**, which results from a combination of insulin resistance and less severe insulin deficiency.

---

Box 27.1

**Aetiological classification of diabetes mellitus, based on classification by the American Diabetes Association**

**Type 1 diabetes**

• Beta-cell destruction, usually leading to absolute insulin deficiency:
  – Immune-mediated
  – Idiopathic

**Type 2 diabetes**

• May range from predominantly insulin resistance with relative insulin deficiency to a predominantly secretory defect with insulin resistance

**Other specific types**

• Genetic defects of β-cell function
• Genetic defects in insulin action (mainly receptor mutations)
• Diseases of the exocrine pancreas:
  – Pancreatitis
  – Trauma/pancreatectomy
  – Neoplasia
  – Cystic fibrosis
  – Haemochromatosis
  – Fibrocalculous pancreatopathy
  – Other
• Endocrinopathies:
  – Acromegaly
  – Cushing syndrome
  – Glucagonoma
  – Phaeochromocytoma
  – Hyperthyroidism
  – Somatostatinoma
  – Aldosteronoma
  – Others
• Drug- or chemical-induced:
  – Vacor (pyrinuron)
– Pentamidine
– Nicotinic acid (niacin)
– Beta-blockers
– Thyroid hormone
– Diazoxide
– Beta-adrenergic agonists
– Thiazides
– Phenytoin
– Interferon-alfa
– Protease inhibitors
– Immunosuppressive agents: glucocorticoids, ciclosporin, tacrolimus, sirolimus
– Anti-psychotic agents: clozapine, olanzapine, others

• Infections
  – Congenital rubella
  – Cytomegalovirus
  – Others

**Uncommon forms of immune-mediated diabetes**

• ‘Stiff person’ syndrome
• Anti-insulin receptor antibodies

**Other genetic syndromes sometimes associated with diabetes**

• Down syndrome
• Friedreich's ataxia
• Huntington's chorea
• Klinefelter syndrome
• Laurence–Moon–Biedl syndrome
• Myotonic dystrophy
• Porphyria
• Prader–Willi syndrome
• Turner syndrome
• Wolfram syndrome
• Other

**Gestational diabetes mellitus**

*Patients with any form of diabetes may require insulin treatment at some stage of their disease. Such use of insulin does not, of itself, classify the patient.*

The key clinical features of the two main forms of diabetes are listed in Box 27.2. Type 1 and type 2 diabetes represent two distinct diseases from the epidemiological point of view, but from a clinical point of view the two conditions should be seen as a spectrum, distinct at the two ends but overlapping in the middle. Hybrid forms are increasingly recognized, and patients with immune-mediated diabetes (type 1) may, for example, also be overweight and insulin-resistant. This is sometimes referred to as ‘double diabetes’. It is more relevant to give patients the right treatment on clinical grounds than to worry about how to label their diabetes. The classification of primary diabetes continues to evolve. Monogenic forms have been identified (see pp. 1249–1250), in some cases with significant therapeutic implications. Although secondary diabetes accounts for barely 1–2% of all new cases at presentation, it should not be missed because the cause can sometimes be treated. All forms of diabetes derive from inadequate insulin secretion relative to the needs of the body, and progressive insulin secretory failure is characteristic of both common forms of diabetes. Thus, some patients with immune-mediated diabetes type 1 may not at first require insulin, whereas many with type 2 diabetes will eventually do so.
