HLA, human leucocyte antigen.
Epidemiology

Type 1 diabetes is a disease of insulin deficiency and is subdivided into type 1A (immune-mediated) and type 1B (non-immune-mediated). The great majority of those affected, especially in Western countries, have type 1A disease. This typically manifests in childhood, reaching a peak incidence around the time of puberty, but can present at any age. A ‘slow-burning’ variant with slower progression to insulin deficiency occurs in later life and is sometimes called latent autoimmune diabetes in adults (LADA). LADA may be difficult to distinguish from type 2 diabetes. Clinical clues are leaner build, rapid progression to insulin therapy following an initial response to other therapies, and the presence of circulating islet autoantibodies. Finland and other Northern European countries have the highest rates of type 1 diabetes (Fig. 27.5). The incidence of type 1 diabetes appears to be increasing in most populations. In Europe, the annual increase is of the order of 2–3%, and is most marked in children under the age of 5 years. The IDF estimated in 2013 that 0.5 million children aged 0–14 years are currently affected by diabetes, and the figure is increasing by 3% annually.

Aetiology

Type 1 diabetes belongs to a family of human leucocyte antigen (HLA)-associated immune-mediated organ-specific diseases. Genetic susceptibility is polygenic, with the greatest contribution from the HLA region. Autoantibodies directed against pancreatic islet constituents appear in the circulation within the first few years of life, and often predate clinical onset by
many years. Autoantibodies are also found in older patients with LADA and carry an increased risk of progression to insulin therapy.

**Genetic susceptibility and inheritance**

Increased susceptibility to type 1 diabetes is inherited but the disease is not genetically predetermined. The identical twin of a patient with type 1 diabetes has a 30–50% chance of developing the disease, which implies that non-genetic factors must also be involved. The risk of developing diabetes by age 20, curiously, is greater with a diabetic father (3–7%) than with a diabetic mother (2–3%). Earlier onset in the parent is associated with increased risk in the child. If one child in a family has type 1 diabetes, each sibling has a approximately 6% risk of developing diabetes by age 20. This risk rises to about 20% in HLA-identical siblings who have the same HLA type as the proband. Since type 1 diabetes can present at any age, the lifetime risk for a sibling or child is at least double the risk by age 20.

**HLA system**

The HLA genes on chromosome 6 are highly polymorphic and modulate the immune defence system of the body. More than 90% of patients with type 1 diabetes carry HLA-DR3-DQ2, HLA-DR4-DQ8 or both, as compared with some 35% of the background population. All DQB1 alleles with an aspartic acid at residue 57 confer neutral to protective effects, with the strongest effect from DQB1*0602 (DQ6), while DQB1 alleles with an alanine at the same position (i.e. DQ2 and DQ8) confer strong susceptibility. Genotypic combinations have a major influence on risk of disease. For example, HLA-DR3-DQ2/HLA-DR4-DQ8 heterozygotes have a considerably increased risk of disease, and some HLA class I alleles also modify the risk conferred by class II susceptibility genes.

**Other genes or gene regions**

Genome-wide association studies have greatly broadened our understanding of the genetic background to type 1 diabetes and more than 50 non-HLA genes or gene regions that influence risk have been identified to date. The greatest genetic contribution still comes from the HLA region but this is modulated by a large number of genes with small effects. These include the gene encoding insulin (INS) on chromosome 11 and a number of genes involved in immune responses, including the cytotoxic T-lymphocyte-associated protein-4 (CTLA4) gene, the lymphoid-specific protein tyrosine phosphatase (PTPN22) gene and the interleukin (IL)-2R α-subunit of the IL-2 receptor complex locus (IL2RA), all of which are implicated in a variety of HLA-associated autoimmune conditions.

**Autoimmunity and type 1 diabetes**

Type 1 diabetes is associated with other organ-specific autoimmune diseases, including autoimmune thyroid disease, coeliac disease, Addison's disease and pernicious anaemia. Autopsies of patients who died following a diagnosis of type 1 diabetes show infiltration of the pancreatic islets by mononuclear cells. This appearance, known as insulitis, resembles that
in other autoimmune diseases such as thyroiditis (Fig. 27.6). Several islet antigens have been characterized and these include insulin itself, the enzyme glutamic acid decarboxylase (GAD), protein tyrosine phosphatase (IA-2) (Fig. 27.7) and the cation transporter ZnT8. The observation that treatment with immunosuppressive agents such as ciclosporin prolongs β-cell survival in newly diagnosed patients has confirmed that the disease is immune-mediated.

![FIGURE 27.6](image)

**FIGURE 27.6** Pancreatic islet showing infiltration by chronic inflammatory cells (insulitis).

![FIGURE 27.7](image)

**FIGURE 27.7** Islet autoantibodies. Islet cell antibodies (ICA) are detected by a fluorescent antibody technique that detects binding of autoantibodies to islet cells. Much of this staining reaction is due to antibodies specific for *glutamic acid decarboxylase* (GAD) and *protein tyrosine phosphatase* (IA-2, also known as ICA512). Not all the staining seen with ICA is due to these two autoantibodies, so it is assumed that other islet autoantibodies are also involved. Insulin autoantibodies also appear in the circulation but do not contribute to the ICA reaction.
Environmental factors

The incidence of childhood type 1 diabetes is rising across Europe at the rate of 2–3% each year, suggesting that environmental factor(s) are involved in its pathogenesis. Islet autoantibodies (see above) appear in the first few years of life, indicating prenatal or early postnatal interactions with the environment. Exposures to dietary constituents, enteroviruses such as Coxsackie B4 and relative deficiency of vitamin D are possible candidates but their role in the causation of the disease has yet to be confirmed. A cleaner environment with less early stimulation of the immune system in childhood may increase susceptibility for type 1 diabetes, as for atopic/allergic conditions (the ‘hygiene hypothesis’; see pp. 142–143), and more rapid weight gain in childhood and adolescence leading to increased insulin resistance might accelerate clinical onset (the ‘accelerator hypothesis’).

Pre-type 1 diabetes and prevention of type 1 diabetes

Children who test positive for two or more autoantibodies have a >80% risk of progression to diabetes, and the risk approaches 100% in those who additionally lose their first-phase insulin response to intravenous glucose and/or develop glucose intolerance. The ability to predict type 1 diabetes with this degree of precision has opened the way to trials of disease prevention, but intervention before clinical onset of diabetes has so far proved unsuccessful.

Type 2 diabetes mellitus

Epidemiology

Type 2 diabetes is common in all populations enjoying an affluent lifestyle, and has increased in parallel with the adoption of a Western lifestyle and increasing obesity. The four major determinants are increasing age, obesity, ethnicity and family history. In poor countries, diabetes is a disease of the rich, but in rich countries, it is a disease of the poor; obesity is the common factor. Glucose intolerance or frank diabetes may be present in a subclinical or undiagnosed form for years before diagnosis, and 25–50% of patients already have some evidence of vascular complications at the time of diagnosis. Onset may be accelerated by the stress of pregnancy, drug treatment or intercurrent illness. The IDF estimates the global lifetime risk of diabetes at 20%, with the highest rates and most rapid increase in the Middle East, South-east Asia and the Western Pacific. There are sometimes 2–3-fold differences in prevalence between populations from different ethnic backgrounds who share the same environment.

Obesity increases the risk of type 2 diabetes 80–100-fold, and this is reflected by the increasing prevalence of diabetes in different populations. On average, the inhabitants of affluent countries gain weight at the rate of 1 g/day or more between the ages of 25 and 55 years. This gain, due to a tiny excess in energy intake over expenditure (90 kcal or one chocolate-coated digestive biscuit per day), is often due to reduced exercise rather than
increased food intake. The proportion of obese young adults with type 2 diabetes is rising rapidly, and epidemic obesity will create a huge public health problem for the future.

Type 2 diabetes is associated with central obesity, hypertension, hypertriglyceridaemia, a decreased high-density lipoprotein (HDL) cholesterol, disturbed haemostatic variables and modest increases in a number of pro-inflammatory markers. Insulin resistance is strongly associated with many of these variables, as is increased cardiovascular risk. This group of conditions is referred to as the **metabolic syndrome** (see p. 209). The IDF has proposed criteria based on increased waist circumference (or body mass index >30) plus two of the following: diabetes (or fasting glucose >6.0 mmol/L), hypertension, raised triglycerides or low HDL cholesterol. On this definition, about one-third of the adult population has features of the syndrome, not necessarily associated with diabetes. Critics argue that the metabolic syndrome is not a distinct entity, but one end of a continuum in the relationship between lifestyle and body weight on the one hand, and genetic make-up on the other, and that diagnosis adds little to standard clinical practice in terms of diagnosis, prognosis or therapy.

### Aetiology

#### Genetic susceptibility and inheritance

Identical twins of patients with type 2 diabetes have more than a 50% chance of developing diabetes; the risk to non-identical twins or siblings is of the order of 25%, confirming a strong inherited component to the disease. Type 2 diabetes is a polygenic disorder and, as with type 1 diabetes, genome-wide studies of associations between common DNA variants and disease have allowed identification of numerous susceptibility loci. Several of these loci subserve β-cell development or function, and there is no overlap with the immune function genes identified for type 1 diabetes. There is no major gene susceptibility, involving the HLA region. However, transcription factor-7-like 2 (TCF7-L2) is the most common variant observed in type 2 diabetes in Europeans, and KCNQ1 (a potassium voltage-gated channel) in Asians. TCF7-L2 carries an increased risk of around 35%, while other common variants account for no more than 10–20%. TCF7-L2 modulates pancreatic islet cell function. Paradoxically, the genes for type 2 diabetes account for a relatively small fraction of its observed heritability. They do not allow subtypes of the condition to be identified with any confidence; nor do they provide useful disease prediction.

#### Environmental factors

An association has been noted between low weight at birth and at 12 months of age and glucose intolerance later in life, particularly in those who gain excess weight as adults. The concept is that poor nutrition early in life impairs β-cell development and function, predisposing to diabetes in later life. Low birth weight has also been shown to predispose to heart disease and hypertension.

### Inflammation
Subclinical inflammatory changes are characteristic of both type 2 diabetes and obesity; in diabetes, high-sensitivity C-reactive protein (CRP) levels are modestly elevated in association with raised fibrinogen and increased plasminogen activator inhibitor-1 (PAI-1), contributing to cardiovascular risk. Circulating levels of the pro-inflammatory cytokines tumour necrosis factor alpha (TNF-α) and IL-6 are elevated in both diabetes and obesity.

**Abnormalities of insulin secretion and action**

The relative role of secretory failure versus insulin resistance in the pathogenesis of type 2 diabetes has been much debated, but even massively obese individuals with a fully functioning β-cell mass do not necessarily develop diabetes, which implies that some degree of β-cell dysfunction is necessary. Insulin binds normally to its receptor on the surface of cells in type 2 diabetes, and the mechanisms of ‘insulin resistance’ are still poorly understood. Insulin resistance is, however, associated with central obesity and accumulation of intracellular triglyceride in muscle and liver in type 2 diabetes, and a high proportion of patients have non-alcoholic fatty liver disease (NAFLD; see p. 465). It has long been stated that patients with type 2 diabetes retain up to 50% of their β-cell mass at the time of diagnosis, as compared with healthy controls, but the shortfall is greater than this when they are matched with healthy individuals who are equally obese. In addition, patients with type 2 diabetes almost all show islet amyloid deposition at autopsy, derived from a peptide known as amylin or islet amyloid polypeptide (IAPP), which is co-secreted with insulin. It is not known if this is a cause or consequence of β-cell secretory failure.

Abnormalities of insulin secretion manifest early in the course of type 2 diabetes. An early sign is loss of the first phase of the normal biphasic response to intravenous insulin. Established diabetes is associated with hypersecretion of insulin by a depleted β-cell mass. Circulating insulin levels are therefore higher than in healthy controls, although still inadequate to restore glucose homeostasis. Relative insulin lack is associated with increased glucose production from the liver (owing to inadequate suppression of gluconeogenesis) and reduced glucose uptake by peripheral tissues. Hyperglycaemia and lipid excess are toxic to β cells, at least in vitro, a phenomenon known as glucotoxicity, and this is thought to result in further β-cell loss and further deterioration of glucose homeostasis. Circulating insulin levels are typically higher than in non-diabetics following diagnosis and tend to rise further, only to decline again after months or years due to secretory failure, an observation sometimes referred to as the ‘Starling curve’ of the pancreas. Type 2 diabetes is thus a condition in which insulin deficiency relative to increased demand leads to hypersecretion of insulin by a depleted β-cell mass and progression towards absolute insulin deficiency, requiring insulin therapy. Its time course varies widely between individuals.

**Overview and prevention**

Genetic predisposition determines whether an individual is susceptible to type 2 diabetes; if and when diabetes develops largely depends on lifestyle. A dramatic reduction in the incidence of new cases of adult-onset diabetes was documented in the Second World War
when food was scarce, and clinical trials in individuals with impaired glucose tolerance have shown that diet, exercise or agents such as metformin have a marked effect in deferring the onset of type 2 diabetes. Established diabetes can be reversed, even if temporarily, by successful dietary changes and weight loss, or by bariatric surgery. Diabetes is therefore largely preventable, although the most effective measures would be directed at the whole population and implemented early in life. Prevention is well worthwhile, for diabetes diagnosed in a man between the ages of 40 and 59 reduces life expectancy by 5–10 years. By contrast, type 2 diabetes diagnosed after the age of 70 has a limited effect on life expectancy.

# Monogenic diabetes mellitus

The genetic causes of some rarer forms of diabetes are shown in Box 27.3. Considerable progress has been made in understanding these uncommon variants of diabetes. Genetic defects of β-cell function (previously called ‘maturity-onset diabetes of the young’, MODY) are dominantly inherited, and several variants have been described, each associated with different clinical phenotypes (Box 27.4). These should be considered in people presenting with early-onset diabetes in association with an affected parent and early-onset diabetes in approximately 50% of relatives.

The glucokinase gene is intimately involved in the glucose-sensing mechanism within the pancreatic β cell. The hepatic nuclear factor (HNF) genes and the insulin promoter factor-1 (IPF-1) gene control nuclear transcription in the β cell, where they regulate its development and function. Abnormal nuclear transcription genes may cause pancreatic agenesis or more subtle progressive pancreatic damage. A handful of families with autosomal dominant diabetes have been described with mutations in neurogenic differentiation factor-1 (NeuroD1).

Infants who develop diabetes before 6 months of age are likely to have a monogenic defect and not true type 1 diabetes. Transient neonatal diabetes mellitus (TNDM) occurs soon after birth and resolves at a median of 12 weeks; some 50% of cases ultimately relapse later in life. Most have an abnormality of imprinting of the ZAC and HYMAI genes on chromosome 6q. The most common cause of permanent neonatal diabetes mellitus (PNDM) is mutations in the KCNJ11 gene encoding the Kir6.2 subunit of the β-cell potassium–adenosine triphosphate (ATP) channel.

Neurological features are seen in 20% of patients. Diabetes is due to defective insulin release rather than β-cell destruction, and patients can be treated successfully with sulphonylureas, even after many years of insulin therapy.

Clinical Approach to the Patient with Diabetes

Presentation

Presentation may be acute, subacute or asymptomatic, or a patient may present with one of the complications of diabetes.

Acute presentation

Young people often present with a 2–6-week history and report the classic triad of symptoms:

- **polyuria** due to the osmotic diuresis that results when blood glucose levels exceed the renal threshold
- **thirst** due to the resulting loss of fluid and electrolytes
- **weight loss** due to fluid depletion and the accelerated breakdown of fat and muscle secondary to insulin deficiency.

Ketonuria is often present in young people and may progress to ketoacidosis if these early symptoms are not recognized and treated.

Subacute presentation

The clinical onset may be over several months or years, particularly in older patients. Thirst, polyuria and weight loss are typically present but patients may complain of such symptoms as lack of energy, visual blurring (owing to glucose-induced changes in refraction), or pruritus vulvae or balanitis that is due to *Candida* infection.

Complications as the presenting feature

These include:

- staphylococcal skin infections
- retinopathy noted during a visit to the optician
- a polyneuropathy causing tingling and numbness in the feet
- erectile dysfunction
- arterial disease, resulting in myocardial infarction or peripheral gangrene.

Asymptomatic diabetes
Glycosuria or a raised blood glucose may be detected on routine examination (e.g. for insurance purposes) in individuals who have no symptoms of ill-health. This is more common in older people, who have a raised renal threshold for glucose. When present, glycosuria is not diagnostic of diabetes but indicates the need for further investigations. Familial renal glycosuria is a monogenic disorder affecting function of the sodium–glucose co-transporter (SGLT2) and found in about 1:400 of the population.

**Physical examination at diagnosis**

Evidence of weight loss and dehydration may be present, and the breath may smell of ketones. Older patients may present with established complications, and the presence of the characteristic retinopathy is diagnostic of diabetes. In occasional patients, there will be physical signs of an illness causing secondary diabetes (see *Box 27.1*). Patients with severe insulin resistance may have acanthosis nigricans, which is characterized by blackish pigmentation at the nape of the neck and in the axillae (see p. 1364).

**Diagnosis and investigations**

Diabetes is easy to diagnose when overt symptoms are present and a random blood glucose measurement of >11 mmol/L confirms the diagnosis. In the absence of clear symptoms, diabetes can be diagnosed by any of three measures of glucose metabolism: the oral glucose tolerance test (OGTT), fasting plasma glucose and haemoglobin A$_1c$ (HbA$_{1c}$) (*Boxes 27.5 and 27.6*). Unfortunately there is limited overlap between these measures, especially in the ‘grey zone’ between diabetes and normality.

---

*Box 27.5*

**World Health Organization diagnostic criteria for diabetes**

- Fasting plasma glucose >7.0 mmol/L (126 mg/dL)
- Random plasma glucose >11.1 mmol/L (200 mg/dL)

  One abnormal laboratory value is diagnostic in symptomatic individuals; two values are needed in asymptomatic people. The glucose tolerance test (see *Box 27.6*) is only required for borderline cases and for diagnosis of gestational diabetes

- HbA$_{1c}$ >6.5 (48 mmol/mol)

---

*There is no such thing as mild diabetes. All patients who meet the criteria for diabetes are liable to develop disabling long-term complications.*
Box 27.6

*a Only a fasting and a 120-min sample are needed. Results are for venous plasma; whole-blood values are lower.

*b Adult 75 g glucose in 300 mL water; child 1.75 g glucose/kg body weight.

Pre-diabetes

Since any marker of abnormal glucose metabolism is associated with an increased risk of progression to diabetes and/or cardiovascular disease, it can be argued that a single abnormality is sufficient for admission into a risk category, which the American Diabetes Association (ADA) has labelled ‘pre-diabetes’. On this basis, 86 million Americans suffer from pre-diabetes, in addition to the 25 million with known or undiagnosed diabetes. The World Health Organization (WHO) and other professional organizations avoid use of the term ‘pre-diabetes’, on the grounds that the majority will never, in fact, develop diabetes, and that the evidence to support screening and intervention is lacking.

Impaired glucose tolerance

Impaired glucose tolerance (IGT) is not a clinical entity but a risk factor for future diabetes and cardiovascular disease. The diagnosis can only be made with a glucose tolerance test, and is complicated by poor reproducibility of the key 2-hour value in this test. The group is heterogeneous; some patients are obese, some have liver disease and others are on medication that impairs glucose tolerance. Individuals with IGT have the same risk of cardiovascular disease as those with frank diabetes, but do not develop the specific microvascular complications.

Impaired fasting glucose

This diagnostic category (fasting plasma glucose between 6.1 and 6.9 mmol/L) has the practical advantage that it avoids the need for a glucose tolerance test. It is not a clinical entity but indicates future risk of frank diabetes and cardiovascular disease. Impaired fasting glucose (IFG) only overlaps with IGT to a limited extent, and the associated risks of cardiovascular disease and future diabetes are not directly comparable. A lower cut-off of 5.6 mmol/L (rather than 6.1 mmol/L) has been recommended by the ADA and would, if implemented, greatly increase the number of those in this category.
Haemoglobin A_1c

Haemoglobin A_1c (HbA_1c; also referred to as A_1c in the USA) is an integrated measure of an individual's prevailing blood glucose concentration over several weeks (see below). Standardization of this measure has enabled it to be proposed as an alternative diagnostic test for diabetes by the ADA. As currently proposed, an HbA_1c of >6.5% (48 mmol/mol) would be considered diagnostic of diabetes, whereas a level of 5.7–6.4% (39–46 mmol/mol) would denote increased risk of diabetes. A WHO consultation also concluded that HbA_1c ‘can be used as a diagnostic test for diabetes’. The ADA has recommended that HbA_1c should be used together with IGT and IFG as a marker of ‘pre-diabetes’, with a range of 5.6–6.4% (38–46 mmol/mol).

Other investigations

No further tests are needed to diagnose diabetes. Other routine investigations include urine testing for protein, a full blood count, urea and electrolytes, liver biochemistry and random lipids. The latter test is useful to exclude associated hyperlipidaemia and, if elevated, should be repeated as a fasting measurement after diabetes has been brought under control. Diabetes may be secondary to other conditions (see Box 27.1), precipitated by underlying illness, and associated with autoimmune disease or hyperlipidaemia. Hypertension is present in 50% of patients with type 2 diabetes and a higher proportion of African and Caribbean patients.

Further reading

Management of Diabetes

The role of patient education and community care

The care of diabetes is based on self-management by the patient, who is helped and advised by those with specialized knowledge. The quest for improved glycaemic control has made it clear that whatever the technical expertise applied, the outcome depends on willing cooperation by the patient. This, in turn, depends on an understanding of the risks of diabetes and the potential benefits of glycaemic control and other measures such as maintaining a lean weight, stopping smoking and taking care of the feet. If accurate information is not supplied, misinformation from friends and other patients will take its place. For this reason, the best time to educate the patient is soon after diagnosis. Organized education programmes involve all healthcare workers, including nurse specialists, dieticians and podiatrists, and should include ongoing support and updates wherever possible.
Diet

The diet for people with diabetes is no different from that considered healthy for everyone. *Box 27.7* lists recommendations on the ideal composition of this diet. To achieve this, food for people with diabetes should be:

- low in sugar (though not sugar-free)
- high in starchy carbohydrate (especially foods with a low glycaemic index), i.e. slower absorption
- high in fibre
- low in fat (especially saturated fat).

**Box 27.7**

**Recommended composition of the diet for people with diabetes**
The overweight or obese should be encouraged to lose weight by a combination of changes in food intake and physical activity.

**Carbohydrates**
The glucose peak seen in the blood after eating pasta is much flatter than that seen after eating the same amount of carbohydrate as white potato. Pasta has a lower ‘glycaemic index’. Foods with a low glycaemic index prevent rapid swings in circulating glucose, and are thus preferred to those with a higher glycaemic index.

**Prescribing a diet**
Most people find it extremely difficult to modify their eating habits, and repeated advice and encouragement are needed if this is to be achieved. A diet history is taken, and the diet prescribed should involve the least possible interference with the person's lifestyle. Advice from dieticians is more likely to affect medium-term outcome than advice from doctors. People

</tbody>
</table>
taking insulin or oral agents have traditionally been advised to eat roughly the same amount of food (particularly carbohydrate) at roughly the same time each day, so that treatment can be balanced against food intake and exercise. Knowledgeable and motivated patients with type 1 diabetes, who have feedback from regular blood glucose monitoring, can vary the amount of carbohydrate consumed, or mealtimes, by learning to adjust their exercise pattern and treatment. This is the basis of the Dose Adjustment for Normal Eating (DAFNE) regimen.

**Exercise**

No treatment for diabetes is complete without exercise. Any increase in activity levels is to be encouraged but participation in more formal exercise programmes is best. Where facilities for this exist, exercise should be prescribed for everyone with diabetes. Several trials have shown that regular exercise reduces the risk of progression to type 2 diabetes by 30–60%, and the lowest long-term morbidity and mortality rates are seen in those with established disease who have the highest levels of cardiorespiratory fitness. Both aerobic and resistance training improve insulin sensitivity and metabolic control in type 1 and type 2 diabetes, although reported effects on metabolic control are inconsistent. Patients on insulin or sulphonylureas should be warned that there is an increased risk of hypoglycaemia for up to 6–12 hours following heavy exertion.

**Tablet treatment for type 2 diabetes**

Diet and lifestyle changes are the key to successful treatment of type 2 diabetes, and no amount of medication will succeed where these have failed. Controlling diabetes is not just a matter of swallowing tablets, and these should never, in general, be prescribed until lifestyle changes have been implemented. Tablets will, however, be needed if satisfactory metabolic control (see pp. 1259–1260) is not established within 4–6 weeks. A consensus treatment pathway is shown in *Figure 27.9* (see p. 1255).

**Biguanide (metformin)**

Metformin is the only biguanide currently in use and remains the best validated primary treatment for type 2 diabetes. It activates the enzyme adenosine monophosphate (AMP) kinase, which is involved in regulation of cellular energy metabolism, but its precise mechanism of action remains unclear. Its effect is to reduce the rate of gluconeogenesis, and hence hepatic glucose output, and to increase insulin sensitivity. It does not affect insulin secretion, does not induce hypoglycaemia and does not predispose to weight gain. It is thus particularly helpful in the overweight, although normal-weight individuals also benefit, and may be given in combination with sulphonylureas, thiazolidinediones, dipeptidyl peptidase-4 (DPP4) inhibitors or insulin. Metformin was as effective as sulphonylurea or insulin in glucose control and reduction of microvascular risk in the UK Prospective Diabetic Study (UKPDS), but proved unexpectedly beneficial in reducing cardiovascular risk, an effect that could not be fully
explained by its glucose-lowering actions. This effect has recently been questioned. **Unwanted effects** include anorexia, epigastric discomfort and diarrhoea, and these prohibit its use in 5–10% of patients. Diarrhoea should never be investigated in a diabetic patient without testing the effect of stopping metformin or changing to a slow-release preparation. Lactic acidosis has occurred in patients with severe hepatic or renal disease, and metformin is contraindicated when these are present. A Cochrane review showed little risk of lactic acidosis with standard clinical use, but most clinicians withdraw the drug when serum creatinine exceeds 150 µmol/L.

Metformin must be stopped prior to intravascular administration of iodinated contrast agent because of the risk of renal failure and subsequent lactic acidosis. Restart no earlier than 48 h after test of renal function has shown no deterioration.

**Sulphonylureas**

Sulphonylureas (*Box 27.8*) act on the β cell to promote insulin secretion in response to glucose and other secretagogues. They are ineffective in patients without a functional β-cell mass, and are usually avoided in pregnancy. Their action is to bind to the sulphonylurea receptor on the cell membrane, which closes ATP-sensitive potassium channels and blocks potassium efflux. The resulting depolarization promotes influx of calcium, a signal for insulin release (see *Fig. 27.2*). Sulphonylureas are cheap and more effective than many other oral agents in achieving short-term (1–3 years) glucose control but their effect wears off as the β-cell mass declines. Some studies have associated use of sulphonylureas with the **unwanted effects** of increased cardiovascular morbidity and mortality, but the evidence is inconsistent. They promote weight gain and are best avoided in the overweight. They can also cause hypoglycaemia and, although the episodes are generally mild, fatal hypoglycaemia may occur, especially in the elderly. Severe cases should always be admitted to hospital, monitored carefully, and treated with a continuous glucose infusion since some sulphonylureas have long half-lives. They should be used with care in patients with liver disease, and patients with renal impairment should use sulphonylureas primarily excreted by the liver. Tolbutamide is the safest drug in the very elderly because of its short duration of action.

**Box 27.8**

*Properties of the most commonly used sulphonylureas*
### Meglitinides

Meglitinides, e.g. repaglinide and nateglinide, are insulin secretagogues. Meglitinides are the non-sulphonylurea moiety of glibenclamide. As with the sulphonylureas, they act via closure of the K\(^+\)-ATP channel in the β cells (see Fig. 27.2). They are short-acting agents that promote insulin secretion in response to meals. Their effects are similar to those of the short-acting sulphonylurea tolbutamide but they are much more costly.

### Thiazolidinediones

The thiazolidinediones (more conveniently known as the ‘glitazones’) reduce insulin resistance by interaction with peroxisome proliferator-activated receptor-gamma (PPAR-γ), a nuclear receptor that regulates large numbers of genes, including those involved in lipid metabolism and insulin action. The paradox that glucose metabolism should respond to a drug that binds to nuclear receptors mainly found in fat cells is still not fully understood. One suggestion is that these drugs act indirectly via the glucose–fatty acid cycle, lowering free fatty acid levels and thus promoting glucose consumption by muscle. They reduce hepatic glucose production, an effect that is synergistic with that of metformin, and also enhance peripheral glucose uptake. Like metformin, the glitazones potentiate the effect of endogenous or injected insulin. The glitazones have yet to demonstrate unique advantages in the treatment of diabetes, and their place in routine diabetes care remains uncertain. Troglitazone and rosiglitazone have been withdrawn because of safety concerns (liver failure and increased cardiovascular risk, respectively), and pioglitazone is the only remaining agent in this class. **Unwanted effects** of pioglitazone include weight gain of 5–6 kg, together with fluid retention, heart failure and a modestly increased risk of bladder cancer. Mild anaemia and osteoporosis resulting in peripheral bone fractures have also been reported.

Dipeptidyl peptidase-4 inhibitors

These enhance the incretin effect (Box 27.9). The enzyme dipeptidyl peptidase-4 (DPP4) rapidly inactivates glucagon-like peptide-1 (GLP-1) as this is released into the circulation. Dipeptidyl peptidase-4 inhibitors increase insulin secretion and lower glucagon secretions, and inhibition of this enzyme thus potentiates the effect of endogenous GLP-1 secretion. Five agents are currently available (alogliptin, linagliptin, saxagliptin, sitagliptin and vildagliptin). They have a moderate effect in lowering blood glucose and are weight-neutral. They are most effective in the early stages of type 2 diabetes, when insulin secretion is relatively preserved, and are currently recommended for second-line use in combination with metformin or a sulphonylurea. Unwanted effects are uncommon: the main side-effect is nausea, and there have been occasional reports of acute pancreatitis. Their place in the management of type 2 diabetes has yet to be fully established and cost remains a constraint. Although the short-term safety record is good, DPP4 is widely distributed in the body, and the long-term consequences of inhibition of this enzyme in other tissues are unknown.

Box 27.9

The incretin effect

The insulin response to oral glucose is greater than the response to intravenous glucose.

Cause

- Two intestinal peptide hormones, glucose-dependent insulino tropic peptide (GIP) and glucagon-like peptide-1 (GLP-1), have a potentiating effect on pancreatic secretion of insulin
- GIP causes 30%, and GLP-1 70%, of the incretin effect
- Both hormones have very short half-lives in the circulation, being degraded predominantly by the enzyme dipeptidyl peptidase-4 (DPP4)
- GIP is secreted from the K cells in the duodenum and GLP-1 from the L cells of the ileum in response to food

Magnitude

- The incretin effect is diminished in type 2 diabetes

Sodium/glucose transporter 2 inhibitors (inhibition of renal glucose transfer)

The sodium/glucose transporter 2 (SGLT2) is a sodium-dependent glucose transport protein located in the proximal renal tubules, whose function is to reabsorb glucose from the renal filtrate and restore it to the circulation. Its activity thus determines the renal threshold for glucose, which normally averages around 10 mmol/L. Specific inhibitors for this transporter have the effect of lowering this threshold, and consequently of increasing excretion of glucose in the urine. This has the effect of removing both glucose and calories from the circulation, thus
lowering blood glucose and facilitating weight loss. Small reductions in systolic blood pressure have also been reported. Canagliflozin, dapagliflozin and empagliflozin are available. **Unwanted effects** include an increase in genital candidiasis and a small increase in urinary tract infections. This approach to therapy has the potential advantage of lowering glucose by a mechanism not mediated by insulin. One recent study showed a decrease in cardiovascular mortality when empagliflozin was added to standard care.

**Injection therapies for type 2 diabetes**

**GLP-1 agonists**

Exenatide, liraglutide and lixisenatide are injectable, long-acting analogues of glucagon-like peptide-1 (GLP-1), a gut hormone involved in the incretin effect (Box 27.9). They increase insulin secretion, inhibit glucagon secretion, delay gastric emptying and have central effects on appetite, thus blunting the postprandial rise in plasma glucose and promoting weight loss. Their main clinical disadvantage is the need for subcutaneous injection, and their major advantage is improving glucose control whilst inducing useful weight reduction. They work well in 70% but have limited benefit in 30% of those treated. **Unwanted effects** include nausea, acute pancreatitis and acute kidney injury. At present, they are used as an alternative to insulin, particularly in the overweight. A once-weekly version of exenatide has been developed.

GLP-1 promotes β-cell replication in immature rodents, but there is no evidence to suggest that it can do so in adult humans. GLP-1 receptors are also present in the exocrine pancreas and have potential growth-promoting effects, but the long-term clinical implications of this observation remain unclear.

**Other therapies**

- **Intestinal enzyme inhibitors** include acarbose, a sham sugar that competitively inhibits α-glucosidase enzymes situated in the brush border of the intestine, reducing absorption of dietary carbohydrate. Undigested starch may then enter the large intestine, where it will be broken down by fermentation. Abdominal discomfort, flatulence and diarrhoea can result, and dosage needs careful adjustment to avoid these side-effects.

- **Orlistat** is a lipase inhibitor that reduces the absorption of fat from the diet. It benefits diabetes indirectly by promoting weight loss in patients under careful dietary supervision on a low-fat diet. This is necessary to avoid unpleasant steatorrhoea.

- **Coleselam**, a bile acid-binding resin that lowers cholesterol, can reduce blood glucose concentrations by reducing release of gastrointestinal peptides.

- **Gastric banding and gastric bypass surgery** (see pp. 210–211) have been used in those with marked obesity unresponsive to 6 months' intensive attempts at dieting and graded exercise. The National Institute for Health and Care Excellence (NICE) recommends consideration of
surgery in those with a body mass index (BMI) of >40, or in those with a BMI of >35 and co-morbidities such as diabetes or hypertension likely to be alleviated by weight loss. In the USA, the Food and Drug Administration (FDA)-recommended BMI thresholds are lower. The risks of surgery are not insignificant, and long-term specialist care and follow-up are needed, including psychological support and nutritional supplements for those with bowel resection, but these concerns should be balanced against the risk of patients staying as they are. Gastric banding is safer than gastric bypass (which involves permanent loss of gastric and duodenal tissue) but is also somewhat less effective. Evidence from randomized controlled clinical trials (RCTs) shows that about one-third of patients become non-diabetic after gastric bypass, but the procedure has life-long implications and diabetes may recur.

**Insulin treatment**

Insulin is found in every vertebrate and the key parts of the molecule show few species differences. Small differences in the amino acid sequence may alter the antigenicity of the molecule. The glucose and insulin profiles in normal subjects are shown in Figure 27.8.

![Figure 27.8](image)

**Figure 27.8** Glucose and insulin profiles in normal subjects.

**Short-acting insulins**

Insulins were historically derived from beef or pig pancreas but these have now been almost entirely replaced by biosynthetic human insulin. This is produced by adding a DNA sequence coding for insulin or proinsulin into cultured yeast or bacterial cells. Short-acting insulins are used for pre-meal injection in multiple-dose regimens, for continuous intravenous infusion in labour or during medical emergencies, and for use in patients using insulin pumps. Human insulin is absorbed slowly, reaching a peak 60–90 minutes after subcutaneous injection, and its
action tends to persist after meals, predisposing to hypoglycaemia. Absorption is delayed because soluble insulin is in the form of stable hexamers (six insulin molecules around a zinc core) and needs to dissociate to monomers or dimers before it can enter the circulation. **Short-acting insulin analogues** have been engineered to dissociate more rapidly following injection without altering the biological effect. **Insulin analogues (Fig. 27.9)** such as the **rapid-acting insulins (insulin lispro, insulin aspart and insulin glulisine)** enter the circulation more rapidly than human soluble insulin, and also disappear more rapidly. Although widely used, the short-acting analogues have little effect on overall glucose control in most patients, mainly because improved postprandial glucose is balanced by higher levels before the next meal. A Cochrane review has concluded that there is little evidence of their benefit in type 2 diabetes.

**Intermediate and longer-acting insulins**

The action of human insulin can be prolonged by the addition of zinc or protamine derived from fish sperm. The most widely used form is NPH (isophane insulin), which has the advantage that it can be premixed with soluble insulin to form stable mixtures (biphasic insulins); the combination of 30% soluble with 70% NPH is most widely used. Long-acting analogues have their structure modified to delay absorption or to prolong their duration of action. **Insulin glargine** is soluble in the vial as a slightly acidic (pH 4) solution but precipitates at subcutaneous pH, thus prolonging its duration of action. **Insulin detemir** has a fatty acid ‘tail’ that allows it to bind to serum albumin, and its slow dissociation from the bound state prolongs its duration of action. **Insulin degludec** is a newer, long-term insulin that has proved non-inferior to insulin glargine, with a small reduction in nocturnal hypoglycaemia.

---

**FIGURE 27.9** Amino acid structure of human insulin. Modification of human insulin produces rapid-acting insulins, of which two examples (lispro and aspart) are shown, and long-acting insulins (glargine and detemir). Lispro is created by reversing the order of the amino acids proline and lysine in positions 28 and 29 of the B chain. Aspart is a similar analogue created by replacing proline at position 28 of the B chain with an aspartic acid residue. Insulin glargine is created by replacing asparagine in position 21 of the A chain with a glycine residue and adding two arginines to the end of the B chain. Detemir discards threonine in position 30 of the B chain and adds a fatty acyl chain to lysine in position B29.
Although popular and widely used, these insulins are much more expensive than, and have little demonstrated advantage over, human NPH, especially in the management of type 2 diabetes, although they are useful in those on intensified therapy or with troublesome hypoglycaemia. NICE advises that insulin analogues should be reserved for those who fail to respond well to human NPH insulin.

**Inhaled insulin**

The first inhaled insulin was withdrawn from the market in 2007 on the grounds of limited clinical demand, although lung cancer was also observed. A new formulation (Afrezza®) received FDA approval in July 2014.

**Practical management of diabetes**

All patients with diabetes require advice about diet and lifestyle. Lifestyle changes – that is, controlling weight, stopping smoking and taking regular exercise – can prevent or delay the onset of type 2 diabetes in people with glucose intolerance. Good glycaemic control is unlikely to be achieved with insulin or oral therapy when diet is neglected, especially when the patient is also overweight. Regular exercise helps to control weight and reduces cardiovascular risk. Blood pressure control is vital using an angiotensin-converting enzyme (ACE) inhibitor or angiotensin II receptor antagonist (see pp. 985–987). Most patients will also benefit from a statin and low-dose aspirin (see p. 1265).

**Type 2 diabetes**

The great majority of patients presenting over the age of 40 will have type 2 diabetes but clinicians should be alert for the occasional type 1 patient presenting late. An approach to their management is illustrated in *Figure 27.10*. Goals of treatment are described on page 1260. Type 2 diabetes is characterized by progressive β-cell failure, and glucose control deteriorates over time, requiring a progressive and pre-emptive escalation of diabetes therapy. Regular review is essential for this to be achieved. Most patients on tablets will eventually require insulin and it is helpful to explain this from the outset. The most widespread error in management at this stage is procrastination; the patient whose control is inadequate on oral therapy should start insulin without undue delay. Targets for glucose control are discussed later (see p. 1260).
FIGURE 27.10 A treatment pathway for type 2 diabetes mellitus. Discussion of lifestyle changes and compliance should be undertaken at every stage. All patients require blood pressure control, statin therapy and low-dose aspirin. GLP-1 agonists and sodium glucose co-transporter 2 inhibitors are also used in many countries. DPP4, dipeptidyl peptidase-4.

NICE recommends NPH as the initial insulin to use in type 2 diabetes, and metformin is a useful adjunct in those able to tolerate it. NPH insulin at night, together with metformin during the day, is initially as effective as multidose insulin regimens in controlling glucose levels and is less likely to promote weight gain. Addition of a morning dose of insulin may become necessary to control postprandial hyperglycaemia. Twice-daily injections of pre-mixed soluble and NPH (biphasic isophane) insulin are widely used and effective (Fig. 27.11, top panel). More aggressive treatment, with multiple injections or continuous infusion pumps, is increasingly used in younger patients with type 2 diabetes.
Type 1 diabetes

Insulin is always indicated in a patient who has been in ketoacidosis, and is usually required in lean patients who present under the age of 40 years.

Principles of insulin treatment

Injections

The needles used to inject insulin are very fine and sharp. Even though most injections are virtually painless, patients are understandably apprehensive and treatment begins with a lesson in injection technique. Insulin is usually administered by a pen injection device but can be drawn up from a vial into special plastic insulin syringes marked in units (100 U in 1 mL). Injections are given into the fat below the skin on the abdomen, thighs or upper arm, and the needle is usually inserted to its full length. Slim adults and children usually use a 31-gauge 6-mm needle and fatter adults a 30-gauge 8-mm needle. Both reusable and disposable pen
devices are available, together with a range of devices to aid injection. The injection site should be changed regularly to prevent areas of lipohypertrophy (fatty lumps). The rate of insulin absorption depends on local subcutaneous blood flow and is accelerated by exercise, local massage or a warm environment. Absorption is more rapid from the abdomen than from the arm, and is slowest from the thigh. All these factors can influence the shape of the insulin profile.

**Insulin administration**

In healthy individuals, a sharp increase in insulin occurs after meals; this is superimposed on a constant background of secretion (see Fig. 27.8). Insulin therapy attempts to reproduce this pattern but ideal control is difficult to achieve for four reasons:

- In normal subjects, insulin is secreted directly into the portal circulation and reaches the liver in high concentration; about 50% of the insulin produced by the pancreas is cleared on first passage through the liver. By contrast, insulin injected subcutaneously passes into the systemic circulation before reaching the liver. Insulin-treated patients therefore have lower portal levels of insulin and higher systemic levels relative to the physiological situation.

- Subcutaneous soluble insulin takes 60–90 min to achieve peak plasma levels, so it is slower to reach its peak, and slower to leave the circulation.

- The absorption of subcutaneous insulin into the circulation is variable.

- Basal insulin levels are constant in healthy people but injected insulin invariably peaks and declines, with resulting swings in metabolic control in those with diabetes.

A multiple-injection regimen with short-acting insulin and a longer-acting insulin at night is appropriate for most younger patients (Fig. 27.11, middle panel). The advantages of multiple-injection regimens are that the insulin and the food go together, so that meal times and sizes can vary without greatly disturbing metabolic control. The flexibility of multiple-injection regimens is of great value to patients who have busy jobs, work shifts and travel regularly. Some recovery of endogenous insulin secretion may occur over the first few months (the ‘honeymoon period’) in type 1 patients and the insulin dose may need to be reduced or even stopped for a period. Requirements rise thereafter. Strict glucose control from diagnosis in type 1 diabetes prolongs β-cell function, resulting in better glucose levels and less hypoglycaemia. Target blood glucose values should normally be 4–7 mmol/L before meals and 4–10 mmol/L after meals, assuming that this can be achieved without troublesome hypoglycaemia.

All patients need careful training for a life with insulin. This is best achieved outside hospital, provided that adequate facilities exist for outpatient diabetes education. A scheme for adjusting insulin regimens is given in Box 27.10. DAFNE is described on page 1252.

When to use insulin analogues

Hypoglycaemia between meals and particularly at night is the limiting factor for many patients on multiple-injection regimens. The more expensive rapid-acting insulin analogues (Fig. 27.11, bottom panel) are a useful substitute for soluble insulin in some patients, and reduce the frequency of nocturnal hypoglycaemia due to reduced carry-over effect from the daytime. They are often used on grounds of convenience, since patients can inject shortly before meals, but overall control is unchanged if standard insulins are injected at the same time. High or erratic fasting plasma glucose can prove a problem for patients on conventional multiple-injection regimens because the bedtime intermediate-acting insulin falls and the absorption is variable. The long-acting insulin analogues, insulin glargine and insulin detemir, may help to overcome these problems and reduce the risk of nocturnal hypoglycaemia.

Infusion devices

Continuous subcutaneous insulin infusion (CSII) is delivered by a small pump strapped around the waist that infuses a constant trickle of insulin via a needle in the subcutaneous tissues. Mealtime doses are delivered when the user instructs the pump to deliver a bolus of insulin at the start of a meal.

This approach is particularly useful in the overnight period, since the basal overnight infusion rate can be programmed to fit each patient's needs. Disadvantages include the nuisance of being attached to a gadget, skin infections, the risk of ketoacidosis if the flow of insulin is broken (since these patients have no protective reservoir of injected depot insulin), and cost. Infusion pumps should only be used by specialized centres able to offer a round-the-clock service to their patients. This form of treatment has revolutionized the lives of some people with type 1 diabetes.

Complications of insulin therapy

Injection site

Shallow injections result in intradermal insulin delivery and painful, reddened lesions or even scarring. Injection site abscesses occur but are extremely rare. Fatty lumps, known as
lipohypertrophy, may occur as the result of overuse of a single injection site with any type of insulin. Local allergic responses sometimes occur early in therapy but usually resolve spontaneously. Generalized allergic responses are exceptionally rare.

**Insulin resistance**

The most common cause of mild insulin resistance is obesity. Occasional unstable patients require massive insulin doses, sometimes with a fluctuating requirement. Some patients benefit from use of U500-strength insulin, which allows them to inject the same dose of insulin in one-fifth of the usual volume. Rare syndromes of insulin resistance may be present but most cases are unexplained. Insulin resistance associated with antibodies directed against the insulin receptor has been reported in patients with acanthosis nigricans (see Box 27.3).

**Weight gain**

Many patients show weight gain on insulin treatment, especially if the insulin dose is increased inappropriately, but this can, to some extent, be overcome by an emphasis on the need for diet and exercise, with the addition of metformin. Patients who are in poor control when insulin is started are more likely to gain weight.

**Hypoglycaemia during insulin treatment**

This is the most common complication of insulin therapy and limits what can be achieved with insulin treatment. It is a major cause of anxiety for patients and relatives. It results from an imbalance between injected insulin and a patient's normal diet, activity and basal insulin requirement. The times of greatest risk are before meals, during the night and during exercise. Irregular eating habits, unusual exertion and alcohol excess may precipitate episodes; other cases appear to be due simply to variation in insulin absorption.

**Symptoms**

Symptoms develop when the blood glucose level falls below 3 mmol/L and typically develop over a few minutes, with most patients experiencing ‘adrenergic’ features of sweating, tremor and a pounding heartbeat. Virtually all patients with type 1 diabetes experience intermittent hypoglycaemia and 1 in 3 will go into a coma at some stage in their lives. A small minority suffer attacks that are so frequent and severe as to be virtually disabling.

**Physical signs**

These include pallor and a cold sweat. Many patients with longstanding diabetes report loss of these warning symptoms (hypoglycaemic unawareness) and are at a greater risk of central nervous dysfunction (neuroglycopenia), resulting in altered behaviour or conscious level. Such patients appear pale, drowsy or detached, signs that their relatives quickly learn to recognize. Behaviour is clumsy or inappropriate, and some individuals become irritable or even aggressive. Others slip rapidly into a hypoglycaemic coma. Occasionally, patients develop convulsions during a hypoglycaemic coma, especially at night. This must not be confused with
idiopathic epilepsy. Another presentation is with a hemiparesis that resolves when glucose is administered.

People with diabetes have an impaired ability to counter-regulate glucose levels after hypoglycaemia. The glucagon response is invariably deficient, even though the α cells are preserved and respond normally to other stimuli. The adrenaline (epinephrine) response may also fail in patients with a long duration of diabetes, and this is associated with hypoglycaemia unawareness. Recurrent hypoglycaemia may itself induce a state of hypoglycaemia unawareness, and the ability to recognize the condition may sometimes be restored by relaxing control for a few weeks.

**Nocturnal hypoglycaemia**

Basal insulin requirements fall during the night but increase again from about 4 a.m. onwards, at a time when levels of injected insulin are falling. As a result, many patients wake with high blood glucose levels, but find that injecting more insulin at night increases the risk of hypoglycaemia in the early hours of the morning. The problem may be helped by the following measures:

- checking that a bedtime snack is taken regularly
- advising patients taking twice-daily mixed insulin that they can separate their evening dose and take the intermediate insulin at bedtime rather than before supper
- reducing the dose of soluble insulin before supper, since the effects of this persist well into the night
- changing to a rapid-acting insulin analogue, with a long-lasting insulin analogue at night
- changing to an insulin infusion pump that can be programmed to deliver lower doses of insulin at the time of night when a patient has been experiencing hypoglycaemia.

**Mild hypoglycaemia**

Any form of rapidly absorbed carbohydrate will relieve the early symptoms, and glucose or sweets should always be carried. Drowsy individuals will be able to take carbohydrate in liquid form (e.g. Lucozade®). All patients and their close relatives need training about the risks of hypoglycaemia. More carbohydrate than necessary should not be taken during the recovery period, since this causes a rebound to hyperglycaemia. Alcohol excess increases the risk of hypoglycaemia and this requires careful explanation, together with a warning about the need to guard against hypoglycaemia while driving.

**Severe hypoglycaemia**

The diagnosis of severe hypoglycaemia resulting in confusion or coma is simple and can usually be made on clinical grounds, backed by a bedside blood test. If real doubt exists, blood should be taken for glucose estimation before treatment is given. Patients should carry a card or wear a bracelet or necklace to say that they have diabetes, and these should be looked for in unconscious patients.
Unconscious patients should be given either intramuscular glucagon (1 mg) or intravenous glucose (25–50 mL of 50% glucose solution) followed by a flush of 0.9% saline to preserve the vein (since 50% glucose scleroses veins). Glucagon acts by mobilizing hepatic glycogen, and works almost as rapidly as glucose. It is simple to administer and can be given at home by relatives. It does not work when liver glycogen levels are low, as after a prolonged fast. Oral glucose is given to replenish glycogen reserves once the patient revives.

**Whole-pancreas and pancreatic islet transplantation**

**Whole-pancreas transplantation** has been performed for some 30 years, usually in diabetic patients who require immunosuppression for a kidney transplant. Surgical advances have greatly improved the outcome of this procedure. In experienced hands, graft function lasts longer with considerable improvement in quality of life. Patient survival is better in those who receive simultaneous pancreas and kidney grafts, mainly because of the delay involved in waiting for a pancreas to become available following renal transplantation. There is some evidence of protection against or reversal of some complications of diabetes, but this comes at the cost of long-term immunosuppression.

**Islet transplantation** is performed by harvesting pancreatic islets from cadavers (two or three pancreata are usually needed); these are then injected into the portal vein and seed themselves into the liver. This form of treatment had limited success for many years but improved treatment protocols have now achieved more promising results. The main indication for islet transplantation is disabling hypoglycaemia, and the main disadvantage is the need for powerful immunosuppressive therapy, with its associated costs and complications.

**Measuring the metabolic control of diabetes**

**Urine tests**

Urine dipstick tests, although less informative than blood tests, offer some feedback on metabolic control. Patients with consistently negative tests and no symptoms of hypoglycaemia are generally well controlled. Nevertheless, the correlation between urine tests and simultaneous blood glucose is poor for three reasons:

- Changes in urine glucose lag behind changes in blood glucose.
- The mean renal threshold is around 10 mmol/L but the range is wide (7–13 mmol/L). The threshold also rises with age.
- Urine tests can give no guidance concerning blood glucose levels below the renal threshold.

**Home blood glucose testing**

Blood tests offer invaluable feedback to everyone affected by diabetes but their routine use varies according to need. Patients soon learn to provide their own profiles using finger-prick blood samples and reagent strips, which can be read with the aid of a meter. Blood is taken
from the side of a finger-tip (not from the top, which is densely innervated) using a special lancet that is usually fitted to a spring-loaded device; a range of these is available. The fasting blood glucose concentration is reproducible in diet- or tablet-treated type 2 diabetes and is therefore a useful guide to therapy, supplemented by occasional tests after meals. Those on insulin treatment require more frequent testing in order to adjust their therapy and avoid hypoglycaemia. Regular profiles (e.g. 4 daily samples on at least 2 days each week) are needed in those on intensified therapy, and should be recorded electronically or in a record book. Patients on insulin are encouraged to adjust their insulin dose as appropriate (Box 27.10) and should be able to obtain advice over the telephone when needed. Blood glucose monitoring does not, in itself, result in better control but is essential to those wishing to achieve it.

**Glycosylated haemoglobin (HbA\(_1\) or HbA\(_1c\)) and fructosamine**

**Glycosylation of haemoglobin** occurs as a two-step reaction, resulting in the formation of a covalent bond between the glucose molecule and the terminal valine of the β chain of the haemoglobin molecule. The rate at which this reaction occurs is related to the prevailing glucose concentration. Glycosylated haemoglobin is expressed as a percentage of the normal haemoglobin (standardized range 4–6.1%; 20–44 mmol/mol). This test provides an index of the average blood glucose concentration over the life of the haemoglobin molecule (approximately 6 weeks). The figure will be misleading if the lifespan of the red cell is reduced or if an abnormal haemoglobin or thalassaemia is present. There is considerable inter-individual variation in HbA\(_1c\) levels, even in health. Although the glycosylated haemoglobin test provides a rapid assessment of glycaemic control in a given patient, blood glucose testing is needed before the clinician can know what to do about it.

**Glycosylated plasma proteins** (‘fructosamine’) may also be measured as an index of control. Glycosylated albumin is the major component, and fructosamine measurement relates to glycaemic control over the preceding 2–3 weeks. It is useful in patients with anaemia or haemoglobinopathy, and in pregnancy (when haemoglobin turnover is changeable) and other situations where a swift means of assessing progress is needed for changes of treatment.

**Does good glucose control matter?**

Diabetes affects not only carbohydrate metabolism, but also the metabolism of lipids and proteins. The microvascular complications of diabetes are, however, glucose-specific (i.e. they occur only in the presence of hyperglycaemia), whereas hyperglycaemia is merely one of a number of risk factors for arterial disease, which is not specific to diabetes. Furthermore, microvascular complications generally occur above a threshold level of glycaemia, which forms the basis for our definition of diabetes, whereas the association of glucose with large-vessel disease extends well into the glucose range of the general population, with no clear cut-off for risk. In light of these observations, it is not surprising that the impact of improved glucose control on small-vessel complications such as retinopathy and nephropathy has been compellingly demonstrated, whereas the benefit of improved glucose control has not been
unequivocally demonstrated in large-vessel disease. This distinction has been demonstrated in a series of major outcome trials.

The Diabetes Control and Complications Trial (DCCT) in the USA compared standard and intensive insulin therapy in a large prospective controlled trial of young patients with type 1 diabetes. Two groups were recruited: those with no evidence of retinopathy or microalbuminuria (primary prevention group), and those with evidence of retinopathy or microalbuminuria (secondary prevention group). Despite intensive therapy, mean blood glucose levels were still 40% above the non-diabetic range, but even at this level of control, the risk of primary progression to retinopathy was reduced by 60%, nephropathy by 30% and neuropathy by 20% over the 7 years of the study. The effect on progression of established microvascular disease was less evident. Coronary disease is uncommon in this age group but long-term follow-up after the end of the study indicated a benefit for tight control.

Near-normoglycaemia should therefore be the goal for all young patients with type 1 diabetes. The unwanted effects of this policy include weight gain and a two- to threefold increase in the risk of severe hypoglycaemia.

The UK Prospective Diabetes Study (UKPDS) compared standard and intensive treatment in a large prospective controlled trial in recently diagnosed type 2 diabetes patients. Intensive treatment was associated with a 25% overall reduction in microvascular disease end-points, a 33% reduction in albuminuria and a 30% reduction in the need for laser treatment for retinopathy in the more intensively treated patients. These benefits persisted for many years after conclusion of the trial (the ‘legacy effect’). This study also showed blood pressure control to be equally necessary in the prevention of retinopathy, but there is no legacy effect and good blood pressure control needs to be maintained. There appeared to be little difference in outcome between the agents used to achieve good metabolic control (metformin, sulphonylurea or insulin). Cardiovascular risk was not reduced by intensive therapy during the trial but did improve in post-trial follow-up, markedly so in those on metformin.

Three large outcome studies have confirmed the benefits of good glucose control on microvascular complications in type 2 diabetes, although these benefits diminish with increasing age. Once again, no short-term cardiovascular benefit or reduction in overall mortality was observed.

**Glucose targets for diabetes management**

It follows that glucose control is a high priority for the prevention of microvascular complications, although blood pressure control is also essential to prevent progression of established disease. Glucose control appears of less value in prevention of arterial disease, and the current trend is to aim for more relaxed glucose control in older patients (e.g. HbA\textsubscript{1c} <8% (<64 mmol/mol)), while attention to blood pressure and lipids should take priority. In the ACCORD study, the use of intensive therapy to target a glycated haemoglobin level <6% in people with type 2 diabetes increased 5-year mortality. Such an intensive strategy thus cannot be recommended, particularly for high-risk patients with advanced complications of type 2 diabetes.
Ideally, all patients should therefore aim to run their glycosylated haemoglobin readings <7.0% (53 mmol/mol) in order to reduce the risk of long-term microvascular complications (Box 27.11). Hypoglycaemia, patterns of eating and lifestyle, weight problems, and difficulties accepting and coping with diabetes limit what can be achieved. Some will be able to reach these target values but most will not, particularly as their duration of diabetes increases. Realistic goals should be set for each patient, taking into account what is likely to be achievable, and this applies in particular to elderly patients and those with a limited prognosis.

Regular checks for patients with diabetes

**Box 27.12** is modified from the guidelines set out in *The European Patients' Charter*, published by the St Vincent Declaration Steering Committee of the WHO. The charter sets out goals for both the healthcare team and the patient.

### Box 27.12

**Regular checks for patients with diabetes**

**Checked each visit**

- Review self-monitoring results and HbA<sub>1c</sub> results
- Review balance between food, exercise and treatment
- Talk about targets and change where necessary
- Talk about any general or specific problems
- Review diabetes educational needs

**Checked at least annually**

- Carry out biochemical assessment of metabolic control (e.g. glycosylated Hb test)
• Measure body weight and body mass index
• Measure blood pressure
• Measure plasma lipids (except in extreme old age)
• Measure visual acuity
• Examine state of retina (ophthalmoscope or retinal photo)
• Test urine for proteinuria/microalbuminuria (albumin:creatinine ratio)
• Test blood for renal function (creatinine, estimated glomerular filtration rate)
• Check condition of feet, pulses and neurology
• Review cardiovascular risk factors
• Review self-monitoring and injection techniques
• Review eating habits

Psychosocial implications of diabetes

Patients starting tablet or insulin treatment should live as normal a life as possible but this is not always easy. Tact, empathy, encouragement and practical support are needed from all members of the clinical team. Diabetes, like any chronic disease, has psychological sequelae. Most patients will experience periods of not coping, of helplessness, of denial and of acceptance, often fluctuating over time. Other problems include the following:
• You cannot take a ‘holiday’ from diabetes – yet the human psyche is poorly developed to cope with unremitting adversity.
• Concessions or sympathy are often denied to the person with diabetes, since its presence is invisible.
• The treatment is complex and demanding, and the person with diabetes must make trade-offs between short-term and long-term wellbeing.
• Embarrassing loss of control over personal behaviour or consciousness can occur in insulin-treated patients when minor miscalculation leads to hypoglycaemia.
• Risk-taking behaviour is indulged in by all humans when emotion is in conflict with logical thought but its effects can be much greater for the person with diabetes (particularly the risks of unplanned pregnancy, alcohol and tobacco).
• Poor self-image is a very common problem.
• Eating disorders are more common in people with diabetes – 30–40% of young women will report disordered eating at some stage of their diabetes.
• Omission of tablets or insulin is common since non-adherence to treatment regimens is universal in all illness. Between 1 in 4 and 1 in 5 tablets prescribed for diabetes is not consumed within the designated treatment period. Insulin omission is not uncommon in young women, in whom the motivation to stay slim may overcome concerns about long-term complications.

Adolescence
Lapses into poor metabolic control, or dropping out of medical care for a time and re-emerging with complications, are very common in adolescence. Diabetic summer camps (e.g. those run by Diabetes UK) help prevent a feeling of isolation and not knowing anyone else with the same problem. Separate adolescent clinics allow:
• treatment without marginalization in a larger group of older people
• meeting peers with similar problems in the waiting room
• gradual separation from parents and assumption of personal responsibility for the illness
• age-appropriate literature to be made available.

Practical aspects
Patients need to inform the driving and vehicle licensing authority and their insurance companies after diagnosis. They would also be wise to inform their family, friends and employers, in case unexpected hypoglycaemia occurs. Insulin treatment can be undertaken by people in most walks of life. A few jobs are unsuitable; these include driving heavy goods or public service vehicles, working at heights, piloting aircraft, or working close to dangerous machinery in motion. Certain professions, such as the police and the armed forces, are barred to all diabetic patients. There are few other limitations, although a considerable amount of ill-informed prejudice exists. Doctors can sometimes help support patients in the face of
misinformed work practices.

**Diabetic ketoacidosis**

Diabetic ketoacidosis (DKA) is the hallmark of type 1 diabetes. It is usually seen in the following circumstances:

- previously undiagnosed diabetes
- interruption of insulin therapy
- the stress of intercurrent illness.

The majority of cases reaching hospital could have been prevented by earlier diagnosis, better communication between patient and doctor, and better patient education. The most common error of management is for patients to reduce or omit insulin because they feel unable to eat, owing to nausea or vomiting. This is a factor in at least 25% of all hospital admissions.  
*Insulin may need adjusting up or down but should never be stopped.*

**Pathogenesis**

Ketoacidosis is a state of uncontrolled catabolism associated with insulin deficiency. Insulin deficiency is a necessary precondition since only a modest elevation in insulin levels is sufficient to inhibit hepatic ketogenesis, and stable patients do not readily develop ketoacidosis when insulin is withdrawn. Other factors include counter-regulatory hormone excess and fluid depletion. The combination of insulin deficiency with excess of its hormonal antagonists leads to the parallel processes shown in *Figure 27.12*. In the absence of insulin, hepatic glucose production accelerates and peripheral uptake by tissues such as muscle is reduced. Rising glucose levels lead to an osmotic diuresis, loss of fluid and electrolytes, and dehydration. Plasma osmolality rises and renal perfusion falls. In parallel, rapid lipolysis occurs, leading to elevated circulating free fatty-acid levels. The free fatty acids are broken down to acetyl-coenzyme A (CoA) within the liver cells, and this, in turn, is converted to ketone bodies within the mitochondria (*Fig. 27.13*). Accumulation of ketone bodies produces a metabolic acidosis. Vomiting leads to further loss of fluid and electrolytes. The excess ketones are excreted in the urine but also appear in the breath, producing a distinctive smell similar to that of acetone. Respiratory compensation for the acidosis leads to hyperventilation,
graphically described as ‘air hunger’. Progressive dehydration impairs renal excretion of hydrogen ions and ketones, aggravating the acidosis. As the pH falls below 7.0 ([H+] >100 nmol/L), pH-dependent enzyme systems in many cells function less effectively. Untreated, severe ketoacidosis is invariably fatal.

**FIGURE 27.12** Dehydration occurs during ketoacidosis as a consequence of two parallel processes. Hyperglycaemia results in osmotic diuresis, and hyperketonaemia results in acidosis and vomiting. Renal hypoperfusion then occurs and a vicious circle is established as the kidney becomes less able to compensate for the acidosis.
During insulin deficiency, lipolysis accelerates and free fatty acids taken up by liver cells form the substrate for ketone formation (acetoacetate, acetone and β-hydroxybutyrate) within the mitochondrion. These ketones pass into the blood, producing acidosis. CoA, coenzyme A.

**Clinical features**

The features of ketoacidosis are those of uncontrolled diabetes with acidosis, and include prostration, hyperventilation (Kussmaul respiration), nausea, vomiting and, occasionally, abdominal pain. The latter is sometimes so severe that it can be confused with a surgical acute abdomen.

Some patients are mentally alert at presentation but confusion and stupor are present in more severe cases. Up to 5% present in coma. Evidence of marked dehydration is present and the eyeball is lax to pressure in severe cases. Hyperventilation is present but becomes less marked in very severe acidosis, owing to respiratory depression. The smell of ketones on the breath allows an instant diagnosis to be made by those able to detect the odour. The skin is dry and the body temperature is often subnormal, even in the presence of infection; in such cases, pyrexia may develop later.

**Diagnosis**

This is confirmed by demonstrating hyperglycaemia with ketonaemia or heavy ketonuria, and acidosis. No time should be lost and treatment is started as soon as the first blood sample has been taken. Hyperglycaemia is demonstrated by dipstick, while a venous blood sample is sent to the laboratory for confirmation. Ketonaemia is confirmed by centrifuging a blood sample and testing the plasma with a dipstick that measures ketones. Hand-held sensors measuring β-
hydroxybutyrate in 30 s are available. An arterial blood sample is taken for blood gas analysis.

The severity of DKA can be assessed as follows. One or more of these features suggests severe DKA.

**Clinical observations**

- Pulse >100 b.p.m. or <60 b.p.m.
- Systolic blood pressure <90 mmHg.
- Glasgow Coma Scale score of <12 (see Box 21.26) or abnormal ‘Alert, Voice, Pain, Unresponsive’ (AVPU) scale.
- O₂ saturation <92% on air (if normal respiratory function).

**Blood tests**

- Blood ketones >6 mmol/L.
- Bicarbonate <12 mmol/L.
- Venous/arterial pH <7.1 ([H⁺] >80 nmol/L).
- Hypokalaemia on admission <3.5 mmol/L.

**Management (and pathophysiology)**

The principles of management are as follows and as shown in **Box 27.14**; these measures should be carried out in a high-dependency area.

- **Replace the fluid losses** with 0.9% saline. Average loss of water is 5–7 L with a sodium loss of 500 mmol.

- **Replace the electrolyte losses**. Patients have a total body potassium deficit of 350 mmol, although initial plasma levels may not be low. Insulin therapy leads to uptake of potassium by the cells with a consequent fall in plasma K⁺ levels. Potassium is therefore given as soon as insulin is started.

- **Restore the acid–base balance**. A patient with healthy kidneys will rapidly compensate for the metabolic acidosis once the circulating volume is restored. Bicarbonate is seldom necessary and is used only if the pH is <7.0 ([H⁺] >100 nmol/L); it is best given as an isotonic (1.26%) solution.

- **Replace the deficient insulin**. Relatively modest doses of insulin lower blood glucose by suppressing hepatic glucose output rather than by stimulating peripheral uptake, and are therefore much less likely to produce hypoglycaemia. Insulin and glucose together both inhibit gluconeogenesis, and thus ketone production, and are needed to metabolize ketones into less harmful substances. Short-acting insulin is given as an intravenous infusion where facilities for adequate supervision exist or as hourly intramuscular injections. The subcutaneous route is avoided because subcutaneous blood flow is reduced in shocked patients.

- **Monitor blood glucose closely** (**Box 27.14**).
Seek the underlying cause. Physical examination may reveal a source of infection (e.g. a perianal abscess). Two common markers of infection are misleading: fever is unusual, even when infection is present; and polymorpholeucocytosis is present, even in the absence of infection. Relevant investigations include a chest X-ray, urine and blood cultures, and an electrocardiogram (to exclude myocardial infarction). The serum amylase may be elevated in the absence of pancreatitis. If infection is suspected, broad-spectrum antibiotics are started once the appropriate cultures have been taken.

Box 27.14

Guidelines for the diagnosis and management of diabetic ketoacidosis

Diagnosis

• Hyperglycaemia: measure blood glucose
• Ketonaemia: test plasma with Ketostix. Finger-prick sample for β-hydroxybutyrate
• Ketonuria: measure urine ketone levels where plasma ketone measurements are not available
• Acidosis: measure:
  – pH in arterial blood
  – Bicarbonate in venous blood.

Immediate measures

1. Assess
2. Send blood samples to laboratory
3. Set up intravenous infusion
   • Blood glucose:
     – Measure baseline and hourly initially
     – Aim for fall of 3–6 mmol/L (55–110 mg/dL) per hour
   • Urea and electrolytes – measure at baseline and hourly until 6 h, then at 12 h and 24 h:
     – Potassium: add when $K^+ < 3.5$ mmol/L. Give 20 mmol with each litre infusion; give 10 mmol/h when $K^+ = 3.5–5$ mmol
   • Full blood count
   • Blood gases: at 0, 2, 6 h
   • Creatinine: at 0, 6, 12, 24 h
   • Bicarbonate: at 0, 1, 2, 3, 6, 12, 24 h.

Phase 1

• Admit to an area where staffing and facilities allow more detailed clinical observation and more frequent medical and nursing assessment than may be found on a general ward
• **Insulin**: soluble insulin i.v. 0.1 U/kg/h by infusion, or 20 U i.m. stat. followed by 6 U i.m. hourly

• **Fluid and electrolyte replacement**: i.v. 0.9% sodium chloride with 20 mmol KCl/L
  – 1 L in 30 min, then
  – 1 L in 1 h
  – 1 L in 2 h
  – 1 L in 4 h
  – 1 L in 8 h

  • Adjust KCl concentration depending on results of regular blood K⁺ measurement

  **IF:**
  • Blood pressure <80 mmHg, give 500 mL 0.9% sodium chloride over 15 min; if no response, give plasma expander
  • pH <7.0 ([H⁺] >100 nmol/L) give 500 mL of sodium bicarbonate 1.26% plus 10 mmol KCl. Repeat if necessary to bring pH up to 7.0

**Phase 2**

• **Insulin and glucose**: when blood glucose falls to 10–12 mmol/L, change infusion fluid to 1 L 5% glucose plus 20 mmol KCl 6-hourly. Continue insulin with dose adjusted according to hourly blood glucose test results (e.g. i.v. 3 U/h glucose 15 mmol/L; 2 U/h when glucose 10 mmol/L).

**Phase 3**

• Once stable and able to eat and drink normally, transfer patient to 4-times-daily s.c. insulin regimen (based on previous 24 hours’ insulin consumption and trend in consumption)

**Other semi-urgent procedures**

• Blood and urine culture
• Cardiac enzymes
• Chest X-ray
• Electrocardiogram (monitor if electrolyte problems or severe diabetic ketoacidosis)
• Catheterization if no urine passed after 3 h of hydration

**Special measures**

• Broad-spectrum antibiotic if infection likely
• Nasogastric tube if drowsy
• Central venous pressure monitoring if shocked or if previous cardiac or renal impairment
• Give s.c. prophylactic low-molecular-weight heparin

**Subsequent management**

• Monitor glucose hourly for 8 hours
• Monitor electrolytes 2-hourly for 8 hours
• Adjust potassium replacement according to blood results

The regimen of fluid replacement set out above is a guide for patients with severe ketoacidosis. Excessive fluid can precipitate pulmonary and cerebral oedema; inadequate replacement may cause renal failure. Fluid replacement must therefore be tailored to the individual and monitored carefully throughout treatment.

Problems of management

• **Hypotension.** This may lead to renal shutdown. Sodium chloride 0.9% is the fluid of choice to increase circulating volume and thus blood pressure and renal perfusion. A central venous pressure line is useful in this situation. A bladder catheter is inserted if no urine is produced within 2 h but routine catheterization is not necessary.

• **Coma.** The usual principles apply (see pp. 825–829). It is essential to pass a nasogastric tube to prevent aspiration, since gastric stasis is common and carries the risk of aspiration pneumonia if a drowsy patient vomits.

• **Cerebral oedema.** This is a rare but serious complication and has mostly been reported in children or young adults. Excessive rehydration and use of hypertonic fluids such as 8.4% bicarbonate may sometimes be responsible. The mortality is high.

• **Hypothermia.** Severe hypothermia with a core temperature <33°C may occur and can be overlooked unless a rectal temperature is taken with a low-reading thermometer.

• **Late complications.** These include pneumonia and deep-vein thrombosis (DVT; prophylaxis is essential – see p. 580) and occur especially in the comatose or elderly patient.

• **Complications of therapy.** These include hypoglycaemia and hypokalaemia, due to loss of $K^+$ in the urine from osmotic diuresis. Over-enthusiastic fluid replacement may precipitate pulmonary oedema in the very young or the very old. Hyperchloraemic acidosis may develop in the course of treatment since patients have lost a large variety of negatively charged electrolytes, which are replaced with chloride. The kidneys usually correct this spontaneously within a few days.

Subsequent management

Intravenous glucose and insulin are continued until the patient feels able to eat and keep food down. The drip is then taken down and a similar amount of insulin is given as four injections of soluble insulin subcutaneously at mealtimes and a dose of intermediate-acting insulin at night.

Sliding-scale regimens are unnecessary and may even delay the establishment of stable blood glucose levels.

The mortality of DKA is around 5% and is increased in older patients. Its treatment is incomplete without a careful enquiry into the causes of the episode and advice as to how to avoid its recurrence.
Hyperosmolar hyperglycaemic state

This condition, in which severe hyperglycaemia develops without significant ketosis, is the characteristic metabolic emergency of uncontrolled type 2 diabetes. Patients present in middle or later life, often with previously undiagnosed diabetes. Common precipitating factors include consumption of glucose-rich fluids, concurrent medication such as thiazide diuretics or steroids, and intercurrent illness. The hyperosmolar hyperglycaemic state and ketoacidosis represent two ends of a spectrum rather than two distinct disorders (Box 27.15). The biochemical differences may partly be explained as follows:

- **Age.** The extreme dehydration characteristic of the hyperosmolar hyperglycaemic state may be related to age. Old people experience thirst less acutely and become dehydrated more readily. In addition, the mild renal impairment associated with age results in increased urinary losses of fluid and electrolytes.

- **The degree of insulin deficiency.** This is less severe in the hyperosmolar hyperglycaemic state. Endogenous insulin levels are sufficient to inhibit hepatic ketogenesis but insufficient to inhibit hepatic glucose production.

### Box 27.15

**Electrolyte changes in diabetic ketoacidosis and the hyperosmolar hyperglycaemic state**

</table>

The normal range of osmolality is 285–300 mOsm/kg. It can be measured directly, or can be calculated approximately from the formula: Osmolality = 2(Na⁺ + K⁺) + glucose + urea.

For instance, in the example of severe ketoacidosis given above:

Osmolality = 2(140 + 5) + 30 + 8 = 328 mOsm/kg

and in the example of the hyperosmolar hyperglycaemic state:

Osmolality = 2(155 + 5) + 50 + 15 = 385 mOsm/kg

The normal anion gap is <17. It is calculated as (Na⁺ + K⁺) – (Cl⁻ + HCO₃⁻). In the example of ketoacidosis, the anion gap is 40, and in the example of the hyperosmolar hyperglycaemic state, the anion gap is 25. Mild hyperchloraemic acidosis may develop in the course of therapy. This will be shown by a rising plasma chloride and persistence of a low bicarbonate, even though the anion gap has returned to normal.

⁺[H⁺] >100 nmol/L.
**Clinical features**

The characteristic clinical features on presentation are dehydration and stupor or coma. Impairment of consciousness is directly related to the degree of hyperosmolality. Evidence of underlying illness, such as pneumonia or pyelonephritis, may be present, and the hyperosmolar state may predispose to stroke, myocardial infarction or arterial insufficiency in the lower limbs.

**Investigations and management**

These are (with some exceptions) according to the guidelines for ketoacidosis. The plasma osmolality is usually extremely high. It can be measured directly or calculated as \(2(Na^+ + K^+) + \text{glucose} + \text{urea}\), all in mmol/L. Many patients are extremely sensitive to insulin and the glucose concentration may plummet. The resultant change in osmolality may cause cerebral damage. It is sometimes useful to infuse insulin at a rate of 3 U/h for the first 2–3 h, increasing to 6 U/h if glucose is falling too slowly. The standard fluid for replacement is 0.9% saline. Avoid 0.45% saline, since rapid dilution of the blood may cause more cerebral damage than a few hours of exposure to hypernatraemia. Prophylactic low-molecular-weight heparin should be given.

**Prognosis**

The reported mortality ranges as high as 20–30%, mainly because of the more advanced age of the patients and the frequency of intercurrent illness. Unlike ketoacidosis, the hyperosmolar hyperglycaemia state is not an absolute indication for subsequent insulin therapy, and survivors may do well on diet and oral agents.

**Lactic acidosis**

The risk of lactic acidosis in patients taking metformin is extremely low, provided that the therapeutic dose is not exceeded and the drug is withheld in patients with advanced hepatic or renal dysfunction.

Patients present in severe metabolic acidosis with a large anion gap (normally <17 mmol/L), usually without significant hyperglycaemia or ketosis. Treatment is by rehydration and infusion of isotonic 1.26% bicarbonate. The mortality is in excess of 50%.

**Further reading**

Complications of Diabetes

People with diabetes still have a reduced life expectancy, although the prognosis has improved considerably over recent decades. The major cause of death in treated patients is cardiovascular problems (60–70%) followed by renal failure (10%) and infections (6%). There is no doubt that the duration and degree of hyperglycaemia play a major role in the production of complications. Improved glucose control can reduce the rate of progression of both nephropathy and retinopathy, and the DCCT trial (see p. 1259) showed a 60% reduction in developing complications over 9 years when the HbA$_{1c}$ was kept at around 7% in type 1 diabetes.

Pathophysiology

The mechanisms leading to damage are ill defined. The following are consequences of hyperglycaemia and may play a role:

- **Non-enzymatic glycosylation** of a wide variety of proteins, such as haemoglobin, collagen, low-density lipoprotein (LDL) and tubulin in peripheral nerves. This leads to an accumulation of advanced glycosylated end-products, causing injury and inflammation via stimulation of pro-inflammatory factors, such as complement and cytokines.

- **Polyol pathway.** The metabolism of glucose by increased intracellular aldose reductase leads to accumulation of sorbitol and fructose. This causes changes in vascular permeability, cell proliferation and capillary structure via stimulation of protein kinase C and transforming growth factor beta (TGF-β).

- **Abnormal microvascular blood flow.** This impairs the supply of nutrients and oxygen. Microvascular occlusion is due to vasoconstrictors, such as endothelins and thrombogenesis, and leads to endothelial damage.

- **Other factors.** These include the formation of reactive oxygen species and stimulation of growth factors TGF-β and vascular endothelial growth factor (VEGF). These growth factors are released by ischaemic tissues and cause endothelial cells to proliferate.

- **Haemodynamic changes.** These take place, for example, in the kidney (see pp. 1269–1270).

  It has been proposed that all of the above mechanisms stem from a single hyperglycaemia-induced process of overproduction of superoxide by the mitochondrial electron chain. This paradigm offers an integrated explanation of how complications of diabetes develop.

Macrovascular complications

(See Box 27.16.) Diabetes is a risk factor for the development of atherosclerosis. This risk is related to that of the background population. For example, people with diabetes in Japan are less likely than European patients to develop atherosclerosis, but more likely to develop it than non-diabetic Japanese.
• Stroke is twice as likely.
• Myocardial infarction is 2–4 times as likely, and women with diabetes lose their
premenopausal protection from coronary artery disease.
• Amputation of a foot for gangrene is 50 times as likely.

### Box 27.16

**Diabetic risk factors for macrovascular complications**

- Duration
- Increasing age
- Systolic hypertension
- Hyperinsulinaemia due to insulin resistance associated with obesity and the metabolic
  syndrome
- Hyperlipidaemia, particularly hypertriglyceridaemia/low high-density lipoprotein (HDL)
- Proteinuria (including microalbuminuria)
- Other factors as for the general population

Several large trials have shown that intensive glucose-lowering treatment of diabetes has a
relatively minor effect on cardiovascular risk; it is vital to tackle all cardiovascular risk
factors together in diabetes, and not just to focus on glucose levels.

- **Hypertension.** The UKPDS demonstrated that aggressive treatment of hypertension produces
  a marked reduction in adverse cardiovascular outcomes, both microvascular and
  macrovascular. To achieve the target for blood pressure (see Box 27.11), the UKPDS found
  that one-third of patients needed three or more antihypertensive drugs in combination, and
  two-thirds of treated patients needed two or more.

- **Smoking:** This is the avoidable risk factor (see pp. 1074–1075). Efforts to help patients stop
  smoking should never be given up.

- **Lipid abnormalities.** Clinical trials suggest that there is no ‘safe’ cut-off for serum
  cholesterol. It seems best to aim for the lowest achievable level, and in practice this means
  that almost all people with type 2 diabetes will be treated with a statin (see p. 1284).

- **Low-dose aspirin** can reduce macrovascular risk but is associated with a morbidity and
  mortality from bleeding. The benefits of aspirin outweigh the bleeding risk when the risk of a
  cardiovascular end-point is >30% in the next 10 years. This risk is reached in patients aged
  under 45 with three strong additional cardiovascular risk factors, those aged 45–54 with three
  additional risk factors, those aged 54–65 with two additional risk factors, or those aged over
  65 with just one additional risk factor.

- **ACE inhibitors/angiotensin II receptor antagonists.** Treating people with diabetes and at
  least one other major cardiovascular risk factor with an ACE inhibitor produces a 25–35%
lowering of the risk of heart attack, stroke, overt nephropathy or cardiovascular death. Angiotensin II receptor antagonists are sometimes preferred initially and are also used for those intolerant to ACE inhibitors. The two agents are not used together.

**Microvascular complications**

In contrast to macrovascular disease, which is prevalent in the West as a whole, microvascular disease is specific to diabetes. Small blood vessels throughout the body are affected but the disease process is of particular danger in three sites:

- retina
- renal glomerulus
- nerve sheaths.

Diabetic retinopathy, nephropathy and neuropathy tend to manifest 10–20 years after diagnosis in young patients but may present earlier in older patients, probably because these individuals have had unrecognized diabetes for months or even years prior to diagnosis. Genetic factors appear to contribute to the susceptibility to microvascular disease. Diabetic siblings of diabetic patients with renal and eye disease have a three- to fivefold increased risk of the same complication in both type 1 and type 2 patients. There are racial differences in the overall prevalence of nephropathy. In the USA, prevalence is: Pima American Indian > Hispanic/Mexican > US black > US white patients.

**Diabetic eye disease**

At least 90% of young patients with type 1 diabetes will develop retinal changes but these only progress to sight-threatening retinopathy in a minority. Some 30–50% will require laser photocoagulation to prevent or limit progression to proliferative retinopathy, and good control of blood pressure is essential. Diabetes is still the most common cause of blindness in under-65-year-olds. It affects the eye in a variety of ways:

- **Cataract** is denaturation of the protein and other components of the lens of the eye, which renders it opaque.

- **Diabetic retinopathy** is damage to the retina and iris caused by diabetes, which can lead to blindness.

- **External ocular palsies** (see p. 806) most commonly affect the sixth and the third nerves. Third nerve palsy is not associated with pain. These nerve palsies usually recover spontaneously within a period of 3–6 months.
Cataract develops earlier in people with diabetes than in the general population. Sustained very poor diabetes control with a degree of ketosis can cause an acute cataract (snowflake cataract), which comes on rapidly. Fluctuations in blood glucose concentration can cause refractive variability, as a result of osmotic changes within the lens (the absorption of water into the lens causes temporary hypermetropia). This presents as fluctuating difficulty in reading. It resolves with better metabolic control of the diabetes.

**Diabetic retinopathy**

Diabetic retinopathy (**Fig. 27.14**) is the most commonly diagnosed diabetes-related complication. Its prevalence increases with the duration of diabetes (**Fig. 27.15**). Some 20% of people with type 1 diabetes will have retinal changes after 10 years, rising to >95% after 20 years (**Box 27.17**); 20–30% of people with type 2 diabetes have retinopathy at diagnosis. The metabolic consequences of poorly controlled diabetes cause intramural pericyte death, and thickening of the basement membrane in the small blood vessels of the retina. This leads initially to increased permeability of the vascular walls, and later to occlusion of the vessels (capillary closure). This process has somewhat different consequences in the peripheral retina and in the macular area.
FIGURE 27.14  Features of diabetic eye disease. A. The normal macula (centre) and optic disc (to left). B. Microaneurysms (small circles) and blot haemorrhage (larger circle) – early background retinopathy. C. Hard exudates (circled) and single cotton wool spot (arrowed) in addition to multiple blot haemorrhages in background retinopathy. D. Intra-retinal microvascular abnormalities (IRMA) – pre-proliferative retinopathy
(circled). E. Venous loop (circled) also indicates pre-proliferative change. F. Fronds of new vessels on the disc and elsewhere (proliferative; circled). G. Pre-retinal haemorrhage in proliferative disease. H. Hard exudates within a disc-width of the macula (maculopathy). I. Cortical cataracts and J. central cataracts can be seen against the red reflex with the ophthalmoscope.

![Graph showing prevalence of retinopathy](image)

**FIGURE 27.15** Prevalence of retinopathy. Prevalence is shown in relation to duration of the disease in patients with type 1 diabetes mellitus diagnosed under the age of 33 years. Almost all eventually develop background change and 60% progress to proliferative retinopathy. (Data from Archives of Ophthalmology 1984; 102:520.)

## Box 27.17

**Grading and management of pathological changes in diabetic retinopathy**
### Peripheral retina

Damage to the wall of small vessels causes *microaneurysms* (small red dots) within the retina. When vessel walls are breached, *superficial (blot) haemorrhages* occur in the ganglion cell and outer plexiform layers. Damaged blood vessels leak fluid into the retina. The fluid is cleared into the retinal veins, leaving behind protein and lipid deposits and causing *hard exudates*. These are eventually cleared by macrophages.

Micro-infarcts within the retina due to occluded vessels cause *cotton wool spots*. The spot itself is due to the accumulation of axoplastic debris. This debris is removed by macrophages. As this occurs, there may be white dots at the site of the previous cotton wool spot (*cytoid bodies*). Damage to the walls of veins causes their calibre to vary (*venous beading*) and elongation to occur, causing *venous loops*. Blockage of blood vessels leads to areas of capillary non-perfusion. Ischaemia in these areas causes the release of vascular growth factors such as VEGF. These factors cause new blood vessels to grow in the retina (*neovascularization*). Some of these new blood vessels are inside the retina and are helpful. These new intraretinal vessels, and other vessels whose walls are damaged and dilated, give the appearance of *intraretinal microvascular abnormalities (IRMAs)*.

Other new vessels emerge through the retina and lie on its surface, usually at the margin of an area of capillary closure. The normal shearing stresses that occur within the eye can cause these poorly supported new vessels to bleed. Small haemorrhages give rise to *pre-retinal*...
haemorrhages (boat-shaped haemorrhages). With further bleeding, vitreous haemorrhage occurs with consequent sudden loss of vision. Later, collagen tissue grows along the margins of the new vessels and gives rise to fibrotic bands. These bands may contract and pull on the retina, causing further haemorrhage and retinal detachment. Sometimes, vessels may be induced to grow on the pupil margin (rubeosis) and in the angle of the anterior chamber of the eye, giving rise to a rapid increase in intraocular pressure (rubeotic glaucoma). These features of retinopathy in the peripheral retina are grouped, according to the risk of visual loss, into three stages (Box 27.17).

**Macular area**

Fluid from leaking vessels is cleared poorly in the macular area because its anatomy differs from that of the rest of the retina. Above a certain rate of formation, clearance fails and macular oedema occurs. This distorts and thickens the retina at the macula. If sustained, this distortion causes loss of central vision. Macular oedema is not visible with the ophthalmoscope or with retinal photography. For this reason, surrogate markers for the presence of macular oedema are used (Box 27.17). Capillary occlusion in the macular area will also cause loss of central vision.

**Examination**

**Bedside examination of the eye**

Visual acuity should be checked using both a pinhole and the patient's distance spectacles. The ocular movements are assessed to detect any ocular motor palsies. The iris is examined for rubeosis and then the pupils dilated with 1% tropicamide. About 20 minutes later, the eye is examined for the presence of a cataract by looking at the lens with a +10.00 lens in the ophthalmoscope and viewing the lens against the red reflex. The retina is then examined systematically looking at the disc, then all four quadrants, and finally the macula. The macula is examined last because this induces the greatest discomfort, and pupillary constriction.

**Eye screening**

Screening for sight-threatening eye disease with universal access is seen as offering the best hope of displacing diabetes as the most common cause of blindness in those under 65 years of age. The National Screening Committee in the UK has helped establish digital photography-based screening across the country, based on a national set of standards. All people with diabetes who are over the age of 12 are offered annual measurement of their acuity and photographs of their retina. Box 27.18 shows standardized criteria for screening schemes; these are regularly inspected.

**Box 27.18**
Criteria for a successful local screening scheme for sight-threatening diabetic retinopathy

- Clearly defined geographical area for the screening programme
- Adequate number of people with diabetes for viability (>12 000)
- Identified screening programme manager
- Identified clinical screening lead
- Identified hospital eye service for diagnosis and laser treatment
- Computer software capable of supporting call/recall of patients and image grading
- Centralized appointment administration
- Single collated list of all people with diabetes in the area over the age of 12
- Equipment to obtain adequate disc- and macula-centred images of each eye
- Single image grading centre
- Process to manage people with poor-quality images
- Clear route of referral for treatment, and for feedback from treatment centre to screening unit
- Accreditation of screening staff
- Annual reporting of service performance

Management of diabetic eye disease
(See Box 27.17.)

Cataract
Extraction and intraocular lens implantation is indicated if the cataract is causing visual disability or an inability to view the retina adequately. Cataract extraction is straightforward if there is no retinopathy present. Pre-existing retinopathy may worsen after cataract extraction.

Retinopathy
The DCCT and UKPDS trials (see pp. 1259–1260) show that the risk of developing diabetic eye disease and the risk of established retinopathy progressing can be reduced by tight metabolic control of both diabetes and blood pressure. Development or progression of retinopathy may be accelerated by rapid improvement in glycaemic control, by pregnancy and by nephropathy, and these groups need frequent monitoring. Fluorescein angiography (a fluorescent dye is injected into an arm vein and photographed in transit through the retinal vessels) is used to define the extent of the potentially sight-threatening diabetic retinopathy. Ocular coherence tomography (OCT) is used to image the content of the layers of the retina at the macula, and in particular to measure retinal thickness. It can detect macular oedema and other macular abnormalities.
Proliferative retinopathy

New vessels are an indication for laser photocoagulation therapy. New vessels on the disc carry the worst prognosis and warrant urgent laser therapy. The laser should be directed at the new vessels and, in addition, at the associated areas of capillary non-perfusion (ischaemia). If the proliferative retinopathy has progressed to development of new vessels on the optic disc, then a technique known as **panretinal photocoagulation (PRP)** is carried out. This involves multiple laser burns to the peripheral retina, especially in the areas of capillary non-perfusion. Rubeosis is also treated with panretinal photocoagulation. If some bleeding has occurred but there is a good view, then laser treatment should be applied. Vitreoretinal surgery is used if bleeding is recurrent and preventing laser therapy. It is also employed to try to salvage some vision after vitreous haemorrhage and to treat fibrotic traction retinal detachment in advanced retinopathy.

Maculopathy

Extrafoveal exudates can be watched. However, if they are beginning to encroach on the fovea, then the centre of any rings of exudates can be treated by laser photocoagulation. This treatment has largely been replaced by new therapies (see below).

New therapies

Anti-VEGF drugs, such as bevacizumab, aflibercept and ranibizumab (see p. 1334), are being used to control diabetic retinopathy and diabetic maculopathy, particularly that which involves the centre of the macula and is causing sight loss. Studies have shown benefit over laser for this type of maculopathy.

The diabetic kidney

The kidney may be damaged by diabetes in three main ways:

- glomerular damage
- ischaemia resulting from hypertrophy of afferent and efferent arterioles
- ascending infection.

Diabetic nephropathy

**Epidemiology**

Clinical nephropathy secondary to glomerular disease usually manifests 15–25 years after diagnosis of diabetes and affects 25–35% of patients diagnosed under the age of 30 years. It is the leading cause of premature death in young diabetic patients. Older patients also develop nephropathy but the proportion affected is smaller. The incidence of end-stage kidney disease has fallen in recent decades, probably due to better control of blood glucose and blood
pressure, but this benefit has been cancelled out by the rising incidence of both types of diabetes.

**Pathophysiology**

The earliest functional abnormality in the diabetic kidney is renal hypertrophy associated with a raised glomerular filtration rate. This appears soon after diagnosis and is related to poor glycaemic control. As the kidney becomes damaged by diabetes, the afferent arteriole (leading to the glomerulus) becomes vasodilated to a greater extent than the efferent glomerular arteriole. This increases the intraglomerular filtration pressure, further damaging the glomerular capillaries. This raised intraglomerular pressure also leads to increased local shearing forces, which are thought to contribute to mesangial cell hypertrophy and increased secretion of extracellular mesangial matrix material. This process eventually leads to glomerular sclerosis. The initial structural lesion in the glomerulus is thickening of the basement membrane. Associated changes result in disruption of the protein cross-linkages that normally make the membrane an effective filter. In consequence, there is a progressive leak of large molecules (particularly protein) into the urine.

**Albuminuria**

The earliest evidence of this is ‘microalbuminuria’ – amounts of urinary albumin so small as to be undetectable by standard dipsticks (see p. 730). Microalbuminuria may be tested for with radioimmunoassay or special dipsticks. It is a predictive marker of progression to nephropathy in type 1 diabetes, and of increased cardiovascular risk in type 2 diabetes. Microalbuminuria may, after some years, progress to intermittent albuminuria followed by persistent proteinuria. Light-microscopic changes of glomerulosclerosis become manifest; both diffuse and nodular glomerulosclerosis can occur. The latter is sometimes known as the Kimmelstiel–Wilson lesion. At the later stage of glomerulosclerosis, the glomerulus is replaced by hyaline material.

At the stage of persistent proteinuria, the plasma creatinine is normal but the average patient is only some 5–10 years from end-stage kidney disease. The proteinuria may become so heavy as to induce a transient nephrotic syndrome, with peripheral oedema and hypoalbuminaemia.

Patients with nephropathy typically show a normochromic normocytic anaemia and a raised erythrocyte sedimentation rate (ESR). Hypertension is a common development and may itself damage the kidney still further. A rise in plasma creatinine is a late feature that progresses inevitably to renal failure, although the rate of progression may vary widely between individuals.

The natural history of this process is shown in **Figure 27.16**.
Ischaemic lesions

Arteriolar lesions, with hypertrophy and hyalinization of the vessels, can occur in patients with diabetes. The appearances are similar to those of hypertensive disease and lead to ischaemic damage to the kidneys.

Infecive lesions

Urinary tract infections are relatively more common in women with diabetes, but not in men. Ascending infection may occur because of bladder stasis resulting from autonomic neuropathy, and infections more easily become established in damaged renal tissue. Autopsy material frequently reveals interstitial changes suggestive of infection, but ischaemia may produce similar changes and the true frequency of pyelonephritis in diabetes is uncertain. Untreated infections in diabetics can result in renal papillary necrosis, in which renal papillae are shed in the urine, but this complication is now very rare.

Diagnosis

The urine of all diabetic patients should be checked regularly (at least annually) for the presence of protein. Many centres also screen younger patients for microalbuminuria since there is evidence that meticulous glycaemic control and early antihypertensive treatment, particularly with ACE inhibitors and angiotensin II blockers, may delay the onset of frank proteinuria. The albumin:creatinine ratio (ACR, tested on a mid-stream first morning urine sample) is <2.5 in healthy men and <3.5 mg/mmol in healthy women. Once proteinuria is
present, other possible causes should be considered (see below), but once these are excluded, a presumptive diagnosis of diabetic nephropathy can be made. For practical purposes, this implies inevitable progression to end-stage kidney disease, although the time course can be markedly slowed by early aggressive antihypertensive therapy. Clinical suspicion of a non-diabetic cause of nephropathy may be provoked by an atypical history, the absence of diabetic retinopathy (usually, but not invariably, present with diabetic nephropathy) and the presence of red-cell casts in the urine. Renal biopsy should be considered in such cases but is rarely necessary or helpful. Regular measurement is made of the plasma creatinine level with estimated glomerular filtration rate (eGFR).

Management

The management of diabetic nephropathy is similar to that of other causes of chronic kidney disease, with the following provisos:

• Aggressive treatment of blood pressure with a target <130/80 mmHg has been shown to slow the rate of deterioration of renal failure considerably. An ACE inhibitor or angiotensin II receptor antagonist is the drug of choice (see p. 1047). These drugs should also be used in normotensive patients with persistent microalbuminuria. Reduction in albuminuria occurs with this treatment.

• Oral hypoglycaemic agents partially excreted via the kidney (e.g. glibenclamide and metformin) should be avoided.

• Insulin sensitivity increases and drastic reductions in insulin dosage may be needed.

• Associated diabetic retinopathy tends to progress rapidly, and frequent ophthalmic supervision is essential.

Management of end-stage disease is made more difficult by the fact that patients often have other complications of diabetes, such as blindness, autonomic neuropathy or peripheral vascular disease. Vascular shunts tend to calcify rapidly and hence chronic ambulatory peritoneal dialysis may be preferable to haemodialysis. The failure rate of renal transplants is somewhat higher than in non-diabetic patients. A segmental pancreatic or islet graft is sometimes performed under cover of the immunosuppression needed for the renal graft, and this has been shown to improve survival, as well as offering freedom from insulin injections.

Diabetic neuropathy

Diabetes can damage peripheral nervous tissue in a number of ways. The vascular hypothesis postulates occlusion of the vasa nervorum as the prime cause. This seems likely in isolated mononeuropathies but the diffuse symmetrical nature of the common forms of neuropathy implies a metabolic cause. Since hyperglycaemia leads to increased formation of sorbitol and fructose in Schwann cells, accumulation of these sugars may disrupt function and structure.

The earliest functional change in diabetic nerves is delayed nerve conduction velocity; the earliest histological change is segmental demyelination, caused by damage to Schwann cells.
In the early stages, axons are preserved, implying prospects of recovery; at a later stage, irreversible axonal degeneration develops.

The following varieties of neuropathy occur (Fig. 27.17):

- symmetrical, mainly sensory polyneuropathy (distal)
- acute painful neuropathy
- mononeuropathy and mononeuritis multiplex
  - cranial nerve lesions
  - isolated peripheral nerve lesions
- diabetic amyotrophy (asymmetrical motor diabetic neuropathy)
- autonomic neuropathy.

**FIGURE 27.17** The neuropathic man.

### Symmetrical, mainly sensory polyneuropathy

This is often unrecognized by the patient in its early stages. Early clinical signs are loss of vibration sense, pain sensation (deep before superficial) and temperature sensation in the feet. At later stages, patients may complain of a feeling of ‘walking on cotton wool’ and can lose their balance when washing the face or walking in the dark owing to impaired proprioception. Early involvement of the hands is less common and should prompt a search for non-diabetic causes. Complications include unrecognized trauma, beginning as blistering due to an ill-fitting shoe or a hot-water bottle, and leading to ulceration.
Sequelae of neuropathy

Involvement of motor nerves to the small muscles of the feet gives rise to interosseous wasting. Unbalanced traction by the long flexor muscles leads to a characteristic shape of the foot, with a high arch and clawing of the toes, which in turn causes abnormal distribution of pressure on walking, resulting in callus formation under the first metatarsal head or on the tips of the toes and perforating neuropathic ulceration. Neuropathic arthropathy (Charcot’s joints) may sometimes develop in the ankle. The hands show small-muscle wasting, as well as sensory changes, but these signs and symptoms must be differentiated from those of the carpal tunnel syndrome, which occurs with increased frequency in diabetes and may be amenable to treatment (see p. 655).

Acute painful neuropathy

A diffuse, painful neuropathy is less common. The patient describes burning or crawling pains in the feet, shins and anterior thighs. These symptoms are typically worse at night and pressure from bedclothes may be intolerable. The condition may present at diagnosis or after sudden improvement in glycaemic control (e.g. when insulin is started). It usually remits spontaneously after 3–12 months if good control is maintained. A more chronic form, developing later in the course of the disease, is sometimes resistant to almost all forms of therapy. Neurological assessment is difficult because of the hyperaesthesia experienced by the patient, but muscle wasting is not a feature and objective signs can be minimal.

Management is firstly to explore for non-diabetic causes (see pp. 884–885). Explanation and reassurance about the likelihood of remission within months may be all that is needed. Duloxetine (NICE recommends this as first-line therapy), tricyclics, gabapentin or pregabalin, mexiletine, valproate and carbamazepine all reduce the perception of neuritic pain somewhat, but usually not as much as patients hope for. Transepidermal nerve stimulation (TENS) benefits some patients. Topical capsaicin-containing creams help occasionally. A few report that acupuncture has been of value.

Mononeuritis and mononeuritis multiplex (multiple mononeuropathy)

Any nerve in the body can be involved in diabetic mononeuritis; the onset is typically abrupt and sometimes painful. Radiculopathy (i.e. involvement of a spinal root) may also occur.

Isolated palsies of nerves to the external eye muscles, especially the third and sixth nerves, are more common in diabetes. A characteristic feature of diabetic third nerve lesions is that pupillary reflexes are retained owing to sparing of pupillomotor fibres. Full spontaneous recovery is the rule for most episodes of mononeuritis over 3–6 months. Lesions are more likely to occur at common sites for external pressure palsies or nerve entrapment (e.g. the median nerve in the carpal tunnel; see p. 882).
Diabetic amyotrophy

This condition is usually seen in older men with diabetes. Presentation is with painful wasting, usually asymmetrical, of the quadriceps muscles. The wasting may be very marked and knee reflexes are diminished or absent. The affected area is often extremely tender. Extensor plantar responses sometimes develop and cerebrospinal fluid (CSF) protein content is elevated. Diabetic amyotrophy is usually associated with periods of poor glycaemic control and may be present at diagnosis. It often resolves in time with careful metabolic control of the diabetes.

Autonomic neuropathy

Asymptomatic autonomic disturbances can be demonstrated on testing in many patients (Box 27.19) but symptomatic autonomic neuropathy is rare. It affects both the sympathetic and parasympathetic nervous systems and can cause disabling postural hypotension.

HR, heart rate; R–R, time between R and next R on ECG.

The cardiovascular system

Vagal neuropathy results in tachycardia at rest and loss of sinus arrhythmia. At a later stage, the heart may become denervated (resembling a transplanted heart). Cardiovascular reflexes, such as the Valsalva manoeuvre (see p. 970), are impaired. Postural hypotension occurs owing to loss of sympathetic tone to peripheral arterioles. A warm foot with a bounding pulse is often seen in a polyneuropathy as a result of peripheral vasodilatation.

The gastrointestinal tract

Vagal damage can lead to gastroparesis, often asymptomatic but sometimes leading to intractable vomiting. Implantable devices that stimulate gastric emptying, and injections of botulinum toxin into the pylorus (to paralyse the sphincter partly), have each shown benefit in cases of this previously intractable problem. Autonomic diarrhoea characteristically occurs at
night, accompanied by urgency and incontinence. Diarrhoea and steatorrhoea may be present, owing to small bowel bacterial overgrowth; treatment is with antibiotics such as tetracycline.

**Bladder involvement**
Loss of tone, incomplete emptying and stasis (predisposing to infection) can occur and may ultimately result in an atonic, painless, distended bladder. Treatment is with intermittent self-catheterization, permanent catheterization if that fails, and prophylactic antibiotic therapy for those prone to recurrent infection.

**Male erectile dysfunction**
This is common. The first manifestation is incomplete erection, which may, in time, progress to total failure; retrograde ejaculation also occurs in patients with autonomic neuropathy. Erectile dysfunction in diabetes has many causes, including anxiety, depression, alcohol excess, drugs (e.g. thiazides and beta-blockers), primary or secondary gonadal failure, hypothyroidism and inadequate vascular supply owing to atheroma in pudendal arteries. The history and examination should focus on these possible causes. Blood is taken for luteinizing hormone, follicle stimulating hormone, testosterone, prolactin and thyroid function. Treatment should ideally include sympathetic counselling of both partners.

Phosphodiesterase type 5 inhibitors (sildenafil, tadalafil, vardenafil, avanafil), which enhance the effects of nitric oxide on smooth muscle and increase penile blood flow, are used in those who do not take nitrates for angina. Some 60% of patients can be expected to benefit from this therapy.

Alternatives for those who fail to improve with a phosphodiesterase inhibitor or who dislike the side-effects (headache and a green tinge to vision the next day), and for those in whom it is contraindicated, are:

- Apomorphine 2 or 3 mg sublingually 20 min before sexual activity.
- Alprostadil (prostaglandin E1 preparation), given as a small pellet inserted with a device into the urethra (125 µg initially to a maximum of 500 µg). If the partner is pregnant, barrier contraception must be used to keep prostaglandin away from the fetus.
- Intracavernosal injection or insertion of a pellet of alprostadil into the urethra (2.5 µg initially to a maximum of 40 µg). Side-effects include priapism, which needs urgent treatment should erection last $>3$ h.
- Vacuum devices.

**The diabetic foot**
A total of 10–15% of diabetic patients develop foot ulcers at some stage in their lives. Diabetic foot problems ([Fig. 27.18](#)) are responsible for nearly 50% of all diabetes-related hospital admissions. Many diabetic limb amputations could be delayed or prevented by more effective patient education and medical supervision. Ischaemia, infection and neuropathy...
combine to produce tissue necrosis. Although all these factors may coexist, the ischaemic and the neuropathic foot (Box 27.20) can be distinguished. In rural India, foot ulcers are commonly due to neuropathic and infective causes rather than vascular causes.

**Management**

Many diabetic foot problems are avoidable, so patients need to learn the principles of foot care (Box 27.21). Older patients should visit a chiropodist/podiatrist regularly and should not cut their own toenails. Once tissue damage has occurred in the form of ulceration or gangrene, the aim is preservation of viable tissue. The four main threats to the skin and subcutaneous tissues are:

- **Infection.** This can take hold rapidly in a diabetic foot. Early antibiotic treatment is essential,
with antibiotic therapy adjusted in the light of culture results. The organism grown from the
skin surface may not be the organism causing deeper infection. Collections of pus are drained
and excision of infected bone is needed if osteomyelitis develops and does not respond to
appropriate antibiotic therapy. Regular X-rays of the foot are needed to check on progress.

• Ischaemia. The blood flow to the feet is assessed clinically and with Doppler ultrasound.
  Femoral angiography is used to localize areas of occlusion amenable to bypass surgery or
  angioplasty. Relatively few patients fall into this category.

• Abnormal pressure. An ulcerated site must be kept non-weight-bearing. Resting the affected
  leg may need to be supplemented with special deep shoes and insoles to move pressure away
  from critical sites, or by removable or non-removable casts of the leg. After healing, special
  shoes and insoles are likely to continue to be needed to protect the feet and prevent abnormal
  pressure repeating damage to a healed area. In neuropathic feet, particularly, sharp surgical
  debridement by a chiropodist is necessary to prevent callus distorting the local wound
  architecture and causing damage through abnormal pressure on normal skin nearby.

• Wound environment. Dressings are used to absorb or remove exudate, maintain moisture,
  and protect the wound from contaminating agents; they should be easily removable. The role
  of expensive new dressings containing growth factors and other biologically active agents is
  being assessed.

---

### Box 27.21

**Principles of diabetic foot care**

- Inspect feet daily
- Moisturize dry skin
- Seek early advice for any damage
- Check shoes inside and out for sharp bodies/areas before wearing
- Use lace-up shoes with plenty of room for the toes
- Keep feet away from sources of heat (hot sand, hot-water bottles, radiators, fires)
- Check the bath temperature before stepping in
- Attend a podiatrist regularly

Good liaison between physician, chiropodist/podiatrist and surgeon is essential if periods in
hospital are to be used efficiently. When irreversible arterial insufficiency is present, it is often
quicker and kinder to opt for an early major amputation rather than subject the patient to a
debilitating sequence of conservative procedures.

### Infections

There is no evidence that diabetic patients with good glycaemic control are more prone to
infection than normal subjects. However, poorly controlled diabetes entails increased susceptibility to the following infections:

- **Skin**
  - staphylococcal infections (boils, abscesses, carbuncles)
  - mucocutaneous candidiasis

- **Gastrointestinal tract**
  - periodontal disease
  - rectal and ischiorectal abscess formation (when control is very poor)

- **Urinary tract**
  - urinary tract infections (in women)
  - pyelonephritis
  - perinephric abscess

- **Lungs**
  - staphylococcal and pneumococcal pneumonia
  - Gram-negative bacterial pneumonia
  - tuberculosis

- **Bone**
  - spontaneous staphylococcal spinal osteomyelitis.

One reason why poor control leads to infection is that chemotaxis and phagocytosis by polymorphonuclear leucocytes are impaired because, at high blood glucose concentrations, neutrophil superoxide generation is impaired.

Conversely, infections may lead to loss of glycaemic control and precipitate hyperglycaemic emergencies. Insulin-treated patients need to increase their dose by up to 25% in the face of infection, and non-insulin-treated patients may need insulin cover while the infection lasts. Patients should be told never to omit their insulin dose, even if they are nauseated and unable to eat; instead, they should test their blood glucose frequently and seek urgent medical advice. Patients should receive pneumococcal vaccine and yearly influenza vaccine.

### Diabetes and cancer

Certain types of cancer are more common in type 2 diabetes. The risk of carcinoma of the uterus and of the pancreas is approximately doubled, and there is a 20–50% increase in the risk of colorectal and breast cancer. These associations appear to be mediated by obesity, which confers similar levels of risk in the absence of hyperglycaemia, although there is also an element of reverse causation with carcinoma of the pancreas, which can precipitate or cause diabetes. Metformin-treated patients have been reported to have a lower cancer risk than those on other therapies, and this agent is under investigation for possible anti-tumour properties.

### Skin and joints
Joint contractures in the hands are a common consequence of childhood diabetes. The sign may be demonstrated by asking the patient to join the hands as if in prayer; the metacarpophalangeal and interphalangeal joints cannot be opposed. Thickened, waxy skin can be noted on the backs of the fingers. These features may be due to glycosylation of collagen and are not progressive (see also p. 1364). The condition is sometimes referred to as diabetic cheiroarthropathy.

Osteopenia in the extremities is also described in type 1 diabetes but rarely has clinical consequences.

**Special Situations in Diabetes**

### Surgery in diabetes

Smooth control of diabetes minimizes the risk of infection and balances the catabolic response to anaesthesia and surgery. The procedure for insulin-treated patients is simple:

- **Long-acting and/or intermediate insulin should be stopped the day before surgery, and soluble insulin substituted.**

- **Whenever possible, diabetic patients should be first on the morning theatre list.**

- **An infusion of glucose, insulin and potassium is given during surgery.** The insulin can be mixed into the glucose solution or administered separately by syringe pump. A standard combination is 16 U of soluble insulin with 10 mmol of KCl in 500 mL of 10% glucose, infused at 100 mL/h.

- **Postoperatively, the infusion is maintained until the patient is able to eat.** Other fluids needed in the perioperative period must be given through a separate intravenous line and must not interrupt the glucose/insulin/potassium infusion. Glucose levels are checked every 2–4 h and
potassium levels are monitored. The amount of insulin and potassium in each infusion bag is adjusted either upwards or downwards, according to the results of regular monitoring of the blood glucose and serum potassium concentrations.

The same approach is used in the emergency situation, with the exception that a separate variable-rate insulin infusion may be needed to bring blood glucose under control before surgery.

**Non-insulin-treated patients** should stop medication 2 days before the operation. Patients with mild hyperglycaemia (fasting blood glucose <8 mmol/L) can be treated as non-diabetic. Those with higher levels are treated with soluble insulin prior to surgery, and with glucose, insulin and potassium during and after the procedure, as for insulin-treated patients.

### Pregnancy in established diabetes

Pregnancy in diabetes was, in the past, associated with high fetal mortality, which has been dramatically reduced by meticulous metabolic control of the diabetes and careful obstetric management. Despite this, the rates of congenital malformation and perinatal mortality remain several times higher than in the non-diabetic population. Type 2 diabetes is now much more prevalent in the maternal population as a result of the changing natural history of this condition.

### Metabolic control of diabetes in pregnancy

Congenital malformations are associated with poor glucose control in the early weeks of pregnancy, and good control should therefore be in place before conception, wherever possible. The mother should perform daily home blood glucose profiles, recording blood tests before and 2 hours after meals. The renal threshold for glucose falls in pregnancy and urine tests are therefore of little value. Insulin requirements rise progressively and intensified insulin regimens are generally used. The aim is to maintain blood glucose and fructosamine (or HbA\textsubscript{1c}) levels as close to the normal range as can be tolerated. Oral antidiabetic therapy should be avoided, except for metformin, which is recognized to be safe in pregnancy.

### General management

The patient is seen at intervals of 2 weeks or less at a clinic managed jointly by physician and obstetrician. Circumstances permitting, the aim should be outpatient management with a spontaneous vaginal delivery at term. Retinopathy and nephropathy may deteriorate during pregnancy. Digital photographic eye screening and urine testing for protein should be undertaken at booking, at 28 weeks and before delivery.

### Obstetric problems associated with diabetes

Congenital malformations associated with maternal diabetes affect cardiac and skeletal development, of which the caudal regression syndrome is an example. Poorly controlled diabetes later in gestation is associated with stillbirth, shoulder dystocia owing to fetal macrosomia, polyhydramnios and pre-eclampsia. Ketoacidosis in pregnancy carries a 50%
fetal mortality, but maternal hypoglycaemia, although highly undesirable, is relatively well tolerated by the fetus.

**Neonatal problems**

Maternal diabetes, especially when poorly controlled, is associated with fetal macrosomia. The infant of a diabetic mother is more susceptible to hyaline membrane disease than non-diabetic infants of similar maturity. In addition, neonatal hypoglycaemia may occur. The mechanism is as follows: maternal glucose crosses the placenta but insulin does not; the fetal islets hypersecrete to combat maternal hyperglycaemia, and a rebound to hypoglycaemic levels occurs when the umbilical cord is cut. These complications are due to hyperglycaemia in the third trimester.

**Gestational diabetes**

This term refers to glucose intolerance that develops or is first recognized in the course of pregnancy; it is typically asymptomatic and usually remits following delivery. Gestational diabetes has been estimated to complicate about 7% of all pregnancies, with wide variation due to differences between populations and diagnostic criteria. Women with a previous history of gestational diabetes, older or overweight women, those with a history of large-for-gestational-age babies, and women from certain ethnic groups are at particular risk, but many affected women are not in any of these categories. For this reason, some advocate screening of all pregnant women on the basis of random plasma glucose testing in each trimester and by oral glucose tolerance testing if the glucose concentration is, for example, 7 mmol/L or more. The Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) study found that the risk of adverse outcomes increased as a function of maternal glucose levels at 24–28 weeks of pregnancy, even when these were within the normal reference range. This has added to the controversy concerning the appropriate cut-off levels for screening and intervention, since the benefits of intervention are marginal at lower glucose levels, while labelling a mother as diabetic may have unwanted consequences, such as a higher rate of caesarean section.

Treatment is with diet in the first instance, followed by metformin if blood glucose targets (fasting 5.3 mmol/L; 2 h after meals 6.4 mmol/L) are not met using changes in diet and exercise within 1–2 weeks. Initial treatment with insulin is used in those with a fasting plasma glucose level >7.0 mmol/L at diagnosis, or between 6.0 and 6.9 mmol/L if macrosomia or hydramnios is present, although many patients come to require insulin as their pregnancy advances. Insulin does not cross the placenta. Many oral agents cross the placenta and are usually avoided because of the potential risk to the fetus, although glibenclamide has been used in gestational diabetes presenting later in pregnancy.

Gestational diabetes has been associated with all the obstetric and neonatal problems described above for pre-existing diabetes, except that there is no increase in the rate of congenital abnormalities. Gestational diabetes typically remits after delivery but signals an increased risk of type 2 diabetes in later life; maintaining a low body weight and keeping
physically active reduce this risk.

Not all diabetes presenting in pregnancy is gestational. True type 1 diabetes may develop and swift diagnosis is essential to prevent the development of ketoacidosis. Hospital admission is required if the patient is symptomatic, or has ketonuria or a markedly elevated blood glucose level.

**Unstable diabetes**

This term is used to describe the condition of patients with recurrent ketoacidosis and/or recurrent hypoglycaemic coma. Of these, the largest group is made up of those who experience recurrent severe hypoglycaemia.

**Recurrent severe hypoglycaemia**

This affects 1–3% of insulin-dependent patients. Most are adults who have had diabetes for >10 years. By this stage, endogenous insulin secretion is negligible in the great majority of patients. Pancreatic α cells are still present in undiminished numbers but the glucagon response to hypoglycaemia is virtually absent. Long-term patients are thus subject to fluctuating hyperinsulinaemia owing to erratic absorption of insulin from injection sites, and lack a major component of the hormonal defence against hypoglycaemia. In this situation, adrenaline (epinephrine) secretion becomes vital, but this too may become impaired in the course of diabetes. Loss of adrenaline (epinephrine) secretion has been attributed to autonomic neuropathy but this is unlikely to be the sole cause; central adaptation to recurrent hypoglycaemia may also be a factor.

The following factors may also predispose to recurrent hypoglycaemia:

- **Over-treatment with insulin.** Frequent biochemical hypoglycaemia lowers the glucose level at which symptoms develop. Symptoms often reappear when overall glucose control is relaxed.

- **An unrecognized low renal threshold for glucose.** Attempts to render the urine sugar-free will inevitably produce hypoglycaemia.

- **Excessive insulin doses.** A common error is to increase the dose when a patient needs more frequent injections to overcome a problem of timing.

- **Endocrine causes.** These include pituitary insufficiency, adrenal insufficiency and premenstrual insulin sensitivity.

- **Alimentary causes.** These include exocrine pancreatic failure and diabetic gastroparesis.

- **Chronic kidney disease.** Clearance of insulin is diminished.

- **Patient causes.** Patients may struggle to understand the principles of diabetes management, may be uncooperative or may manipulate their therapy.

**Recurrent ketoacidosis**

This usually occurs in adolescents or young adults, particularly girls. Metabolic
decompensation may develop very rapidly. A combination of chaotic food intake and insulin omission, whether conscious or unconscious, is the primary cause of this problem. It almost always occurs in the context of considerable psychosocial problems, particularly eating disorders. This area needs careful and sympathetic exploration in any patient with recurrent ketoacidosis. It is perhaps not surprising that in an illness where much of one's life is spent thinking of and controlling food intake, 30% of women with diabetes have had some features of an eating disorder at some time. Other causes include:

- **Iatrogenic factors.** Inappropriate insulin combinations may be a cause of swinging glycaemic control. For example, a once-daily regimen may cause hypoglycaemia during the afternoon or evening and pre-breakfast hyperglycaemia due to insulin deficiency.
- **Intercurrent illness.** Unsuspected infections, including urinary tract infections and tuberculosis, may be present. Thyrotoxicosis can also manifest as unstable glycaemic control.

### Further reading

### Hypoglycaemia in the Non-Diabetic Patient

Hypoglycaemia develops when hepatic glucose output falls below the rate of glucose uptake by peripheral tissues. Hepatic glucose output may be reduced by:

- inhibition of hepatic glycogenolysis and gluconeogenesis by insulin
- depletion of hepatic glycogen reserves by malnutrition, fasting, exercise or advanced liver disease
- impaired gluconeogenesis (e.g. following alcohol ingestion).

In the first of these categories, insulin levels are raised, the liver contains adequate glycogen stores and the hypoglycaemia can be reversed by injection of glucagon. In the other two situations, insulin levels are low and glucagon is ineffective. Peripheral glucose uptake is accelerated by high insulin levels and by exercise, but these conditions are normally balanced by increased hepatic glucose output.

The most common symptoms and signs of hypoglycaemia are neurological. The brain consumes about 50% of the total glucose produced by the liver. This high energy requirement is needed to generate ATP, used to maintain the potential difference across axonal membranes.

### Insulinomas

Insulinomas are pancreatic islet cell tumours that secrete insulin. Most are sporadic but some patients have multiple tumours arising from neural crest tissue (multiple endocrine neoplasia).
Some 95% of these tumours are benign. The classic presentation is with fasting hypoglycaemia, but early symptoms may also develop in the late morning or afternoon. Recurrent hypoglycaemia is often present for months or years before the diagnosis is made, and the symptoms may be atypical or even bizarre; the presenting features in one series are given in Box 27.22. Common misdiagnoses include psychiatric disorders, particularly pseudodementia in elderly people, epilepsy and cerebrovascular disease. Whipple’s triad remains the basis of clinical diagnosis. This is satisfied when:

- symptoms are associated with fasting or exercise
- hypoglycaemia is confirmed during these episodes
- glucose relieves the symptoms.

### Box 27.22

**Presenting features of insulinoma**

- Diplopia
- Sweating, palpitations, weakness
- Confusion or abnormal behaviour
- Loss of consciousness
- Grand mal seizures

A fourth criterion – demonstration of inappropriately high insulin levels during hypoglycaemia – may usefully be added.

The diagnosis is confirmed by the demonstration of hypoglycaemia in association with inappropriate and excessive insulin secretion. Hypoglycaemia is demonstrated by:

- Measurement of overnight fasting (16 h) glucose and insulin levels on three occasions. About 90% of patients with insulinomas will have low glucose and non-suppressed (normal or elevated) insulin levels.
- A prolonged 72-h supervised fast if overnight testing is inconclusive and symptoms persist.

Autonomous insulin secretion is demonstrated by lack of the normal feedback suppression during hypoglycaemia. This may be shown by measuring insulin, C-peptide or proinsulin during a spontaneous episode of hypoglycaemia.

### Management

The most effective therapy is surgical excision of the tumour but insulinomas are often very small and difficult to localize. Many techniques can be used to attempt to localize insulinomas. Sensitivity and specificity vary between centres and between operators. These include highly selective angiography, contrast-enhanced high-resolution computed tomography scanning, scanning with radiolabelled somatostatin (some insulinomas express somatostatin receptors),
and endoscopic and intraoperative ultrasound scanning. Venous sampling for the detection of ‘hot spots’ of high insulin concentration in the various intra-abdominal veins is still used occasionally.

Medical treatment with diazoxide is useful when the insulinoma is malignant, when a tumour cannot be located and when elderly patients have mild symptoms. Symptoms may also remit on treatment with a somatostatin analogue (octreotide or lanreotide).

### Hypoglycaemia with other tumours

Hypoglycaemia may develop in the course of advanced neoplasia and cachexia, and has been described in association with many tumour types. Certain massive tumours, especially sarcomas, may produce hypoglycaemia owing to the secretion of insulin-like growth factor-1. True ectopic insulin secretion is extremely rare.

### Postprandial hypoglycaemia

If frequent venous blood glucose samples are taken following a prolonged glucose tolerance test, about 1 in 4 subjects will have at least one value below 3 mmol/L. The arteriovenous glucose difference is quite marked during this phase, so that very few are truly hypoglycaemic in terms of arterial (or capillary) blood glucose content. Failure to appreciate this simple fact led some authorities to believe that postprandial (or reactive) hypoglycaemia was a potential ‘organic’ explanation for a variety of complaints that might otherwise have been considered psychosomatic. An epidemic of false ‘hypoglycaemia’ followed, particularly in the USA. Later work showed a poor correlation between symptoms and biochemical hypoglycaemia. Even so, a number of otherwise normal people occasionally become pale, weak and sweaty at times when meals are due, and report benefit from advice to take regular snacks between meals.

True postprandial hypoglycaemia may develop in the presence of alcohol, which ‘primes’ the cells to produce an exaggerated insulin response to carbohydrate. The person who substitutes alcoholic beverages for lunch is particularly at risk. Postprandial hypoglycaemia sometimes occurs after gastric surgery, owing to rapid gastric emptying and mismatching of nutrient absorption and insulin secretion. This is referred to as ‘dumping’ but it is now rarely encountered (see p. 381).

### Hepatic and renal causes of hypoglycaemia

The liver can maintain a normal glucose output despite extensive damage, and hepatic hypoglycaemia is uncommon. It is, however, a particular problem with acute hepatic failure.

The kidney has a subsidiary role in glucose production (via gluconeogenesis in the renal cortex), and hypoglycaemia is sometimes a problem in terminal renal failure.

Hereditary fructose intolerance occurs in 1 in 20 000 live births and can cause hypoglycaemia (see p. 1285).
Endocrine causes of hypoglycaemia

Deficiencies of hormones antagonistic to insulin are rare but well-recognized causes of hypoglycaemia. These include hypopituitarism, isolated adrenocorticotrophic hormone (ACTH) deficiency and Addison's disease.

Drug-induced hypoglycaemia

Many drugs have been reported to produce isolated cases of hypoglycaemia, but usually only when other predisposing factors are present:

• Sulphonylureas may be used in the treatment of diabetes or may be taken by non-diabetics in suicide attempts.
• Quinine may produce severe hypoglycaemia in the course of treatment for *falciparum* malaria.
• Salicylates may cause hypoglycaemia, usually after accidental ingestion by children.
• Propranolol can induce hypoglycaemia in the presence of strenuous exercise or starvation.
• Pentamidine, used in the treatment of resistant *Pneumocystis* pneumonia, may produce hypoglycaemia (see p. 349).

Alcohol-induced hypoglycaemia

Alcohol inhibits gluconeogenesis. Alcohol-induced hypoglycaemia occurs in poorly nourished chronic alcohol users, binge drinkers, and children who have taken relatively small amounts of alcohol, since they have a diminished hepatic glycogen reserve. They present with coma and hypothermia (hypothermia is a feature of hypoglycaemia, due to the suppression of central thermoregulation, particularly the shivering response; children manifest hypothermia more frequently due to their high ratio of surface area to body mass).

Factitious hypoglycaemia

This is a relatively common variant of self-induced disease and is more common than an insulinoma. Hypoglycaemia is produced by surreptitious self-administration of insulin or sulphonylureas. Many patients in this category have been extensively investigated for an insulinoma. Measurement of C-peptide levels during hypoglycaemia should identify patients who are injecting insulin; sulphonylurea abuse can be detected by chromatography of plasma or urine.

Disorders of Lipid Metabolism

**Physiology**

Lipids are insoluble in water and are transported in the bloodstream as macromolecular complexes. In these complexes, lipids (principally triglyceride, cholesterol and cholesterol esters) are surrounded by a stabilizing coat of phospholipid. Proteins (called apoproteins) embedded into the surface of these ‘lipoprotein’ particles exert a stabilizing function and allow the particles to be recognized by receptors in the liver and the peripheral tissues. The structure of a chylomicron (one type of lipoprotein particle) is illustrated in *Figure 28.1*. 
Five principal types of lipoprotein particles are found in the blood (Fig. 28.2). They are structurally different and can be separated in the laboratory by their density and electrophoretic mobility. The larger particles give postprandial plasma its cloudy appearance. More than half of all patients under 60 years of age who have angiographically confirmed coronary artery disease have a lipoprotein disorder.
FIGURE 28.2 The sites of origin of the major lipoprotein particles, showing their interaction and fate. HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein

The genes for all the major apoproteins and that for the low-density lipoprotein (LDL) receptor have been isolated and sequenced, and their chromosomal sites have been mapped. Production of abnormal apoproteins is known to give rise, or predispose, to several types of lipid disorder, and it is likely that others will be discovered.

Chylomicrons

Chylomicrons (see Fig. 28.1) are synthesized in the small intestine postprandially, passing initially into the intestinal lymphatic drainage, then along the thoracic duct into the bloodstream. They contain triglyceride and a small amount of cholesterol and its ester, and provide the main mechanism for transporting the digestion products of dietary fat to the liver and peripheral tissues. Each newly formed chylomicron contains several different apoproteins (B48, AI, AII), and acquires apoproteins CII and E by transfer from high-density lipoprotein (HDL) particles in the bloodstream. Apoprotein CII binds to specific receptors in adipose
tissue, skeletal muscle and the liver, where the endothelial enzyme, lipoprotein lipase, hydrolyses most of the triglyceride into fatty acids, which are used as an energy source or stored. The remaining chylomicron remnant particle, which contains the bulk of the original cholesterol, is taken up by the liver. Apoprotein E on the particle's surface binds with liver clearance receptors.

**Very-low-density lipoprotein particles**

Very-low-density lipoprotein (VLDL) particles are synthesized continuously in the liver; they contain most of the body's endogenously synthesized triglyceride and a smaller quantity of cholesterol. They are the body's main source of energy during prolonged fasting. Apoprotein B100 is an essential component of VLDL. Apoproteins CII and E are incorporated later into VLDL by transfer from HDL particles. As they pass round the circulation, VLDL particles bind through apoprotein CII, allowing triglyceride to be progressively removed by lipoprotein lipase in the capillary endothelium. This leaves a particle, now depleted of triglyceride and apoprotein CII, called an intermediate-density lipoprotein particle.

**Intermediate-density lipoprotein particles**

Intermediate-density lipoprotein (IDL) particles have apoprotein B100 and apoprotein E molecules on the particle surface. Most IDL particles bind to liver LDL receptors through the apoprotein E molecule and are then catabolized. Some IDL particles have further triglyceride removed (by the enzyme hepatic lipase), producing LDL particles.

**Low-density lipoprotein particles**

Low-density lipoprotein (LDL) particles are the main carrier of cholesterol, and deliver it both to the liver and to peripheral cells. The surface of the LDL particle contains apoprotein B100 and also apoprotein E. Apoprotein B100 is the principal ligand for the LDL clearance receptor. This receptor lies within coated pits on the surface of the hepatocyte. Once bound to the receptor, the coated pit invaginates and fuses with liposomes, which destroy the LDL particle (*Fig. 28.3*).
Receptor-mediated endocytosis. Low-density lipoprotein (LDL) receptors are formed in the endoplasmic reticulum and transported via the Golgi apparatus to the surface of a hepatocyte. LDLs bind to these receptors, and are internalized and taken up by the endosome. The receptor is recycled back to the surface, while the LDL is broken down by the lysosomes, freeing the cholesterol needed for membrane synthesis.

This process is, in part, regulated by a serine protease, proprotein convertase subtilisin/kexin type 9 (PCSK9). When PCSK9 binds to an LDL–LDL clearance receptor complex, the receptor is destroyed along with the LDL particle. If PCSK9 does not bind, the receptor returns to the surface of the cell and removes more cholesterol. The number of hepatic LDL clearance receptors regulates the circulating LDL concentration. This is also influenced by the activity of the rate-limiting enzyme in the cholesterol synthetic pathway, hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase.

LDL particles can deposit lipid into the walls of the peripheral vasculature. Not all the cholesterol synthesized by the liver is packaged immediately into lipoprotein particles. Some is oxidized into bile salts. Both bile salts and cholesterol are excreted in the bile; both are then reabsorbed through the terminal ileum and recirculated (enterohepatic circulation; see p. 443).

LDL particles become Lp(a) lipoproteins as a result of the linkage of apoprotein (a) to apoprotein B100 with a single disulphide bond. Raised levels of Lp(a) lipoprotein are a risk factor for cardiovascular disease.

High-density lipoprotein particles
Nascent high-density lipoprotein (HDL) particles are produced in both the liver and the intestine. They are disc-shaped and seemingly inert, and contain apoprotein AI. They are transmuted into mature particles by the acquisition of phospholipids, and the E and C apoproteins from chylomicrons and VLDL particles in the circulation. The more mature HDL particles take up cholesterol from cells in the peripheral tissues, aided by cholesterol-efflux regulatory protein – a product of the ATP-binding cassette transporter 1 gene (ABCI gene). As
it is taken up, the enzyme lecithin cholesterol acyltransferase (LCAT), activated by the apoprotein A on the particle's surface, esterifies the sequestered cholesterol. The HDL particle transports cholesterol away from the periphery and may transfer it indirectly to other particles, such as VLDL, in the circulation, or deliver its cholesterol directly to the liver (reverse cholesterol transport) and steroid-synthetic tissues (ovaries, testes, adrenal cortex).

This direct delivery takes place through scavenger-receptor B1. In experimental animals, the absence of scavenger-receptor B1 dramatically accelerates the development of atheroma, and genetically programmed over-production suppresses atheroma formation.

Measurement

When a laboratory measures fasting serum lipids, the majority of the total cholesterol concentration consists of LDL particles with a 20–30% contribution from HDL particles. The triglyceride concentration largely reflects the circulating number of VLDL particles, since chylomicrons are not normally present in the fasted state. If the patient is not fasted, the total triglyceride concentration will be raised, owing to the additional presence of triglyceride-rich chylomicrons.

Epidemiology

**LDL and total cholesterol**

Population studies have repeatedly demonstrated a strong association between both total and LDL cholesterol concentration and coronary heart risk. There is a strong link between mean fat consumption, mean serum cholesterol concentration and the prevalence of coronary heart disease between countries. The exception is France, where the cardiovascular risk is only moderate – perhaps owing to high alcohol consumption. Studies of migrants, particularly of Japanese men migrating to Hawaii, have shown that, as diet changes and cholesterol concentrations rise, so does the cardiovascular risk. Such studies demonstrate the role of the environment rather than the genetic make-up of a population.

The Multiple Risk Factor Intervention Trial (MRFIT) screened one-third of a million American men for various cardiovascular risk factors and then followed them for 6 years. Data from this study have shown that, although cardiovascular risk rises progressively as total cholesterol concentration increases (*Fig. 28.4*), the increase in risk is modest for individuals with no other cardiovascular risk factors. With each additional risk factor, the effect produced by the same difference in cholesterol concentration becomes greatly magnified. The Framingham Study has reproduced these findings in a separate population.
HDL cholesterol
Epidemiological studies have shown that higher HDL concentrations protect against cardiovascular disease. Raising HDL by pharmacological means does not, however, necessarily reduce cardiovascular risk. HDL also has effects on the function of platelets and of the haemostatic cascade. These properties may favourably influence thrombogenesis.

VLDL particles (triglycerides)
There is a relatively weak independent link between raised concentrations of (triglyceride-rich) VLDL particles and cardiovascular risk. Very raised triglyceride concentrations (>6 mmol/L) cause a greatly increased risk of acute pancreatitis and retinal vein thrombosis. Hypertriglyceridaemia tends to occur in association with a reduced HDL concentration. Much of the cardiovascular risk associated with ‘hypertriglyceridaemia’ turns out, on multivariate analysis, to be due to the associated low HDL levels and not to the hypertriglyceridaemia itself.

Chylomicrons
Excess chylomicrons do not confer an excess cardiovascular risk but do raise the total plasma triglyceride concentration.

Hyperlipidaemia
Hyperlipidaemia results from genetic predisposition interacting with an individual’s diet.

Secondary hyperlipidaemia
If a lipid disorder has been detected, it is vital to carry out a clinical history, examination and simple special investigations to detect the causes of secondary hyperlipidaemia (Box 28.1), which may need treatment in their own right. Hypothyroidism, diabetes, renal disease and abnormal liver function can all raise plasma lipid levels.

### Box 28.1

**Causes of secondary hyperlipidaemia**

- Hypothyroidism
- Diabetes mellitus (when poorly controlled)
- Obesity
- Chronic kidney disease
- Nephrotic syndrome
- Dysglobulinaemia
- Hepatic dysfunction and cholestasis
- Alcohol in susceptible individuals
- Anorexia nervosa
- Drugs:
  - Oral contraceptives in susceptible individuals
  - Retinoids, thiazide diuretics, corticosteroids, beta-blockers, sirolimus (and other immunosuppressive agents), anti-retrovirals

---

**Primary hyperlipidaemia**

The functional/genetic classification has the advantage that the genetic disorders may be grouped on the results of simple lipid biochemistry into causes of:

- disorders of VLDL and chylomicrons – hypertriglyceridaemia alone
- disorders of LDL – hypercholesterolaemia alone
- disorders of HDL
- combined hyperlipidaemia.

### Disorders of VLDL and chylomicrons – hypertriglyceridaemia alone

The majority of cases appear to be due to multiple genes acting together to produce a modest excess of circulating concentration of VLDL particles, such cases being termed polygenic hypertriglyceridaemia.

In a proportion of cases, there will be a family history of a lipid disorder or its effects (e.g. pancreatitis). Such cases are often classified as familial hypertriglyceridaemia. The defect
underlying the majority of such cases is not understood. Apoprotein A5 deficiency underlies some cases. The main clinical feature is a history of attacks of pancreatitis or retinal vein thrombosis in some individuals.

Lipoprotein lipase deficiency and apoprotein CII deficiency

These are rare diseases that produce greatly elevated triglyceride concentrations owing to the persistence of chylomicrons (and not VLDL particles) in the circulation. The chylomicrons persist because the triglyceride within cannot be metabolized if the enzyme lipoprotein lipase is defective, or because the triglycerides cannot gain access to the normal enzyme owing to deficiency of the apoprotein CII on their surface. Patients present in childhood with eruptive xanthomas, lipaemia retinalis and retinal vein thrombosis, pancreatitis and hepatosplenomegaly. If disease is not identified in childhood, it can present in adults with gross hypertriglyceridaemia resistant to simple measures. The presence of chylomicrons floating like cream on top of fasting plasma suggests this diagnosis. It is confirmed by plasma electrophoresis or ultracentrifugation. An abnormality of apoprotein C can be deduced if the hypertriglyceridaemia improves temporarily after infusing fresh frozen plasma, and lipoprotein lipase deficiency is likely if it does not.

Disorders of LDL – hypercholesterolaemia alone

Heterozygous familial hypercholesterolaemia

This is an autosomal dominant monogenic disorder present in 1 in 500 of the normal population. The average primary care physician would therefore be expected to have four such patients, but because of clustering within families the prevalence varies. There is an increased prevalence in some racial groups (e.g. French Canadians, Finns, South Africans). Surprisingly, most individuals with this disorder remain undetected. Patients may have no physical signs, in which case the diagnosis is made on the presence of very high plasma cholesterol concentrations that are unresponsive to dietary modification and are associated with a typical family history of early cardiovascular disease. Diagnosis can more easily be made if typical clinical features are present. These include xanthomatous thickening of the Achilles tendons and xanthomas over the extensor tendons of the fingers. Xanthelasma may be present but is not diagnostic of familial hypercholesterolaemia.

The most common genetic defect is under-production or malproduction of the LDL cholesterol clearance receptor in the liver (Box 28.2). Over 150 different mutations in the LDL receptor have been described to date. Mutations affecting the serine protease activity of PCSK9 (see p. 1278) are rarer and also cause familial hypercholesterolemia. Fifty per cent of men with the disease will die by the age of 60, most from coronary artery disease, if untreated.

Homozygous familial hypercholesterolaemia

This condition is very rare indeed. Affected children have no LDL receptors in the liver. They have a hugely elevated LDL cholesterol concentration, and massive deposition of lipid in arterial walls, aorta and skin. The natural history is for death from ischaemic heart disease in late childhood or adolescence. Repeated plasmapheresis has been used to remove LDL cholesterol with some success. Liver transplantation is a ‘cure’. Plasma lipids normalize and xanthomas regress after transplantation, but the number of patients having undergone this procedure is small. Two orphan drugs are licensed for use (Box 28.3).

Mutations in the apoprotein B100 gene
These cause another relatively common single-gene disorder. Since LDL particles bind to their clearance receptor in the liver through apoprotein B100, this defect also results in high LDL concentrations in the blood, and a clinical picture that closely resembles classical heterozygous familial hypercholesterolaemia. The two disorders can be distinguished clearly only by genetic tests. The approach to treatment is the same.

Polygenic hypercholesterolaemia
This is a term used to lump together patients with raised serum cholesterol concentrations, but without one of the monogenic disorders above. They exist in the right-hand tail of the normal distribution of cholesterol concentration. The precise nature of the polygenic variation in plasma cholesterol concentration remains unknown. Variations in the apoprotein E gene (chromosome 19) and in the sterol-regulatory element-binding protein (SREBP)-2 gene are involved in some individuals in this heterogeneous group.

Disorders of HDL (very low HDL, low total cholesterol)
Tangier disease
This is an autosomal recessive disorder characterized by a low HDL cholesterol
concentration. Cholesterol accumulates in reticuloendothelial tissue and arteries, causing enlarged, orange-coloured tonsils and hepatosplenomegaly. Cardiovascular disease, corneal opacities and a polyneuropathy also occur. It is due to a gene mutation (ABC1 gene; see Box 28.2), which normally promotes cholesterol uptake from cells by HDL particles.

Other mutations in this gene have been found in a few families with autosomal dominant HDL deficiency. It is as yet unknown whether abnormalities of this gene contribute to the low HDL cholesterol concentrations commonly seen in cardiovascular disease patients.

**Combined hyperlipidaemia (hypercholesterolaemia and hypertriglyceridaemia)**

The most common patient group is characterized by a polygenic combined hyperlipidaemia. Patients have an increased cardiovascular risk due to both high LDL concentrations and suppression of HDL by the hypertriglyceridaemia.

**Familial combined hyperlipidaemia**

This is relatively common, affecting 1 in 200 of the general population. The genetic basis for the disorder has not yet been characterized. It is diagnosed by finding raised cholesterol and triglyceride concentrations in association with a typical family history. There are no typical physical signs.

**Remnant hyperlipidaemia**

This is a rare (1 in 5000) cause of combined hyperlipidaemia. It is due to accumulation of LDL remnant particles and is associated with an extremely high risk of cardiovascular disease. It may be suspected in a patient with raised total cholesterol and triglyceride concentrations by finding xanthomas in the palmar creases (diagnostic) and the presence of tuberous xanthomas, typically over the knees and elbows (Fig. 28.5). Remnant hyperlipidaemia is almost always due to the inheritance of a variant of the apoprotein E allele (apoprotein E2), together with an aggravating factor such as another primary hyperlipidaemia. When suspected clinically, the diagnosis can be confirmed using ultracentrifugation of plasma or by phenotyping apoprotein E.
Management of hyperlipidaemia

The lipid-lowering diet

Studies have shown that dieticians helping patients to adjust their own diet to meet the nutritional targets set out below produce a better lipid-lowering effect than does the issuing of standard diet sheets and advice from a doctor. The main elements of a lipid-lowering diet are similar to those for people with diabetes (see Box 27.7). Additional specific measures are to:

- reduce consumption of liver, offal and fish roes to lower dietary cholesterol
- reduce alcohol consumption, since this may worsen primary lipid disorders at doses that would not affect normal individuals
- include foods containing plant stanols in the diet.

Plant stanols reduce the absorption of cholesterol from the intestine by competing for space in the micelles that deliver lipid to the mucosal cells of the gut. They are largely unabsorbed and are excreted in the stool. Increasing the amount of plant stanol in the diet tenfold by using a margarine (e.g. Benecol) containing added stanol esters lowers LDL cholesterol by approximately 0.35–0.5 mmol/L. A reduction in the risk of heart disease of about 25% would be expected if this reduction in LDL cholesterol were applied to a population.

Exercise, weight loss and smoking

Taking regular physical exercise, losing weight and stopping smoking all reduce the level of cardiovascular risk, irrespective of lipid levels.

Drugs

The classes of drugs used to treat hyperlipidaemia are described in Box 28.3 and principles of use in Box 28.4. Statins are the most widely used lipid-lowering agents. Generalized muscular aches are the most common adverse effect, occasionally leading to a frank myopathy. These
adverse events occur more frequently in people with a single nucleotide polymorphism (SNP) in a gene region coding for a liver-specific organic anion transporter protein (solute carrier organic anion transporter \( IBI - SLCOIB1 \)), which leads to a decreased hepatic uptake of the statin and higher statin levels in the serum. New classes of lipid-lowering drugs in development are listed in Box 28.5.

HDL, high-density lipoprotein; LDL, low-density lipoprotein.

Screening

Most patients with hyperlipidaemia are asymptomatic and have no clinical signs. Many are discovered during the screening of high-risk individuals. Whose lipids should be measured? There are great doubts as to whether blanket screening of plasma lipids is warranted. Selective screening of people at high risk of cardiovascular disease should be undertaken in these circumstances:

- a family history of coronary heart disease (especially below 50 years of age)
- a family history of lipid disorders
- the presence of a xanthoma
- the presence of xanthelasma or corneal arcus before the age of 40 years
- obesity
- diabetes mellitus
- hypertension
- acute pancreatitis
- patients undergoing renal replacement therapy.

Where one family member is known to have a monogenic disorder, such as familial hypercholesterolaemia (1 in 500 of the population), siblings and children must have their plasma lipid concentrations measured. It is also worth screening the prospective partners of any patients with this heterozygous monogenic lipid disorder because of the small risk of producing children who are homozygous for the condition.

Acute severe illnesses, such as myocardial infarction, can derange plasma lipid concentrations for up to 3 months. Plasma lipid concentrations should be measured either within 48 hours of an acute myocardial infarction (before derangement has had time to occur)
or 3 months later.

Serum cholesterol concentration does not change significantly after a meal and as a screening test a random blood sample is sufficient. If the total cholesterol concentration is raised, HDL cholesterol, triglyceride and LDL cholesterol concentrations should be quantitated on a fasting sample. If a test for hypertriglyceridaemia is needed, a fasting blood sample is mandatory.

**Management of hypertriglyceridaemia**

A serum triglyceride concentration below 2.0 mmol/L is normal. In the range 2.0–6.0 mmol/L, no specific intervention will be needed unless there are coincident cardiovascular risk factors, and in particular a strong family history of early cardiovascular death. In general, patients should be alerted to the fact that they have a minor lipid problem; they should be offered advice on weight reduction if obese, and on correction of other cardiovascular risk factors.

If the triglyceride concentration is above 6.0 mmol/L, there is a risk of pancreatitis and retinal vein thrombosis. Patients should be advised to reduce their weight if overweight and start a formal lipid-lowering diet (see above). A proportion of individuals with hypertriglyceridaemia have livers that respond to even moderate degrees of alcohol intake by allowing accumulation or excess production of VLDL particles. If hypertriglyceridaemia persists, lipid measurements should be repeated before and after a 3-week interval of complete abstinence from alcohol. If a considerable improvement results, life-long abstinence may prove necessary. Other drugs, including thiazides, oestrogens and glucocorticoids, can have a similar effect to alcohol in susceptible patients.

If the triglyceride concentration remains above 6.0 mmol/L, despite the above measures, drug therapy is warranted (see Boxes 28.3 and 28.4). The severe hypertriglyceridaemia associated with the rare disorders of lipoprotein lipase deficiency and apoprotein CII deficiency may require restriction of dietary fat to 10–20% of total energy intake and the use of special preparations of medium-chain triglycerides in cooking in place of oil or fat. Medium-chain triglycerides are not absorbed via chylomicrons (see p. 1277).

**Management of hypercholesterolaemia (without hypertriglyceridaemia)**

**Familial hypercholesterolaemia**

Individuals often require treatment with dietary measures and more than one cholesterol-lowering drug. The cholesterol absorption inhibitor ezetimibe is a logical addition to a statin and has a low side-effect profile (see Boxes 28.3 and 28.4). Bile acid sequestrants are an alternative to ezetimibe but there are problems with tolerability. Concurrent therapy with statins and fibrates, particularly fenofibrate, can be used in severe cases. Checking for muscle symptoms and measuring creatine kinase are necessary.

**Primary prevention for people with risk factors**
Lipid-lowering therapy with a statin, or alternatives as above, is used in asymptomatic individuals with type 2 diabetes alone, unless there are no other risk factors and the LDL cholesterol is particularly low (<1.8 mmol/L). It is also used in people with two or more of the following factors: positive family history of cardiovascular disease, albuminuria, hypertension and smoking.

**Primary prevention for people without risk factors**

In the absence of risk factors, lipid-lowering therapy can be used in asymptomatic men with LDL cholesterol levels persistently above 5.0 mmol/L despite dietary change. The situation for women is less clear.

**Secondary prevention**

As a generality, statin treatment is warranted for any patient with known macrovascular disease (coronary artery disease, transient ischaemic attack or stroke, peripheral vascular disease), irrespective of the total or LDL cholesterol level (treatment target is total cholesterol <4.0 mmol/L and LDL <2 mmol/L; alternatively, the maximum tolerated statin dose can be used). If a statin is not tolerated, combinations of other agents are tried (see Box 28.4).

**Risk prediction tables**

An array of risk prediction tables (see p. 993) is available to allow quantification of the risk of a patient having a cardiovascular event within the next 10 years. The authors side with those who have reservations over their use. Such risk analyses are a useful approach in helping to decide whether to use treatments such as aspirin. Aspirin probably has no effect until the day an atherosclerotic plaque ruptures, when it may then prevent thrombosis leading to a heart attack or stroke. Furthermore, it has a significant associated morbidity and mortality (from bleeding). At a 10-year cardiovascular risk level of 15%, the benefit : risk ratio for aspirin becomes favourable. At the 30% level, the benefits are clear.

By contrast, the use of lipid-lowering agents, if initially tolerated, has a low associated morbidity and mortality. These agents probably reduce the rate of atheroma accumulation over decades. When a patient is young, the chance that atheroma will be bad enough to cause a heart attack or stroke within the next 10 years will be small, even if atheroma is accumulating at a swift rate. The level of cardiovascular risk will only rise when the patient gets older. It seems bizarre, however, not to treat the gradual accumulation of atheroma when the patient is young with a low 10-year risk, and then to start treatment when age causes the 10-year risk levels to rise to a particular threshold, if all other factors are the same. In choosing whether or not to prescribe, the authors prefer to consider whether the patients will live long enough to collect some pension and see their grandchildren, rather than asking whether they will have a heart attack or stroke within the next 10 years. The answers to these two questions are very different. The American Heart Association risk calculator predicts both 10-year risk and lifetime risk, and aids discussion of treatment with patients.
Management of combined hyperlipidaemia

Treatment is the same for all varieties of combined hyperlipidaemia (hypercholesterolaemia and hypertriglyceridaemia). For any given cholesterol concentration, the hypertriglyceridaemia found in the combined hyperlipidaemias increases the cardiovascular risk considerably. Treatment is aimed at reducing serum cholesterol below 4.0 mmol/L and triglycerides below 2.0 mmol/L. Therapy is with diet in the first instance and then with drugs if an adequate response has not occurred. Fibrates are the treatment of choice since these reduce both cholesterol and triglyceride concentrations, and also have the benefit of raising cardioprotective HDL concentrations. Combination with other agents is often needed (see Box 28.4).

Other lipid disorders

Hypolipidaemia

Low lipid levels can be found in severe protein–energy malnutrition. They are also seen occasionally with severe malabsorption and in intestinal lymphangiectasia.

Hypobetalipoproteinaemia (see Box 28.2) is a benign familial condition that is increasingly recognized. The cholesterol levels are in the range 1–3.5 mmol/L.

Abetalipoproteinaemia

This is described on page 402.

Inborn Errors of Carbohydrate Metabolism

Glycogen storage disease

All mammalian cells can manufacture glycogen, but the main sites of production are the liver and muscle. Glycogen is a high-molecular-weight glucose polymer made up of 1–4 linked
glucose units, with a 1–6 branch point every 4–10 residues. In glycogen storage disease (GSD), there is either an abnormality in the molecular structure or an increase in glycogen concentration owing to a specific enzyme defect. Almost all of these conditions are autosomal recessive in inheritance and present in infancy, except for McArdle's disease, which presents in adults.

Box 28.6 shows the classification and clinical features of some of these diseases. Five types – GSDI, GSDIII, GSDVI and GSD VIII involving liver, and GSDII involving skeletal muscle – make up the majority of cases.

Box 28.6

*Tissue obtained is used for the biochemical assay of the enzyme. % = percentage of total number of cases in USA and Europe.

---

**Galactosaemia**

Galactose is normally converted to glucose. However, a deficiency of the enzyme *galactose-1-phosphate uridyl-transferase* or, less commonly, *uridine diphosphate galactase-4-epimerase*, results in accumulation of galactose-1-phosphate in the blood. The transferase deficiency, inherited as an autosomal recessive condition, is due in 70% of patients to a
glutamine-to-arginine missense mutation in Q188R. Galactose ingestion (i.e. milk) leads to inanition, failure to thrive, vomiting, hepatomegaly and jaundice, diabetes, cataracts and developmental delay. A lactose-free diet stops the acute toxicity, but poor growth and problems with speech and mental development still occur with the transferase deficiency. A newborn screening programme to detect galactosaemia is in place in parts of the USA and other countries.

Prenatal diagnosis and diagnosis of the carrier state are possible by measurement of red cell galactose-1-phosphate activity. DNA analysis is available for common mutations.

*Galaktokinase deficiency* also results in galactosaemia and early cataract formation.

### Defects of fructose metabolism

Absorbed fructose is chiefly metabolized in the liver to lactic acid or glucose. Three defects of metabolism in the liver and intestine occur, all of which are inherited as autosomal recessive traits:

- **Fructosuria** is due to fructokinase deficiency. It is a benign asymptomatic condition.

- **Hereditary fructose intolerance** is due to fructose-1-phosphate aldolase deficiency. Fructose-1-phosphate accumulates after fructose ingestion, inhibiting both glycogenolysis and gluconeogenesis, resulting in symptoms of severe hypoglycaemia. Hepatomegaly and renal tubular defects occur but are reversible on a fructose- and sucrose-free diet. Intelligence is normal and there is an absence of dental caries.

- **Hereditary fructose-1,6-diphosphatase deficiency** leads to a failure of gluconeogenesis. Infants present with hypoglycaemia, ketosis and lactic acidosis. Dietary control can lead to normal growth.

### Inborn Errors of Amino Acid Metabolism

Inborn errors of amino acid metabolism are chiefly inherited as autosomal recessive conditions. The major ones are shown in *Box 28.7*.

#### Box 28.7

The major inborn errors of amino acid metabolism
There are many other enzyme defects producing, for example, alaninaemia, ammonaemia, argininaemia, citrullinaemia, isovaleric acidaemia, lysinaemia, ornithinaemia or tyrosinaemia.

**Amino acid transport defects**

Amino acids are filtered by the glomerulus, but 95% of the filtered load is reabsorbed in the proximal convoluted tubule by an active transport mechanism. Aminoaciduria results from:

- abnormally high plasma amino acid levels (e.g. phenylketonuria)
- any inherited disorder that damages the tubules secondarily (e.g. galactosaemia)
- tubular reabsorptive defects, either generalized (e.g. Fanconi syndrome) or specific (e.g. cystinuria).

Amino acid transport defects can be congenital or acquired.

**Generalized aminoacidurias**

**Fanconi syndrome**
This occurs in a juvenile form (De Toni–Fanconi–Debré syndrome); in adult life, it is often acquired through, for example, heavy metal poisoning, drugs or some renal diseases. There is a generalized defective proximal tubular reabsorption of most amino acids, glucose, urate and phosphate, resulting in hypophosphataemic rickets and bicarbonate, with failure to transport hydrogen ions, causing a renal tubular acidosis that then produces a hyperchloremic acidosis (see pp. 177–178).

Other abnormalities include potassium depletion, primary or secondary to the acidosis, polyuria, and increased excretion of immunoglobulins and other low-molecular-weight proteins.

Various combinations of the above abnormalities have been described.

The juvenile form begins at the age of 6–9 months, with failure to thrive, vomiting and thirst. The clinical features are as a result of fluid and electrolyte loss and the characteristic vitamin D-resistant rickets.

In the adult, the disease is similar to the juvenile form but osteomalacia is a major feature.

Treatment of the bone disease is with large doses of vitamin D (e.g. 1–2 mg of 1-α-hydroxycholecalciferol with regular blood calcium monitoring). Fluid and electrolyte loss needs to be corrected.

Specific aminoacidurias

Cystinuria

There is a defective tubular reabsorption and jejunal absorption of cystine and the dibasic amino acids, lysine, ornithine and arginine. Cystinuria is either a completely or an incompletely autosomal recessive disorder with mutations in two genes, SLC3A1 and SLC7A9. Cystine absorption from the jejunum is impaired but, nevertheless, cystine in peptide form can be absorbed. Cystinuria leads to urinary stones and is responsible for approximately 1–2% of all urinary calculi. The disease often starts in childhood, although most cases present in adult life.

Treatment is described on pages 756–757.

The condition cystinosis must not be confused with cystinuria. Cystinosis is characterized by the accumulation of cystine in different organs, leading to organ dysfunction, e.g. photophobia and ocular problems, and chronic kidney disease. Management is with cysteamine.

Hartnup's disease

There is defective tubular reabsorption and jejunal absorption of most neutral amino acids but not their peptides. The resulting tryptophan malabsorption produces nicotinamide deficiency (see p. 199). Patients can be asymptomatic but others develop evidence of pellagra (see pp. 199–200).

Management is with nicotinamide.
**Other aminoacidurias**

Tryptophan malabsorption syndrome (blue diaper syndrome), familial iminoglycinuria and methionine malabsorption syndrome have all been described.

**Lysosomal Storage Diseases**

Lysosomal storage diseases are due to inborn errors of metabolism, which are mainly inherited in an autosomal recessive manner.

---

**Glucosylceramide lipidoses: Gaucher's disease**

This is the most prevalent lysosomal storage disease and is caused by a deficiency in glucocerebrosidase, a specialized lysosomal acid β-glucosidase. This results in accumulation of glucosylceramide in the lysosomes of the reticuloendothelial system, particularly the liver, bone marrow and spleen. Over 200 mutations have been characterized in the glucocerebrosidase gene (1q21), the most common being a single base change (N370S) that causes the substitution of arginine for serine; this is seen in 70% of Jewish patients. The typical Gaucher cell, a glucocerebroside-containing reticuloendothelial histiocyte, is found in the bone marrow, producing many cytokines such as CD14.

There are three clinical types, the most common presenting in childhood or adult life with an insidious onset of hepatosplenomegaly (**type 1**). There is a high incidence in Ashkenazi Jews (1 in 3000 births), and patients have characteristic pigmentation on exposed parts, particularly the forehead and hands. The clinical spectrum is variable, with patients developing anaemia, evidence of hypersplenism and pathological fractures that are due to bone involvement. Nevertheless, many have a normal lifespan. The diagnosis is made on finding reduced glucocerebrosidase in leucocytes. Mutational analysis will confirm the diagnosis. Plasma chitotriosidase (an enzyme secreted by activated macrophages) is grossly elevated in Gaucher's disease and other lysosomal disorders; it is used to monitor enzyme replacement therapy.

Acute Gaucher's disease (**type 2**) presents in infancy with rapid onset of hepatosplenomegaly, and neurological involvement owing to the presence of Gaucher cells in the brain. The outlook is very poor.

**Type 3** presents in childhood or adolescence with a variable progression of hepatosplenomegaly, neurodegeneration and bone disease. Again, the outlook is poor.
Management

There are currently four glucocerebrosidases available (eliglustat, imiglucerase, taliglucerase alfa and velaglucerase). These are produced by recombinant DNA technology and are given intravenously; they are typical ‘orphan drugs’. They are used in people with type 1 disease, and in most with type 3 disease. This enzyme replacement treatment decreases liver and splenic size and reverses other manifestations. Glucocerebrosidase treatment costs the price of a small house per patient per year. Oral miglustat (an inhibitor of glucosylceramide synthase) prevents the production of glucocerebroside and is used for mild to moderate type 1 Gaucher's disease.

Sphingolipidoses: Niemann–Pick disease

This condition is due to a deficiency of lysosomal sphingomyelinase, which results in the accumulation of sphingomyelin cholesterol and glycosphingolipids in the reticuloendothelial macrophages of many organs, particularly the liver, spleen, bone marrow and lymph nodes. The disease usually presents within the first 6 months of life with mental retardation and hepatosplenomegaly; a particular type (11c) presents in adults with dementia. The gene frequency is 1:100 in Ashkenazi Jews, the diagnosis being made in the group by targeted mutation analysis. Typical foam cells are found in the marrow, lymph nodes, liver and spleen.

Mucolipidosis

The mucolipidoses are a group of disorders caused by the deficiency of lysosomal enzymes (e.g. α-L-iduronidase) required for the catabolism of glycosaminoglycans (mucopolysaccharides).

The catabolism of dermatan sulphate, heparan sulphate, keratin sulphate or chondroitin sulphate may be affected either singularly or together.

Accumulation of glycosaminoglycans in the lysosomes of various tissues results in the disease. Ten forms of mucopolysaccharidosis (MPS) have been described; all are chronic but progressive, and a wide spectrum of clinical severity can be seen within a single enzyme defect. The MPS types show many clinical features, though in variable amounts, with dysostosis, abnormal facies, poor vision and hearing, and joint dysmobility (either stiff or hypermobile) frequently seen. Mental retardation is present in, for example, Hurler (MPS IH) and San Filippo A (MPS IIIA) types, but normal intelligence and lifespan are seen in Scheie syndrome (MPS IS). L-aronidase infusion reduces lysosomal storage, resulting in clinical improvement.

The GM2 gangliosidoses

In these conditions, there is accumulation of GM2 gangliosides in the central nervous system
and peripheral nerves. It is particularly common (1 in 2000) in Ashkenazi Jews. Tay–Sachs disease is the severest form, where there is a progressive degeneration of all cerebral function, with fits, epilepsy, dementia and blindness, and death usually occurs before 2 years of age. The macula has a characteristic cherry spot appearance.

### Fabry's disease

This X-linked recessive condition involves the glycosphingolipid pathway. There is a deficiency of lysosomal hydrolase (α-galactosidase A). This enzyme is encoded by the gene on the Xq22.1 region of the X chromosome. Many mutations have been described and genetic analysis is used in the diagnosis, causing an accumulation of globotriaosylceramide with terminal α-galactosyl moieties in the lysosomes of various tissues, including the liver, kidney, blood vessels and the ganglion cells of the nervous system. The patients present with peripheral nerve involvement, gastrointestinal symptoms/abdominal pain, diarrhoea and early satiety, but eventually most have a cardiomyopathy, strokes and kidney disease in adult life. An absent or very low level of α-galactosidase A in leucocytes confirms the diagnosis. Genetic testing is available. Treatment is with agalsidase α-β infusions.

### Diagnosis

Many of the sphingolipidoses can be diagnosed by demonstrating the enzyme deficiency, usually in peripheral blood leucocytes.

Prenatal diagnosis is possible in a number of the conditions by obtaining specimens of amniotic cells. Carrier states can also be identified, so that sensible genetic counselling can be given.

www.genetests.org Information on genetic testing.

### Amyloidosis

Amyloidosis is a disorder of protein metabolism, in which there is extracellular deposition of pathological insoluble fibrillar proteins in organs and tissues. Characteristically, the amyloid protein consists of β-pleated sheets that are responsible for its insolubility and resistance to proteolysis.

Amyloidosis can be acquired or inherited. Classification is based on the nature of the precursor plasma proteins (at least 20) that form the fibrillar deposits. The process for the production of these fibrils appears to be multifactorial and differs amongst the various types of amyloid.
**AL amyloidosis (immunoglobulin light chain-associated)**

This is a plasma cell dyscrasia, related to multiple myeloma, in which clonal plasma cells in the bone marrow produce immunoglobulins that are amyloidogenic. This may be the outcome of destabilization of light chains owing to substitution of particular amino acids into the light chain variable region. There is a clonal dominance of amyloid light (AL) chains – either the dominant κ or γ isotype – which are excreted in the urine (Bence Jones proteins). This type of amyloid is often associated with lymphoproliferative disorders, such as myeloma, Waldenström's macroglobulinaemia or non-Hodgkin's lymphoma. It rarely occurs before the age of 40 years.

The clinical features are related to the organs involved. These include the kidneys (presenting with proteinuria and the nephrotic syndrome) and the heart (presenting with heart failure). Autonomic and sensory neuropathies are relatively common, and carpal tunnel syndrome with weakness and paraesthesia of the hands may be an early feature. Sensory neuropathy is common. There is an absence of central nervous system involvement.

On examination, hepatomegaly and, rarely, splenomegaly, cardiomyopathy, polyneuropathy and bruising may be seen. Macroglossia occurs in about 10% of cases and periorbital purpura in 15%.

**Familial amyloidoses (transthyretin-associated, ATTR)**

These are autosomal dominant transmitted diseases where the mutant protein forms amyloid fibrils, starting usually in middle age. The most common form is due to a mutant – transthyretin – which is a tetrameric protein with four identical subunits. It is a transport protein for thyroxine and retinol-binding protein, and is mainly synthesized in the liver. Over 80 amino acid substitutions have been described; for example, a common substitution is that of methionine for valine at position 30 (Met 30) in all racial groups, and alanine for threonine (Ala 60) in the English and Irish. These substitutions destabilize the protein, which precipitates following stimulation, and can cause disorders such as familial amyloidotic polyneuropathy (FAP), cardiomyopathy or the nephrotic syndrome. Major foci of FAP occur in Portugal, Japan and Sweden.

Other less common variants include mutations of apoprotein Al, gelsolin, fibrinogen Aα and lysozyme.

Clinically, peripheral sensorimotor and autonomic neuropathy is common, with symptoms of autonomic dysfunction, diarrhoea and weight loss. Renal disease is less prevalent than with AL amyloidosis. Macroglossia does not occur. Cardiac problems are usually those of conduction. There may be a family history of unidentified neurological disease.

Other hereditary systemic amyloidoses include various familial amyloid polyneuropathies (e.g. Portuguese, Icelandic, Dutch). There is a familial Creutzfeldt–Jakob disease. In familial Mediterranean fever, renal amyloidosis is a common serious complication.
Reactive systemic (secondary AA) amyloidoses

These are due to amyloid formed from serum amyloid A (SAA), which is an acute phase protein. It is, therefore, related to chronic inflammatory disorders and chronic infection. Clinical features depend on the nature of the underlying disorder. Chronic inflammatory disorders include rheumatoid arthritis, inflammatory bowel disease and untreated familial Mediterranean fever. In developing countries, it is still associated with infectious diseases such as tuberculosis, bronchiectasis and osteomyelitis. AA amyloidosis often presents with chronic kidney disease, with hepatomegaly and splenomegaly. Macroglossia is not a feature and cardiac involvement is rare. The degree of renal failure correlates with the SAA level in a more favourable outcome in patients with low normal levels.

Other amyloids

Cerebral amyloidosis, Alzheimer's disease and transmissible spongiform encephalopathy

The brain is a common site of amyloid deposition, although it is not directly affected in any form of acquired systemic amyloidosis. Intracerebral and cerebrovascular amyloid deposits are seen in Alzheimer's disease. Most cases are sporadic, but hereditary forms caused by mutations have been reported. In hereditary spongiform encephalopathies, several amyloid plaques have been seen.

Amyloid deposits are frequently found in the elderly, particularly cerebral deposits of A4 protein. This is also seen in Down syndrome. Apoprotein E (involved in LDL transport; see pp. 1277–1278) interacts directly with β-A4 protein in senile plaques and neurofibrillary tangles in the brain. The gene for apoprotein E is on chromosome 19 and may be a susceptibility factor in the aetiology of Alzheimer's disease.

Local amyloidosis

Deposits of amyloid fibrils of various types can be localized to various organs or tissues (e.g. skin, heart and brain).

Dialysis-related amyloidosis

This is due to the β2-microglobulin-producing amyloid fibrils in chronic dialysis patients (see p. 784). It frequently presents with the carpal tunnel syndrome.

Diagnosis

This is based on clinical suspicion and, if possible, on tissue histology. Amyloid in tissues appears as an amorphous, homogeneous substance that stains pink with haematoxylin and eosin, and stains red with Congo red. It also has a green fluorescence in polarized light. Tissue
can be obtained from the rectum, gums or fat pad. The bone marrow may show plasma cells in amyloidosis or a lymphoproliferative disorder. A paraproteinaemia and proteinuria with light chains in the urine may also be seen in AL amyloidosis. In secondary or reactive amyloidosis, there will be an underlying disorder. Scintigraphy using $^{123}$I-labelled serum amyloid P component is useful for the assessment of AL, ATTR and AA amyloidosis, but it is not widely available and is expensive.

**Management**

This is symptomatic or relates to the associated disorder. The nephrotic syndrome and congestive cardiac failure require the relevant therapies. Treatment of any inflammatory source or infection should be instituted. Colchicine may help familial Mediterranean fever. Eprodisate, which interferes with interactions between amyloid proteins and glycosaminoglycans, inhibits polymerization of amyloid fibroids; it slows the fall in renal function in AA amyloidosis. Chemotherapy is with melphalan plus dexamethasone in AL amyloidosis. Stem cell therapy is also used. In ATTR amyloidosis, where transthyretin is predominantly synthesized in the liver, liver transplantation (when there would be a disappearance of the mutant protein from the blood) is considered as the definitive therapy.

**The Porphyrias**

This heterogeneous group of rare inborn errors of metabolism is caused by abnormalities of enzymes involved in the biosynthesis of haem, resulting in overproduction of the intermediate compounds called ‘porphyrins’ *(Fig. 28.6)*. The porphyrias show extreme genetic heterogeneity. For example, in acute intermittent porphyria, more than 90 mutations have been identified in the porphobilinogen deaminase gene. One mutation has a high prevalence in patients in northern Sweden, suggesting a common ancestor.
Structurally, porphyrins consist of four pyrrole rings. These pyrrole rings are formed from the precursors glycine and succinyl-CoA, which are converted to δ-aminolaevulinic acid (δ-ALA) in a reaction catalysed by the enzyme δ-ALA synthase. Two molecules of δ-ALA condense to form a pyrrole ring.

Porphyrins can be divided into uroporphyrins, coproporphyrins or protoporphyrins, depending on the structure of the side-chain. They are termed type I if the structure is symmetrical, and type III if it is asymmetrical. Both uroporphyrins and coproporphyrins can be excreted in the urine.

The sequence of enzymatic changes in the production of haem is shown in Figure 28.6. The chief rate-limiting step is the enzyme δ-ALA synthase. This has two isoforms, ALA-N (non-erythroid) and ALA-E (erythroid). ALA-N is under negative feedback by haem but is upregulated by drugs and chemicals; there is no known inherited deficiency and the gene is on 3p21. Conversely ALA-E, encoded by Xp11.21, is unaffected by drugs or haem, and an inherited deficiency causes X-linked sideroblastic anaemia (Fig. 28.6). Consequently:

• Haem (endogenous or exogenous) produces remission of hepatic porphyria.
• Chemicals and drugs can produce disease.
• Erythropoietic porphyria gives constant symptoms and is affected by sunlight.

Clinical features

All of the haem intermediates shown in Figure 28.6 are potentially toxic. Three patterns of
symptoms occur in the various types of porphyria:

• neurovisceral (Box 28.8)

---

**Box 28.8**

**Porphyria**

**Neurovisceral symptoms**

</tbody>
</table>

• photosensitive

• haemolytic anaemia.

The most common types of porphyria are acute intermittent porphyria (AIP), porphyria cutanea tarda (PCT) and erythropoietic porphyria (EPP).

**Neurovisceral pattern**

**Acute intermittent porphyria**

Acute intermittent porphyria (AIP) is an autosomal dominant disorder (Fig. 28.6). Presentation is in early adult life, usually around the age of 30 years, and women are affected more than men. It may be precipitated by alcohol and by drugs such as barbiturates and oral contraceptives; these are mostly cytochrome P450-inducers but a wide range of lipid-soluble drugs has also been incriminated. Acute attacks present with neurovisceral symptoms (Box 28.8). Symptoms of the rare, autosomal recessive aminolaevulinic acid dehydrogenase porphyria (ADP) are similar.

**Investigations**

A rapid semi-quantitative spot urine test for porphobilinogen (PBG) is often available. The urine turns red–brown or red on standing.

• **Blood count** is usually normal, with occasional neutrophil leucocytosis.
Liver biochemical tests demonstrate elevated bilirubin and aminotransferases.

Serum urea is often raised.

Urinary ALA and PBG are raised (24-h collection).

Erythrocyte PBG deaminase is decreased.

Screening

Family members should be screened to detect latent cases. Urinalysis is not adequate but measurement of erythrocyte PBG deaminase and ALA synthase is extremely sensitive.

Mixed neurovisceral and photocutaneous pattern

Variegate porphyria

Variegate porphyria (VP) combines neurovisceral symptoms with those of a cutaneous photosensitive porphyria (Fig. 28.6). A bullous eruption develops on exposure to sunlight owing to the activation of porphyrins deposited in the skin.

Investigation shows an elevated urinary ALA and PBG. Fluorescence emission spectroscopy of plasma differentiates this from other cutaneous porphyrias.

Hereditary coproporphyria

Hereditary coproporphyria (HCP) is extremely rare but is broadly similar in presentation to variegate porphyria.

Photocutaneous pattern

Porphyria cutanea tarda (cutaneous hepatic porphyria)

Porphyria cutanea tarda (PCT), which has a genetic predisposition, presents with a bullous blistering eruption on exposure to sunlight; the eruption heals with scarring. Alcohol is the most common aetiological agent but smoking, oestrogens, hepatitis C, iron overload/haemochromatosis or human immunodeficiency virus (HIV) can also precipitate the disease. Evidence of biochemical or clinical liver disease may also be present. Polychlorinated hydrocarbons have been implicated and porphyria cutanea tarda has been seen in association with benign or malignant tumours of the liver.

Hepatoerythropoietic porphyria (HEP; Fig. 28.6) is a rare disease that is clinically very similar to congenital erythropoietic porphyria and presents in childhood; haemolytic anaemia occurs. The defect in HEP is similar to that in PCT.

Diagnosis depends on demonstration of increased levels of plasma or urinary porphyrins. Histology of the skin shows subepidermal blisters with perivascular deposition of periodic acid–Schiff-staining material. The serum iron and transferrin saturation are often raised. Liver
biopsy shows mild iron overload, as well as features of alcoholic liver disease.

**Congenital erythropoietic porphyria**

Congenital erythropoietic porphyria (CEP) is extremely rare and is transmitted as an autosomal recessive trait. Patients show extreme sensitivity to sunlight and develop disfiguring scars. Dystrophy of the nails, blindness due to lenticular scarring, and brownish discoloration of the teeth also occur.

**Erythropoietic protoporphyria**

Erythropoietic protoporphyria (EPP) is more common than congenital erythropoietic porphyria and is inherited as an autosomal dominant trait. It presents with irritation and a burning pain in the skin, non-blistering, on exposure to sunlight. The liver is usually normal but protoporphyrin deposition can occur. Diagnosis is made by fluorescence of the peripheral red blood cells and by detection of increased protoporphyrin (total and free) in the red cells and stools.

**Management of porphyrias**

**Neurovisceral pattern**

**Acute episodes**

The management of acute episodes is largely supportive. Precipitating factors, such as drugs, should be stopped. Analgesics should be given (avoiding drugs that may aggravate an attack). Intravenous carbohydrates, such as glucose, inhibit ALA synthase activity. Intravenous haem arginate (human haemin) infusion reduces ALA and PBG excretion by exerting a negative effect on ALA synthase-N activity *(Fig. 28.6)* and shortens the duration of an attack; this is useful in a severe attack. Calorie and fluid intake should be maintained.

**Prevention in remission period**

This is by avoidance of possible precipitating factors, such as drugs and alcohol. Smoking cessation, treatment of infections and stress avoidance are helpful. Surgery can precipitate attacks. A high-carbohydrate diet should be maintained and haemin infusions may also help.

**Photocutaneous episodes**

**Acute episodes**

Acute attacks following exposure to ultraviolet light can only be treated symptomatically. However, venesection, which reduces urinary porphyria, can be used for PCT in both acute and remission phases. Chloroquine can also aid excretion by forming a water-soluble complex with uroporphyrins. Liver transplantation is used for severe cases.
Prevention

This is with avoidance of sunlight, and use of zinc-containing sunscreens and protective clothing. Oral β-carotene, which quenches free radicals, provides effective protection against solar sensitivity in EPP.

**Prescribing in pregnancy** 1309
Women are affected by both general and gender-specific medical problems. They have
predictable long-term reproductive healthcare needs and more frequent interactions with health services than men. Some 70% of women will have one or more pregnancies during their lives. In addition to complications relating to pregnancy and childbirth, and genital tract and breast cancers (see pp. 631–635), they also experience more severe forms of anaemia and osteoporosis (see pp. 711–715).

Women are also adversely affected by domestic violence and rape to a far greater extent than men. These determinants of ill-health and morbidity remain largely unrecognized alongside more general socioeconomic factors and mental health; women are more likely than men to report symptoms of common mental disorders.

**The Life Course Approach**

A life course approach (**Fig. 29.1**) addresses the long-term effects of biological, social and behavioural exposures during gestation, childhood, adolescence and young adulthood upon health, wellbeing and disease in later life and across generations. This perspective recognizes that early life events can have an impact on long-term outcomes, and that early interventions may reduce the risk and severity of disease.

![The life course approach: major health issues specifically affecting women as they age. HPV, human papillomavirus.](image)

Women's reproductive and sexual health needs are largely predictable across their lifespan. The vast majority of women want to enjoy healthy sexual relationships and control their own
Sexual health education

Early sexual health education for girls provides information on:
• optimal methods of contraception to avoid unplanned pregnancy
• risks of sexually transmitted diseases
• vaccination and screening programmes to prevent adult disease.

For example, human papillomavirus (HPV) vaccination for girls aged 11–13 years and Chlamydia trachomatis screening for those under 25 are linked to the prevention of cervical cancer, ectopic pregnancy and tubal infertility. These encounters provide early opportunities to discuss the long-term benefits of adopting a healthier lifestyle before embarking on a first pregnancy.

Early sex education has been shown to reduce the teenage pregnancy rate. Teenage mothers have some of the worst obstetric outcomes; 90% drop out of school and 20% become pregnant again. Forty per cent of pregnancies in the UK are unplanned and opportunities to provide general preconceptual advice on diet, weight, exercise, smoking, alcohol use and folic acid intake are often missed until the young woman presents pregnant.

• The provision of contraceptive, preconception and antenatal services is poorly integrated.
• Pre-pregnancy counselling allows a review of recent medication and ensures that a management plan for the pregnancy is in place.

The UK Confidential Enquiry into maternal mortality and morbidity reported in December 2014 that three-quarters of all the women who died had coexisting medical or mental health problems identified before they became pregnant and should have been offered pre-pregnancy advice and joint specialist and maternity care (see pp. 1302–1309).

The physiological response to pregnancy

The mother's physiological response to her pregnancy reveals information about risks of disease in later life. For example:
• Pre-eclampsia and gestational diabetes resolve after delivery but are associated with higher cardiovascular mortality in later life.
• Roughly 50% of women with gestational diabetes will develop type 2 diabetes within 10 years and children born of diabetic pregnancies are more likely to develop diabetes.
• Teenage pregnancies and premature deliveries repeat across generations.
• Mental health problems during pregnancy and the puerperium are associated with low birth weight and impaired intellectual development, as measured by lower IQ at age 3 years.

Pregnancy should be viewed as the Health Care Opportunity of Two Lifetimes (HOOTL, Fig. 29.2 ), which offers major potential for population health gain and is the first step on the
way to tackling and interrupting the cross-generational transmission of ill-health.

FIGURE 29.2 The Healthcare Opportunity of Two Lifetimes – HOOTL. IUGR, intrauterine growth retardation; PET, pre-eclampsia.

The postnatal visit

The postnatal visit is an ideal time to plan future healthcare needs for mother and baby, and can have a positive impact on lifestyle issues such as obesity, exercise, dental health, contraception, smoking and drug misuse. Review of the recent pregnancy will provide valuable predictions about future problems and their long-term prevention.

Nearly 20% of women in the UK now choose to remain childless. A smaller, but growing, number of women are pursuing assisted conception to overcome their age-related decline in fertility. These are at increased risk of serious complications during pregnancy due to medical co-morbidities.

The normal menstrual cycle

Definitions, including some disorders

• **Puberty** (see p. 1214). The mean age of menarche is 12.8 years but it may take several years for the menstrual cycle to establish a regular pattern. The initial cycles are usually anovulatory and frequently unpredictable.

• **Precocious puberty** (see pp. 1214–1215). This is defined as menses before the age of 8 years.

• **Delayed puberty** (see p. 1215). This is defined as the absence of secondary sex characteristics after 14 years. It may be due to a central defect (including anorexia, excessive exercise, chronic illness or pituitary tumour) or to a failure of gonadal function (Turner syndrome, XX gonadal dysgenesis).

• **Amenorrhoea** (see pp. 1218–1219). This is defined as primary in a girl who fails to menstruate by 16 years of age, and secondary when the menses stop for more than 6 months in a normal female who is not pregnant, lactating or menopausal.
• **Menorrhagia.** This is defined as menses with abnormally heavy or prolonged bleeding.

• **Premenstrual syndrome (PMS)** (see p. 902). This is extremely common. In 5–15%, the severity of the progesterone-induced bloating, weight gain, mastalgia, headaches, depression and irritability in the luteal phase are so debilitating that lifestyle and personal relationships are adversely affected. Treatment success, using lifestyle modifications, hormonal preparations, cognitive behavioural therapy, selective serotonin reuptake inhibitors (SSRIs) and surgery, is highly variable.

• **Premature ovarian insufficiency (POI)** (see p. 1220). This is defined as cessation of periods before 40 years of age and occurs in 1% of women.

• **Menopause.** The average age of menopause among Western women is 51–52 years (see below).

• **Postmenopausal bleeding (PMB).** The majority of cases of PMB are due to benign atrophic vaginitis and respond to topical oestrogens. Approximately 10% of cases of PMB will have atypical hyperplasia or cancer requiring staging and surgical clearance of the uterus and ovaries, with or without adjuvant therapy. Investigate by ultrasound to assess endometrial thickness, proceeding to tissue sampling when it exceeds 3–5 mm. Women on tamoxifen medication for breast disease may have irregular, thickened and cystic endometrium, and require hysterectomy and directed tissue biopsy.

## Menopause

The menopause, or cessation of periods, naturally occurs at about the age of 45–55 years. Female life expectancy has increased significantly over the last century, with many women now living into their eighties or nineties. During the late forties, follicle stimulating hormone (FSH) concentrations initially and then luteinizing hormone (LH) concentrations begin to rise, probably as follicle supply diminishes. Oestrogen levels fall and the cycle becomes disrupted. Most women notice irregular, scanty periods coming on over a variable period, though, in some, sudden amenorrhoea or menorrhagia occurs. Eventually, the menopausal pattern of low oestradiol levels with grossly elevated LH and FSH levels (usually >50 and >25 U/L, respectively) is established. Premature menopause may also occur surgically, with radiotherapy to the ovaries and with ovarian disease.

### Clinical features

Features of oestrogen deficiency are hot flushes (which occur in most women and can be disabling), vaginal dryness and atrophy of the breasts. There may also be symptoms of loss of libido, loss of self-esteem, non-specific aches and pains, sleep disturbance, irritability, depression, loss of concentration and weight gain.

Women show a rapid loss of bone density in the 10 years following the menopause (osteoporosis; see pp. 711–715) and the premenopausal protection from ischaemic heart disease disappears.
Management

Hormone replacement therapy

Symptomatic patients should usually be treated but the previous widespread use of hormone replacement therapy (HRT) has been thrown into doubt by a number of large prospective studies that have reported in recent years. Although scientific debate continues, the overall benefits and risks are summarized in Box 29.1. Absolute risks and benefits for individual women clearly depend on their background risk of a specific disease, and there is as yet no evidence on the relative risks of different hormone preparations or routes of administration (oral, transdermal or implant). Overall, the Women's Health Initiative (WHI) study estimated that, over 5 years of treatment, one extra woman in every 100 would develop an illness that would not have occurred had she not been taking HRT. However, the decision about whether or not a woman takes HRT is now very much an individual one and is based on:

• the severity of the woman's menopausal symptoms
• her personal risk of conditions that may be prevented or made more likely by HRT
• individual patient choice.

### Box 29.1

Risks and benefits of hormone replacement therapy

**Potential benefits**

- **Symptomatic improvement in most menopausal symptoms** for the majority of women. Oestrogen-deficient symptoms respond well to oestrogen replacement; the vaguer general symptoms may or may not improve. Vaginal symptoms also respond to local oestrogen preparations.

- **Protection against fractures of wrist, spine and hip, secondary to osteoporosis** (~24–33%) (see pp. 711–715), owing to protection of predominantly trabecular bone (see p. 707). However, this is not a recommended indication to prevent osteoporosis.

- **Significant reduction in the risk of large bowel cancer** (~33%).

- **Possible increase in general wellbeing**, although hopes for a reduction in the incidence of Alzheimer's disease have not been confirmed.

**Potential risks**

- **Significant increase in the risk of breast cancer** (+26%) but no change in breast cancer mortality. This is primarily a risk of combined oestrogen–progesterone HRT. Some studies suggest that breast cancers diagnosed on HRT are easier to treat effectively.

- **Significant increase in the risk of endometrial cancer** when unopposed oestrogens are given to women with a uterus.
HRT is not recommended purely for prevention of postmenopausal osteoporosis in the absence of menopausal symptoms. **Symptomatic** treatment is the main indication, with the lowest effective dose being given for short-term rather than long-term treatment.

**Selective oestrogen receptor modulators** (SERMs; e.g. raloxifene) offer a potentially attractive combination of positive oestrogen effects on bone and cardiovascular system with no effects on oestrogen receptors of uterus and breast, and a possible reduction in breast cancer incidence; long-term outcome studies, however, are still awaited.

The Women's Health Initiative and Million Women Study suggested an association between longer-term usage of HRT and an increased risk of breast cancer, stroke and venous thromboembolism, but this has recently been challenged. The incidence of ischaemic heart disease increases after the menopause but this is 10 years later than in men. There is increasing evidence of the value of HRT in menopausal women to prevent cardiovascular morbidity.

---

**Contraception**

Control of fertility has positive effects on a woman's health and wellbeing. Those who lack access to contraceptive methods are at increased risk of mortality and morbidity, due to
obstetric complications and the consequences of illegal abortion. More than 30% of maternal deaths and 10% of child mortality can be prevented by ensuring a 2-year interval between each pregnancy.

Women require expert advice about the safest and most suitable methods of contraception available to them at different ages. In general, contraception is extremely safe, although some methods do have rare but serious side-effects. The combined oestrogen–progestogen pill also protects against both ovarian and endometrial cancer, and many hormonal methods help control heavy or painful periods. Barrier methods prevent sexually transmitted infections and protect against cervical cancer.

The efficacy of any contraceptive method depends on how it works and how easy it is to use. There is a wide choice of contraception options now available. They include barrier methods (condoms, diaphragms), the combined oestrogen–progestogen or progestogen-only pill, long-acting progestogen injection or implant, and intrauterine systems. Each has its advantages and disadvantages.

**Oral contraception**

The combined oestrogen–progestogen pill is widely used for contraception and has a low failure rate (<1 per 100 woman-years). ‘Pills’ contain 20–40 µg of oestrogen, usually ethinylestradiol, together with a variable amount of one of several progestogens. The mechanism of action is twofold:

- suppression by oestrogen of gonadotrophins, thus preventing follicular development, ovulation and luteinization
- progestogen effects on cervical mucus, making it hostile to sperm, and on tubal motility and the endometrium.

Side-effects of these preparations are shown in Box 29.2. Most of the serious ones are rare and are less common with typical modern 20–30 µg oestrogen pills, although evidence suggests that thromboembolism may be slightly more common with ‘third-generation pills’ containing desogestrel and gestodene (approximately 30/100 000 woman-years compared with 15/100 000 on older pills and 5/100 000 on no treatment). While some problems require immediate cessation of the pill, other milder side-effects must be judged against the hazards of pregnancy occurring with inadequate contraception, especially if other effective methods are not practicable or acceptable.

</table>
• Loss of libido
• Pigmentation (chloasma)
• Breast tenderness
• Increased growth rate of some malignancies

**Cardiovascular**

• Increased blood pressure
• Deep vein thrombosis
• Myocardial infarction
• Stroke (migraine is a risk factor)

**Gastrointestinal**

• Nausea and vomiting
• Abnormal liver biochemistry
• Gallstones increased
• Hepatic tumours

**Nervous system**

• Headache
• Migraine
• Depression

**Malignancy**

• Increase in cancer of the breast (but reduced risk of ovarian and endometrial cancer)

**Gynaecological**

• Amenorrhoea
• ‘Spotting’
• Cervical erosion

**Haematological**

• Increased clotting tendency

**Endocrine/metabolic**

• Mild impairment of glucose tolerance
• Worsened lipid profile, though variable

**Drug interactions**

• Antibiotics
• Barbiturates
Phenytoin
• Carbamazepine
• Rifampicin
• St John's wort

“Common reasons for stopping oral contraceptives. Reduced contraceptive effect owing to enzyme induction.

Hazards of the combined pill are increased in smokers, in obesity and in those with other risk factors for cardiovascular disease (e.g. hypertension, hyperlipidaemia, diabetes), especially in women aged over 35 years (avoid if over 50 years). The ‘mini-pill’ (progestogen-only, usually norethisterone) is less effective but is often suitable where oestrogens are contraindicated (Box 29.2).

Long-acting reversible contraceptives
Long-acting reversible contraceptive (LARC) methods, such as implants, injectables and intrauterine devices, all have lower failure rates than user-dependent contraception and tend to have better continuation rates since they cannot be easily abandoned. They have also been shown to be more cost-effective than oral contraceptives.

Barrier methods
Condoms, diaphragms, spermicides and sponges, which require users to remember to employ them correctly every time they have sexual intercourse, have the highest failure rates but offer protection against sexually transmitted infections.

Combined oral contraceptive pills, patches and vaginal rings
These prevent ovulation, make the endometrium hostile to implantation and alter the cervical mucous. They are highly effective but only if used correctly and consistently. Minor side-effects may lead to discontinuation and include headaches, mood swings, bloating, weight gain and breast tenderness. The more significant risks relate to cardiovascular disease, including venous thromboembolism (three- to fivefold increase), myocardial infarction and stroke (rare). Progestogen-only preparations avoid the side-effects of oestrogen and are available as a pill, subdermal implant (Implanon), injectables (Depoprovera) and intrauterine system (Mirena). They all act on cervical mucous and the endometrium, but the higher-dose preparations also inhibit ovulation. Common side-effects include irregular bleeding, simple ovarian cysts, breast tenderness and acne.

• Pills are taken every day and have a higher failure rate but are suitable for women who are breast-feeding, are older, are smokers and have cardiovascular risks (hypertension, diabetes).
• Injectables are given intramuscularly and are effective for 12 weeks. Side-effects include weight gain, irregular periods or amenorrhoea, and delays in return of fertility of up to 6 months.
**Subdermal implants** are inserted in the upper arm with local anaesthetic and last for 3 years. They are a highly effective long-term method of contraception and offer a rapid return of fertility after removal. Irregular bleeding is common.

**Intrauterine contraceptive devices**

Intrauterine contraceptive devices (IUDs) are a highly effective and increasingly popular method of contraception that is independent of intercourse and user compliance. The device is inserted into the uterine cavity by trained healthcare personnel and a thread is left protruding from the cervix into the vagina, which allows the IUD to be removed by traction.

Copper IUDs are cheap, licensed for 10 years of use, and cause much less menstrual disruption than the older plastic models. They have a toxic effect on both egg and sperm before fertilization occurs.

Mirena is a levonorgestrel hormone-releasing intrauterine system and is licensed for contraception, the treatment of heavy menstrual bleeding and use as part of HRT regimens. The duration of use is 5 years, during which time many women become amenorrhoeic. Irregular vaginal spotting is common initially but may resolve. Some women complain of greasier skin, breast tenderness and mood swings but these symptoms often settle with time.

**Emergency contraception**

Emergency contraception can be used following unprotected intercourse. Levonorgestrol is available over the counter and needs to be taken within 72 hours. Ulipristal acetate can be used up to 120 hours after intercourse but is available on prescription only. Insertion of a copper IUD within 5 days is highly effective. Permanent contraception may be achieved by male or female sterilization, but both carry a late failure rate quoted as 1 : 2000 and 1 : 200, respectively.

**Miscarriage**

Miscarriage is a pregnancy that ends spontaneously before the fetus reaches a viable gestational age. The term includes all pregnancy losses between the time of conception and 24 weeks of gestation. Sporadic miscarriage is the most common complication of pregnancy and the majority are due to random genetic abnormalities in the embryo or fetus. The incidence of clinically recognized miscarriage is generally quoted as 15–20%, but the total number of very early conceptions that are lost is in the region of 50%. The miscarriage rate decreases with advancing gestation, reaching 10% by 8 weeks and 3% after a heartbeat is seen on ultrasound scan. By 13 weeks (the start of the second trimester), no more than 1% of viable pregnancies are lost.

Maternal age at conception and previous reproductive history are strong and independent risk factors for miscarriage. The risk of fetal loss rises steeply after the age of 35 years, reaching 75% by 45 years, as the increase in poor-quality oocytes leads to chromosomally abnormal conceptions. Delayed childbearing has resulted in increased rates of miscarriage,
ectopic pregnancy, stillbirth and other later complications of pregnancy. Less common factors contributing to early pregnancy loss are uterine abnormalities, infections, medical/endocrine disorders and exposure to drugs and chemicals.

The different types of miscarriage can be classified by the clinical presentation and the results of investigations (Box 29.3). Vaginal bleeding in early pregnancy is common and the differential diagnosis includes a threatened, inevitable or incomplete miscarriage, bleeding from a viable pregnancy, ectopic pregnancy, lower genital tract pathology or trophoblastic disease. Sensitive home pregnancy testing kits have identified many biochemical pregnancies that fail to implant successfully and resolve spontaneously as a delayed and/or heavy menstrual period.

PV, per vaginam.

Women presenting with vaginal bleeding in pregnancy need to have a detailed clinical history and examination performed.

• Speculum examination assesses the state of the cervix and excludes lower genital tract pathology such as cervical polyps or ectropion.

• Transvaginal ultrasound determines the location, gestation, nature and viability of the pregnancy. It also offers the woman valuable reassurance if fetal heart activity can be shown.

Bleeding and pain associated with products of conception distending the cervical canal can be very severe and prompt removal with sponge forceps should be performed. Serial measurements of serum beta-human chorionic gonadotrophin (β-HCG) levels may be necessary when the site of pregnancy is unknown.
Severe pain localized to either iliac fossa and peritonism are suggestive of ectopic pregnancy and may warrant urgent laparoscopic assessment and treatment. However, many ectopic gestations resolve spontaneously by being resorbed or miscarried from the tube into the peritoneal cavity.

**Management**

This depends on clinical presentation and patient choice. Most miscarriages can be managed expectantly, although urgent surgical evacuation may be required if the bleeding becomes heavy.

- **Follow-up urinary pregnancy test or pelvic scan** confirms whether the miscarriage is complete.

- **Prostaglandins** (oral or vaginal misoprostol) to induce uterine contractions and expulsion are cheap and effective.

- **Subsequent surgical evacuation of the uterus** is required by a small number of women.

  The success rate of medical management is increased by using a progesterone antagonist (mifepristone) prior to administering the misoprostol. Surgical evacuation of the retained products of conception (ERPC) can be performed by suction under general anaesthesia or by manual vacuum aspiration (MVA) under local anaesthesia. It is associated with a small but finite morbidity, including uterine perforation, cervical trauma, intrauterine adhesion formation and postoperative pelvic infection.

**Recurrent miscarriage**

Recurrent miscarriage (RM), the loss of three or more consecutive pregnancies, affects 1–2% of women trying to conceive and is associated with significant psychological morbidity. Investigation includes a search for parental translocations and for anatomical, infective, endocrine, immune and thrombophilic causes. Most cases remain unexplained, which is a good prognosis for future pregnancy outcome.

  Currently, the most treatable cause of RM is the antiphospholipid syndrome (see p. 695), which is present in 15–20% of all women with RM. When it is managed with low-dose aspirin and heparin, a live birth rate of more than 75% can be achieved.

  Women with a history of recurrent miscarriage are at greater risk of pre-eclampsia, fetal growth restriction and prematurity when they achieve a successful pregnancy because all of these problems are determined by the quality and depth of early implantation. They are also more likely to suffer strokes at an earlier age than women with no miscarriage history.

  Miscarriages can cause acute anxiety, depression, denial, anger, blame, severed relationships and a sense of loss and inadequacy. Compassionate counselling services and access to support groups for women who have experienced pregnancy loss are needed.

**Stillbirths**

Miscarriage and stillbirth are pregnancy losses defined on when the loss occurs. This varies
from 20 to 28 weeks. WHO bases this on fetal weight of 1000 g or more, an assumed equivalent of 28 weeks’ gestation. Worldwide, there were 2.6 million third-trimester stillbirths in 2015. Although there was a reduction in maternal and child mortality, both targeted in the Millennium Development Goals (MDGs), the number of stillbirths annually remains high with sadly little reduction in the past decade. Intrapartum losses are extremely high, at 1.3 million, and are preventable.

Heavy Menstrual Bleeding

Heavy menstrual bleeding (HMB) accounts for 1 in 5 gynaecology clinic consultations and is the most common cause of iron deficiency anaemia. Objective methods to quantify menstrual blood loss are inaccurate and therefore clinical assessment based on the woman's perception of blood loss and how it impacts on her quality of life is needed. Periods characterized by the passage of large blood clots, severe pain or flooding that prevents the woman leaving home require investigation and management.

Take a detailed menstrual and general medical history. On examination, search for signs of anaemia. Abdominal and pelvic examination is carried out to exclude pelvic masses, visualize the cervix, perform a smear if needed, and take swabs if infection is suspected. Investigations are as follows:

- **full blood count** – to assess the need for iron replacement and, in extreme cases, blood transfusion
- **history** consistent with a coagulation disorder – refer for a haematological opinion
- **ultrasound scan** – if a pelvic mass is palpated or the bleeding pattern suggests endometrial pathology
- **endometrial biopsy** (at the outpatient clinic or at hysteroscopy in women aged > 45 years) – for irregular or intermenstrual bleeding and where drug therapy fails
- **ultrasound and haematological investigation** – young women presenting with menorrhagia from their first period.

Selecting the most appropriate treatment for HMB involves patient preference, risk/benefit analysis of available options, the woman's fertility and contraceptive requirements, and any contraindications to medical or surgical therapies. A summary of the National Institute for Health and Care Excellence (NICE) guidelines for HMB is shown in **Figure 29.3**.
Management

First-line medical therapies
These include:

- **Tranexamic acid.** This antifibrinolytic agent is associated with a 50% reduction in HMB and/or
- **Mefenamic acid.** This non-steroidal anti-inflammatory drug (NSAID) is associated with a 25% reduction in bleeding and is taken during the menses.
- **The combined oral contraceptive pill.** This has the added advantage of providing effective
contraception but may be contraindicated in women with risk factors for thromboembolism or breast cancer, smokers over the age of 35 and obese women.

- **Oral progestogens.** Taken on days 6–26 of the menstrual cycle, these may regulate the bleeding pattern, but are not contraceptive and can cause breakthrough bleeding.

- **Levonorgestrel intrauterine system** (LNG-IUS or Mirena coil). This has revolutionized the treatment of HMB. It results in a 95% reduction in blood loss (30% of women are amenorrhoic within 1 year of insertion), is an effective contraceptive, improves dysmenorrhoea and has few side-effects. It should be considered in the majority of women with HMB as an alternative to surgical treatment. Some women are troubled by irregular bleeding and persistent spotting for the first 3–9 months after insertion.

  Gonadotrophin-releasing hormone (GnRH) agonist drugs act on the pituitary and result in amenorrhoea. They are only suitable for short-term use because they produce a hypo-oestrogenic state that predisposes to osteoporosis.

### Surgical treatments

Surgical treatments for HMB should be restricted to women for whom medical treatments have failed and who have completed their family.

- **Endometrial ablation techniques.** These destroy the endometrial lining to a depth that prevents cyclical regeneration. The second-generation microwave and thermal ablation techniques are highly successful in treating HMB and are undertaken as day-case procedures.

- **Hysterectomy.** Removal of the uterus may be abdominal, vaginal or laparoscopic, depending on the size of the uterine body, the degree of laxity of the pelvic muscular floor and the skill set of the surgeon. Histology of the uterus is normal in about 40% of cases. The vaginal and laparoscopic surgical procedures usually mean shorter hospital stays and a faster return to normal activities.

### Uterine fibroids (leiomyomata)

These are the most common solid pelvic tumours in women of reproductive age. The prevalence increases with age and is higher in Afro-Caribbean women. Heavy and/or prolonged periods, pressure symptoms due to the pelvic mass, and reproductive dysfunction are common presenting symptoms. The mechanism(s) by which fibroids cause HMB are poorly understood but submucosal lesions within the uterine cavity are particularly troublesome.

### Management

Treatment is surgical excision or uterine artery embolization, both of which may adversely affect fertility. GnRH agonists or selective progesterone receptor modulators (SPRM) can be used to alleviate HMB as a short-term measure or to shrink the overall size and vascularity of the fibroids prior to surgery.
Abortion/Termination of Pregnancy

Unintended pregnancy is common and abortion is one of the most frequently performed gynaecological procedures. One in three women will have an abortion in their lifetime. However, abortion remains a controversial subject, mostly related to cultural, moral and religious beliefs.

Every year, an estimated 210 million pregnancies occur worldwide: 80 million are unplanned and 50 million are terminated by abortion, 20 million of them illegally. Where abortion for unintended pregnancy is illegal, it is invariably unsafe and frequently has tragic sequelae. Approximately 70 000 maternal deaths occur each year due to unsafe abortion, 99% of them in developing countries.

In developed countries that have legalized abortion, the procedure is extremely safe. The risk of death from an early surgical termination of pregnancy is less than 1 per 100 000, which is far lower than the maternal mortality associated with a full-term pregnancy. Abortion was legalized in the UK in 1967 and 95% of the 190 000 procedures performed yearly are for Clause C of the Abortion Act. This states that the pregnancy has not exceeded its 24th week and that continuance of the pregnancy would involve risk, greater than if the pregnancy were terminated, of injury to the physical or mental health of the pregnant woman. Only 1% of abortions are done because of a risk that the child would be born handicapped.

**Induced abortion** can be undertaken surgically under local or general anaesthesia or using drug regimens that induce miscarriage. The type of procedure is generally dictated by the gestation of the pregnancy, availability of methods and the wishes of the woman concerned. The earlier an abortion is performed, the safer it is. Currently, 91% of abortions in the UK are carried out before 13 weeks' gestation.

**Early medical abortion** (before 9 weeks' gestation) using the antiprogestogen drug mifepristone, followed 36–48 hours later by vaginal misoprostol to expel the products, achieves a complete abortion in over 95% of cases. Asthma and cardiac disease are contraindications to medical abortion. Most women remain in the clinical facility for 4–6 hours after the misoprostol insertion to abort the pregnancy, but some units support women to remain at home during an early medical abortion.

**Surgical abortions** before 14 weeks are usually performed as suction terminations under general anaesthesia. Preoperative priming of the cervix with oral or vaginal misoprostol reduces the risk of cervical trauma and haemorrhage. Early abortions before 7 weeks can be performed with a manual vacuation aspiration (MVA) syringe under local anaesthesia.

With modern early abortion techniques and routine screening for pelvic infection in high-risk women, the risk of future subfertility is extremely low. Later medical and surgical abortions are associated with more complications: in particular, incomplete procedures, pelvic infection and trauma to the genital tract. Contraception should be discussed before the abortion and started immediately after the procedure to avoid a further unplanned pregnancy.

Many women are emotionally vulnerable following an abortion. Feelings of guilt and regret are frequently mixed with relief that the ordeal is over. There is no evidence of an increase in
serious psychiatric disease after abortion. Psychological problems can be minimized with careful counselling before the procedure and access to post-abortion support services.

**Urinary Incontinence**

Urinary incontinence (UI; see also p. 793) is common and has a negative impact on a woman's quality of life. One in three women over the age of 60 years suffers from some urinary leakage and the majority are too embarrassed to seek help for their problem, despite the fact that the symptoms can often be alleviated by simple, non-pharmacological interventions. As our ageing population continues to expand, UI will become an even more prevalent problem, placing an increasingly large demand on our healthcare resources.

The NICE guidelines offer a simple classification of female UI (summarized in Box 29.4; see also p. 793).

**Box 29.4**

**Classification of urinary incontinence (UI) in women**

- **Stress UI** is involuntary urine leakage on effort or exertion or on sneezing or coughing
- **Urgency UI** is involuntary urine leakage accompanied or immediately preceded by urgency (a sudden compelling desire to urinate that is difficult to delay)
- **Mixed UI** is involuntary urine leakage associated with both urgency and exertion, effort, sneezing or coughing
- **Overactive bladder (OAB)** is defined as urgency that occurs with or without urgency UI, and usually with frequency and nocturia

Lifestyle interventions, including weight loss, smoking cessation, caffeine reduction and timed fluid restriction, can alleviate the symptoms of UI significantly. Physiotherapy and bladder retraining may be helpful in cases of stress and urgency, respectively, and also for mixed UI. In postmenopausal women, oestrogen deficiency exaggerates many urinary symptoms and topical vaginal or systemic HRT is a treatment option.

Referral for specialist management may include detailed assessment of the pelvic floor and any prolapse, urinary tract imaging and urodynamic evaluation where appropriate. Discussion of further management is based on the type of incontinence, the woman's preferences and future fertility wishes.

**Domestic Abuse and Violence**

Domestic violence is the cause of considerable hidden morbidity and mortality. One in four women in England and Wales experience some form of domestic abuse or violence – whether it be psychological, physical, sexual, financial or emotional – during their lifetime. One in ten
women experience rape. Domestic violence accounts for one-third of violent crimes, and the cost of domestic violence in human and economic terms is enormous – an estimated £23 billion per annum in the UK alone.

There are several groups of people who are more vulnerable to becoming victims. Around 30% of domestic abuse begins or escalates during pregnancy. After road accidents, domestic abuse is the second leading cause of trauma during pregnancy, and pregnant women are more likely to have multiple sites of injury. The prevalence among women requesting a termination of pregnancy is six times higher than among women attending antenatal clinics. The disabled are also at greater risk of abuse: the odds of being a victim of violence are twofold higher in people with a physical disability and threefold higher for those with a mental illness. Sex workers, trafficked women and certain ethnic groups also have a higher prevalence of domestic violence.

Victims of domestic abuse are significantly more likely to commit suicide. Domestic violence and abuse are serious health concerns and healthcare professionals are particularly well placed to identify abuse and intervene, as the victims frequently present to departments of Emergency Medicine, Psychiatry, and Obstetrics and Gynaecology. Healthcare professionals have an important role to play in tackling the problem and are often the first and only point of contact to whom the isolated and vulnerable victim reaches out. All healthcare workers need to be trained to recognize the signs of violence and abuse, use targeted questioning, and know how to act and refer to ensure the women's safety. The key actions to reduce violence against women and girls are shown in Figure 29.4.

Further reading

Royal College of Obstetricians and Gynaecologists. The Care of Women Requesting
Medical Problems in Pregnancy

The prevalence of medical conditions complicating pregnancy is increasing, partly because:

- Women in Western countries are delaying childbearing until they are older.
- Fifty per cent of pregnant women are now overweight or obese, resulting in more women with diabetes, hypertension and associated co-morbidities.
- Women with chronic medical diseases, such as congenital heart disease, diabetes, chronic kidney disease (CKD) and cystic fibrosis, now survive into their child-bearing years because of better medical care.
- Widening access to assisted conception services, including the use of donor eggs, mean that age is no longer a barrier to pregnancy.
- Maternal death (during or soon after pregnancy) in the UK is now more often due to medical than obstetric complications. Confidential enquiries show that inadequate knowledge and care are implicated in one-quarter of deaths from medical conditions in pregnancy.

The anatomical and physiological changes that occur as an adaptation to normal pregnancy can result in a number of symptoms and signs. These overlap with those associated with diseases outside pregnancy. Most of the symptoms and signs are benign, but clinicians need to be aware of those that warrant further investigation and may be associated with disease.

Women with pre-existing disease should be made aware of the normal adaptation to
pregnancy, as symptoms may worsen or improve, depending on the body system involved. The stress of pregnancy may also result in previously subclinical disease presenting for the first time.

Infectious diseases are a major problem in pregnancy, particularly in low- and middle-income countries. There is an increased mortality in both the mother and the fetus. See individual diseases in Chapter 11.

**Hypertensive disorders**

During normal pregnancy, there is a reduction in blood pressure due to a fall in systemic vascular resistance that is maximal by weeks 22–24.

**Chronic/pre-existing hypertension**

This is present at the initial booking visit or before 20 weeks, or the patient is already taking medication for hypertension.

**Management**

- *Angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs) and chlorothiazide agents* that are associated with congenital abnormalities should be **discontinued**.
- **Dietary salt intake** should be kept low (2 g or 100 mmol daily).
- **Aspirin 75 mg** should be given from 12 weeks until birth to women at moderate or high risk of pre-eclampsia.
- **Oral labetalol** is first-line therapy during pregnancy. Second-line agents are **methyldopa** and **nifedipine**. Treatment may be required for several weeks postpartum.
- **Target blood pressure** is <150 mmHg systolic and 80–85 mmHg diastolic. If blood pressure is <160/110 mmHg, birth should not be offered before 37 weeks.

In **breast-feeding**, ACE inhibitors, beta-blockers and nifedipine are safe. Methyldopa should be avoided because of the risk of depression.

**Gestational hypertension**

This is defined as blood pressure of >140/90 mmHg after 20 weeks' gestation in a previously normotensive woman.

**Investigations and management**

- **Blood tests** should include full blood count, urea and electrolytes with serum creatinine, calcium, liver biochemistry and liver function tests. Estimated glomerular filtration rate
(eGFR) is not validated for use in pregnancy.

- **Blood pressure measurements** once a week.
- **Urine tests** for protein, as there is an increased risk of pre-eclampsia developing.
- **Treatment of moderate hypertension** (159–150/109–100 mmHg) with oral labetalol.
- **Admission to hospital** if blood pressure is ≥160/110 mmHg.
  
  Treatment may be required for several weeks post-partum.

---

### Pre-eclampsia

Pre-eclampsia is a common direct (obstetric) cause of maternal and perinatal death, and a significant cause of maternal and neonatal morbidity. The risk factors are shown in **Box 29.5**. It is a heterogeneous multisystem endothelial disorder that has widespread effects.

#### Box 29.5

**Risk factors for pre-eclampsia**

- Age >40 years
- Obesity: body mass index (BMI) >30
- Family history
- Primiparity
- Multiple pregnancy
- Previous pre-eclampsia
- Long birth interval
- Hydrops with a large placenta
- Hydatidiform mole
- Triploidy (particular association with pre-eclampsia of very early onset (before 24 weeks' gestation))
- Medical disorders:
  - Pre-existing hypertension
  - Renal disease (even without renal impairment)
  - Diabetes mellitus (pre-existing or gestational)
  - Antiphospholipid syndrome
  - Autoimmune rheumatic diseases
  - Sickle cell disease

  There is some evidence that low dose aspirin is beneficial in patients with mid to high risk of developing pre-eclampsia; it is safe in pregnancy and is stopped 10 days before delivery.
Clinical features

Pre-eclampsia varies in severity, timing, progression and order of onset of different clinical features. Symptoms include severe headache, visual blurring or flashing, nausea and vomiting, severe epigastric or right upper quadrant pain, and rapidly progressive oedema of the hands, feet and face. Signs include new hypertension >20 weeks, oedema and proteinuria (>0.3 g/24 h or urinary protein : creatinine ratio >30 mg/mmol on a ‘spot’ sample); these are the most common manifestations of pre-eclampsia. Hyper-reflexia may be seen. Pre-eclampsia (including eclampsia) may present ante-, intra- or postpartum. Postpartum disease is more likely to be associated with symptoms. Complications and crises are shown in Box 29.6.

Box 29.6

Complications and crises seen in pre-eclampsia

- Eclampsia
- HELLP syndrome (haemolysis, elevated liver enzymes, low platelets)
- Pulmonary oedema
- Placental abruption
- Cerebral haemorrhage
- Cortical blindness
- Disseminated intravascular coagulation
- Acute kidney injury
- Hepatic rupture
- Transient left ventricular systolic or diastolic dysfunction

Investigations

- **Full blood count** – thrombocytopenia.
- **Urea, electrolytes, creatinine** – to monitor for acute kidney injury.
- **Liver biochemistry** – raised transferases.
- **Urine protein : creatinine ratio**.
- **Ultrasound fetus** – for fetal growth.
- sFlt-1/PIGF ratio is a novel immunoassay recommended by NICE to rule out pre-eclampsia, following clinical assessment.

Management

Patients should be admitted and treated for hypertension with regular blood pressure
measurements (4 times/day) and blood tests (2–3/week).

Close fetal monitoring is required because of the risks of placental insufficiency and intrauterine growth restriction.

Delivery is the only cure for pre-eclampsia and this may be indicated for fetal or maternal reasons. The recurrence risk of pre-eclampsia is increased with early-onset disease.

Women whose pregnancy has been complicated by pre-eclampsia are significantly more likely to develop hypertension, ischaemic heart disease, cerebrovascular disease and CKD in later life.

If a patient develops eclampsia (convulsions or coma) and/or HELLP syndrome, she should be admitted to a critical care or high-dependency unit and may require intravenous hydralazine, labetalol and magnesium sulphate 4 g over 5 minutes then maintenance 1 g/h (for convulsions), and prompt delivery. Patients should be given steroids (betamethasone 12 mg i.m. for fetal lung maturation, repeated at 24 h if delivery is likely within 7 days). HELLP is a syndrome describing haemolysis, elevated liver enzymes and low platelets (<100 × 10⁹/L) in a pregnant woman. It is a form of severe pre-eclampsia, more common in multiparous women, and can occur in the second and third trimesters or postpartum. The haemolysis is due to a microangiopathic haemolytic anaemia (see p. 548). Hypertension and proteinuria may be absent or mild. Clinically, patients complain of epigastric/right upper quadrant pain, nausea, vomiting and jaundice (5%). If symptoms are severe, prompt delivery is necessary and is advised in all patients who are beyond 34 weeks' gestation.

Further reading

Liver disease

Liver function is not impaired in pregnancy. Any liver disease (see p. 437), from whatever cause, can occur incidentally and coincide with pregnancy. For example, viral hepatitis accounts for 40% of all cases of jaundice during pregnancy. Pregnancy does not necessarily exacerbate established liver disease, but it is uncommon for women with advanced liver disease to conceive.

The following effects are seen:

• Plasma and blood volumes increase during pregnancy but the hepatic blood flow remains constant.

• The proportion of cardiac output delivered to the liver therefore falls from 35% to 29% in
late pregnancy; drug metabolism can thus be affected.

• The size of the liver remains constant.

• Liver biochemistry remains unchanged, apart from a rise in serum alkaline phosphatase from the placenta (up to three to four times increased) and a decrease in total protein owing to increased plasma volume.

• Triglycerides and cholesterol levels rise, and caeruloplasmin, transferrin, α₁-antitrypsin and fibrinogen levels are elevated owing to increased hepatic synthesis.

• During pregnancy and particularly postpartum, there is a tendency to hypercoagulability, and acute Budd–Chiari syndrome (see p. 482) can occur.

There are a number of liver diseases that complicate pregnancy.

Hyperemesis gravidarum
Pathological vomiting during pregnancy can be associated with liver dysfunction and jaundice. Liver dysfunction resolves when vomiting subsides.

Intrahepatic cholestasis of pregnancy
This condition of unknown aetiology usually presents with pruritus alone in the third trimester. It has a familial tendency and there is a higher prevalence in Scandinavia, Chile and Bolivia.

Investigations
Liver biochemistry shows raised aminotransferases, which occasionally can be very high. The hallmark is raised bile acids but serum bilirubin and gamma-glutamyl transferase (γ-GT) may be slightly raised. Jaundice is rare. Liver biopsy is not indicated but would show centrilobular cholestasis.

Management
Treatment is symptomatic with ursodeoxycholic acid 1–2 g daily in divided doses. Prognosis is usually excellent for the mother but there is increased fetal loss. The condition resolves after delivery. Recurrent cholestasis may occur during subsequent pregnancies or with the ingestion of oestrogen-containing oral contraceptive pills.

Acute fatty liver of pregnancy
Acute fatty liver of pregnancy (AFLP) is a rare but serious condition occurring in the third trimester and affecting 1 in 6000–20 000 pregnancies. It is more common in women with multiple gestations. Patients present with abdominal pain, vomiting and jaundice. Polyuria and thirst due to diabetes insipidus may occur because of reduced breakdown of placentally
derived vasopressinase. In fulminant AFLP patients, haematemesis, encephalopathy, coagulopathy, hypoglycaemia, lactic acidosis and acute kidney injury can occur. It may be associated with features of pre-eclampsia.

### Investigations

- Full blood count
- Urea, electrolytes, serum creatinine
- Serum glucose ↓
- Serum uric acid ↑
- Liver biochemistry shows hepatocellular damage (raised serum aminotransferase and raised bilirubin).
- Thrombocytopenia and rarely disseminated intravascular coagulation (DIC)

**Liver biopsy** is rarely performed; it shows fine droplets of fat (microvesicular) in the hepatocytes with a little necrosis but is not necessary for diagnosis.

### Management

Treatment is as for acute liver failure (see p. 463). Immediate delivery may save both the baby and the mother. Early diagnosis and treatment have reduced the mortality to less than 20%.

### Cardiac disease

Cardiac disease, both congenital and acquired, is commonly encountered in pregnancy and is mostly benign. Many women experience palpitations and breathlessness due to awareness of physiological sinus tachycardia, ventricular premature/ectopic beats and increased minute ventilation.

Cardiac disease, predominantly acquired, is the most common cause of maternal death in the UK. The main conditions causing severe morbidity and mortality are myocardial infarction, aortic dissection, and peripartum cardiomyopathy.

- **Myocardial infarction** in pregnancy is more often due to coronary artery dissection or thrombus than in non-pregnant women. Intervention with primary angioplasty and coronary artery stenting is appropriate.

- **Peripartum cardiomyopathy** is defined as the development of heart failure with left ventricular ejection fraction <45% at the end of pregnancy or in the months following delivery, where no other cause of heart failure is found. It is a dilated cardiomyopathy (see p. 1040) and is more common in obese and multiparous women. It should be treated with conventional heart failure therapy (including thromboprophylaxis), except that ACE inhibitors and ARBs are withheld until after delivery. Nearly half of these patients will recover to normal within 6 months.
• **Pulmonary hypertension** (see pp. 1029–1030) and fixed pulmonary vascular resistance are dangerous and often (10–20%) fatal in pregnancy.

Other contraindications to pregnancy are shown in **Box 29.7** and include a dilated aortic root >4.5 cm, severe left heart obstruction from critical mitral or aortic stenosis, and severe impairment of left ventricular function.

![Box 29.7](image)

**Box 29.7**

**Counselling against pregnancy where risk to the mother from cardiac conditions is high**

- Pulmonary arterial hypertension
- Systemic ventricular dysfunction – left ventricular ejection fraction <30% (New York Heart Association (NYHA) class III/IV; see p. 984)
- Previous peripartum cardiomyopathy (PPCM) with any residual left ventricular impairment
- Severe mitral stenosis
- Severe symptomatic aortic stenosis
- Aortic root >4.5 cm in Marfan syndrome
- Ascending aorta >5 cm with bicuspid aortic valve
- Severe aortic coarctation

Women with significant heart disease need multidisciplinary care in a specialist centre by obstetricians, cardiologists and anaesthetists who have expertise in the care of heart disease in pregnancy. Agreed management plans should be documented.

If **pregnancy is contraindicated**, then appropriate contraceptive advice is essential. The levels of risk associated with pregnancy for individual conditions are summarized in **Box 29.8**, based on the European Society of Cardiology Guidelines.

![Box 29.8](image)

**Box 29.8**

**Pregnancy-associated risks of different cardiac diseases**

**Low risk**

- Uncomplicated small or mild PS, PDA, MVP
- Successfully repaired ASD, VSD, PDA
- Atrial and ventricular ectopic beats

**Small increased risk of mortality/moderate increased risk of morbidity**
- Unrepaired ASD, VSD
- Repaired tetralogy of Fallot
- Most arrhythmias

**Moderate increased risk of mortality or severe morbidity**
- Mild LV dysfunction, HCM
- Repaired coarctation
- Most native or tissue valve disease (except those in extremely high risk)

**Significant increased risk of mortality or severe morbidity**
- Mechanical valves
- Systemic RV
- Fontan circulation
- Unrepaired cyanotic congenital heart disease

**Extremely high risk of mortality or severe morbidity**
- Pulmonary arterial hypertension
- Severe LV impairment (<30%), NYHA III/IV
- Previous PPCM with any residual LV impairment
- Severe MS/symptomatic AS
- Severe aortic coarctation

AS, aortic stenosis; ASD, atrial septal defect; HCM, hypertrophic cardiomyopathy; LV, left ventricular; MS, mitral stenosis; MVP, mitral valve prolapse; NYHA, New York Heart Association; PDA, patent ductus arteriosus; PPCM, peripartum cardiomyopathy; PS, pulmonary stenosis; RV, right ventricle; VSD, ventricular septal defect.

---

### Pregnancy and prosthetic heart valves

See page 1017.

*Any strategy for anticoagulation* for a pregnant woman with a mechanical heart valve is associated with risks to the mother and/or fetus. *Pre-pregnancy counselling*, explaining that warfarin is the safest option for the mother but associated with a 5% risk of warfarin embryopathy and increased risks of miscarriage, stillbirth and fetal intracranial haemorrhage, is essential. The alternative is full anticoagulant doses of low-molecular-weight heparin, given twice daily and titrated upwards in pregnancy based on *regular monitoring of anti-factor Xa* levels.

Regitz-Zagrosek V, Blomstrom Lundqvist C, Borghi C et al. ESC guidelines on the
Thromboembolic disease

Pulmonary embolism is the most common direct cause of death in pregnancy and the puerperium. Pregnancy and especially the puerperium are associated with a sixfold increased risk of thrombosis. Although the risks are highest after emergency caesarean section, women with risk factors (Box 29.9) are at risk antenatally, especially if admitted to hospital, and after vaginal delivery.

Diagnosis

Objective diagnosis of deep vein thrombosis (DVT) and pulmonary embolism (PE) must be made in those with a suggestive history and risk factors. **D-dimers** are not useful in pregnancy, as the levels are often raised. DVT is much more common in the left leg (ratio 9:1) than the right in pregnancy because the gravid uterus compresses the left common iliac vein, which lies under the right common iliac artery. **Ventilation/perfusion** (V/Q) **scans** and computed tomography **pulmonary angiograms** (CTPAs) are associated with negligible radiation to the fetus and are safe, but V/Q scans are preferred, as they do not irradiate the maternal breast and increase the risk of breast cancer.

Management

Treatment of venous thromboembolism (VTE) in pregnancy involves the following:

- Larger doses of low-molecular-weight heparins (LMWHs), e.g. enoxaparin, are given.
- Warfarin and new oral anticoagulants are avoided.
- LMWH must be continued for the rest of the pregnancy and the puerperium.

Decisions regarding thromboprophylaxis in pregnancy relate to past history of VTE, the presence of thrombophilia and other risk factors (**Box 29.9**). 

Women with previous VTE should receive antenatal and postnatal thromboprophylaxis with LMWH. This should begin as early in pregnancy as possible. LMWH and warfarin are safe to use in lactating mothers.

Further reading

Respiratory disease

Asthma

The treatment of asthma (see pp. 1096–1110) in pregnancy does not differ from management in the non-pregnant patient. Pregnancy itself does not usually influence the severity of asthma. For the majority of women, asthma has no adverse effect on pregnancy outcome.

- Poorly controlled severe asthma presents more of a risk to the fetus than the medication used to prevent or treat it. This small risk is minimized with good control.
• Education and reassurance, ideally prior to pregnancy, concerning the safety of asthma medications during pregnancy are integral parts of management.

• Decreasing or stopping inhaled anti-inflammatory therapy during pregnancy causes deterioration in disease control.

• Inhaled, oral and intravenous steroids, inhaled, nebulized and intravenous short- and long-acting $\beta_2$-agonists, and the leukotriene receptor antagonist montelukast are safe to use in pregnancy and while breast-feeding.

• Effective control of the disease process and its accompanying symptoms is a priority. An increase in the dose or frequency of inhaled steroids should be the first step if symptoms are not optimally controlled on the current dose of inhaled steroids and the inhaler technique is good.

### Pneumonia

The bacteria that cause pneumonia (see p. 1105) are no different in pregnancy. Chest X-rays are safe in pregnancy. Most antibiotics are safe to use in pregnancy and during lactation. Aminoglycosides should not be used unless essential and tetracycline/doxycycline should not be given. A high dose (500 mg x 3 daily) of amoxicillin is required in pregnancy. Varicella and influenza A pneumonia may be fatal in pregnancy and active steps must be taken to prevent chickenpox infection. Non-immune pregnant women exposed to varicella or prescribed steroids in pregnancy should be given varicella zoster immunoglobulin (VZIG). If a pregnant woman does contract chickenpox, she should be treated with aciclovir as soon as possible.

All pregnant women should receive immunization against seasonal influenza and influenza A H1N1.

### Tuberculosis

Tuberculosis (TB) is particularly common in Asia and Africa. Perform a chest X-ray if TB is suspected and seek the advice of a respiratory physician. Extrapulmonary TB is as common as pulmonary TB in pregnancy. Diagnosis must be confirmed bacteriologically, which may necessitate bronchoscopxy or biopsy, and is often delayed because of inappropriate reluctance to perform invasive investigations in pregnancy. The neonate should be given bacille Calmette–Guérin (BCG) vaccination.

### Sarcoidosis

The course of sarcoidosis is unaltered by pregnancy. Flare-up of the disease is more likely postpartum. Erythema nodosum may occur in a normal pregnancy. Serum ACE is not reliable for the diagnosis of sarcoidosis in pregnancy. Systemic steroids should be used if indicated (see p. 1120).
Cystic fibrosis

Women with cystic fibrosis often reach child-bearing age with adequate lung function or will have received a lung transplant to be able to consider pregnancy. Pre-pregnancy counselling, with consideration of lung function and concomitant diabetes, is required. Joint care with a cystic fibrosis centre should be maintained throughout pregnancy. Pregnancy outcome is related to pre-pregnancy lung function. Perinatal outcome is usually good but preterm delivery rates are high. Maternal outcome is variable, and worse in the presence of pulmonary hypertension. Specialist dietary advice with additional energy supplements should be given. Chest physiotherapy can and should be continued in pregnancy and infective exacerbations should be treated aggressively. There is a risk of gestational diabetes.

Severe restrictive lung disease

Women with severe lung disease are better able to tolerate pregnancy than women with severe cardiac insufficiency. If the forced vital capacity (FVC) is over 1 litre, a successful pregnancy is usually possible but individual assessment is necessary. Immunosuppression for diffuse parenchymal lung disease should be continued in pregnancy. Respiratory diseases complicated by pulmonary hypertension have a poor prognosis in pregnancy.

Neurological disease

Epilepsy

Birth defects

The overall risk of birth defects in babies of mothers who take one antiepileptic drug (AED) is around 7%, as compared with 3% in women without epilepsy. In most women, the frequency of seizures is not altered in pregnancy, provided there is compliance to the AEDs. Free drug levels tend to fall in pregnancy and increased doses of AEDs, particularly lamotrigine, may be required. The risk to the fetus of uncontrolled seizures is greater than the risks of continuing AED treatment; poorly controlled epilepsy and recurrent seizures are associated with adverse outcomes for the fetus, such as an increased risk of sudden unexplained death in epilepsy (SUDEP). If drugs cannot be safely stopped, monotherapy is preferable at the minimum effective dose. Sodium valproate is associated with a higher rate of serious malformations (e.g. neural tube defects) and long-term neurodevelopmental defects (e.g. a reduced IQ, increased risk of autism spectrum disorder and attention deficit disorder (ADHD)), and should be stopped or substituted if necessary.

Management

Counselling before conception is essential. Folic acid (5 mg/day) supplements should be taken
before conception and throughout the first trimester. Vitamin K (10–20 mg orally) should also be taken by women receiving enzyme-inducing AEDs in the last 4 weeks before delivery to prevent neonatal haemorrhage. Antenatal screening for congenital abnormalities is necessary.

Breast-feeding
Mothers taking AEDs need not, in general, be discouraged from breast-feeding, though manufacturers are often hesitant in assuring that there is no risk to the baby.

Contraception
AEDs inducing hepatic enzymes (e.g. carbamazepine, phenytoin and phenobarbital) reduce the efficacy of oral contraceptives. A combined contraceptive pill containing a higher dose of oestrogen or the progesterone-only pill provides greater contraceptive security. An IUD or barrier method of contraception is often used in preference to oral contraceptives.

Migraine
Migraine can occur as a pregnancy-related phenomenon in women without a prior history of migraine. Those with pre-existing migraine often improve in pregnancy. Hemiplegic migraine, particularly aura without headache, can mimic transient ischaemic attacks (TIAs). Ergotamine should be avoided in pregnancy. Sumatriptan may be used to treat migraine. Low-dose aspirin, beta-blockers, tricyclic antidepressants and pizotifen are used for prophylaxis.

Multiple sclerosis
Pregnancy has no effect on the long-term prognosis of multiple sclerosis. Relapses are less likely during pregnancy but more likely in the postpartum period. Prophylactic treatments, such as interferon beta, glatiramer and natalizumab, are usually avoided in pregnancy and breast-feeding but benefit may outweigh risk for some women. Those with disability may require extra help during pregnancy and while caring for the infant following delivery. There is no contraindication to epidural anaesthesia, except that documentation of pre-existing neurological deficit in the legs is necessary to avoid any postpartum exacerbation of multiple sclerosis being inappropriately attributed to the regional block.

Myasthenia gravis
The course of myasthenia gravis (MG) in pregnancy is unpredictable, but in women with stable disease pregnancy outcome is usually normal. Postpartum exacerbations occur in 30% of women. Usual immunosuppressant therapy with steroids, azathioprine and calcineurin inhibitors should be continued. Increased doses of long-acting anticholinesterases may be required. Many drugs should be avoided in MG and consultation with an experienced obstetric anaesthetist should be obtained. Transient neonatal MG may develop in 10–20% of neonates
born to myasthenic mothers due to transplacental passage of immunoglobulin G acetylcholine receptor antibodies.

### Stroke

The risks of arterial ischaemic stroke, cerebral venous thrombosis and intracranial haemorrhage are increased, particularly in the puerperium. In pregnancy, the prevalence of haemorrhagic stroke equals that of ischaemic stroke, in contrast to non-pregnant women, where ischaemic stroke is more common (>75% of strokes).

**Ischaemic causes** of stroke in pregnancy include:

- cardiac causes, e.g. arterial emboli or arrhythmias
- peripartum cardiomyopathy (see p. 1042)
- paradoxical embolus (in situations causing increased right compared with left atrial pressure) through an atrial septal defect or patent foramen ovale
- aortic/carotid artery dissection
- antiphospholipid syndrome
- sickle-cell disease

**Haemorrhagic causes** include:

- pre-eclampsia/eclampsia.

### Depression

This is discussed on pages 907 and 914.

### Endocrine disease

#### Diabetes mellitus

This is discussed on page 1274.

#### Thyroid and parathyroid disease

**Thyrotoxicosis**

Untreated thyrotoxicosis (see pp. 1207–1208) is dangerous for both the mother and her fetus, increasing the risk of miscarriage, fetal growth restriction and preterm delivery. Graves' disease affects about 0.2% of pregnancies and often improves during pregnancy, but there is a risk of flare postpartum. Both carbimazole and propylthiouracil (PTU) cross the placenta, and in high doses may cause fetal hypothyroidism and goitre. The lowest possible maintenance dose of antithyroid drug should be used. Despite the advice in guidelines to avoid carbimazole
in the first trimester, the risk of teratogenesis is very low. It is therefore also not logical to avoid PTU because of the risk of liver failure in the general population, but use it specifically in women planning pregnancy or in the first trimester. Women do not need to be swapped from one antithyroid drug to another before or during pregnancy; they should remain on whichever drug is controlling their disease. For those with good control of thyrotoxicosis on doses of carbimazole <15 mg/day or PTU <150 mg/day, the maternal and fetal outcome is usually good and unaffected by the thyrotoxicosis. Women may safely breast-feed on these doses of antithyroid drugs. Beta-blockers are safe to use in the short term, if required for control of thyrotoxic symptoms. Neonatal or fetal thyrotoxicosis due to transplacental passage of thyroid-stimulating antibodies is rare, but occurs most commonly in women with active disease in pregnancy and those with high levels of thyroid-stimulating antibodies.

**Hypothyroidism**

Hypothyroidism (see pp. 1202–1204) affects about 1% of pregnancies. Untreated hypothyroidism is associated with infertility, an increased rate of miscarriage, and fetal loss. For those on adequate replacement therapy, maternal and fetal outcome is usually good and is unaffected by the hypothyroidism. Very little thyroxine crosses the placenta and the fetus is not at risk of thyrotoxicosis from maternal thyroxine replacement therapy. Provided they are euthyroid at the beginning of pregnancy, most women do not usually require any adjustment to thyroxine dose during pregnancy or in the puerperium. Any dose increase should be based on thyroid function tests, interpreted using reference ranges for pregnancy (see p. 1203). There is no evidence to support the widespread recommendation for a target thyroid-stimulating hormone (TSH) of <2.5 mU/L.

**Subclinical hypothyroidism** affects 5% of the general population and is more common in women, particularly those who have anti-thyroid antibodies. Studies fail to demonstrate a consistent association between any adverse pregnancy outcome and subclinical hypothyroidism in pregnancy, and there is insufficient evidence that thyroxine replacement in subclinical hypothyroidism affects pregnancy outcome.

**Postpartum thyroiditis** is more common in women with a family history of hypothyroidism, thyroid peroxidase antibodies and type 1 diabetes. Presentation is usually between 3 and 4 months postpartum. Disease may present with symptoms of hyper- or hypothyroidism but a high index of suspicion is needed. The condition is caused by a destructive autoimmune lymphocytic thyroiditis. Most patients recover spontaneously and treatment is not always required. Postpartum thyroiditis often recurs and is a significant predictor of future hypothyroidism.

**Hyperparathyroidism**

Hypercalcaemia may be improved by pregnancy and the fetal demand for calcium. The risks to the mother are from acute pancreatitis and hypercalcaemic crisis, especially postpartum, when maternal transfer of calcium to the fetus stops abruptly. There is an increased risk of miscarriage, intrauterine death and preterm labour. Fetal mortality rates are up to 40% when
the maternal hypercalcaemia is severe (>3.5 mmol/L). Up to 25% of women with hyperparathyroidism develop hypertension or pre-eclampsia. The risk to the neonate is from tetany and hypocalcaemic convulsions, caused by suppression of fetal parathyroid hormone (PTH) by high maternal calcium levels. Acute neonatal hypocalcaemia usually presents at 5–14 days after birth but may be delayed by up to 1 month if the infant is breast-fed. The ideal treatment is surgery and this may be safely performed in pregnancy. Surgery is usually delayed until the second trimester.

| Pituitary disease (pp. 1183–1190) |

Prolactinomas
Prolactinomas are the most common pituitary tumours encountered in pregnancy but rarely cause problems. The prolactin level should not be measured during pregnancy, as it is invariably raised. Those with microprolactinomas usually have no problems in pregnancy. The risk of tumour enlargement during pregnancy is increased with macroprolactinomas. Dopamine-receptor agonists are safe for use in pregnancy and are usually continued in women with macroprolactinomas. Visual fields should be measured in each trimester in those with macroprolactinomas. If tumour enlargement is suspected, magnetic resonance imaging (MRI) of the pituitary is indicated. If women with macroprolactinomas wish to breast-feed, their dopamine-receptor agonists may be discontinued in the last few weeks of pregnancy and during breast-feeding, but serial visual field examinations and pituitary MRIs are required, and cabergoline or bromocriptine should be reintroduced if there is concern regarding tumour expansion.

Diabetes insipidus (pp. 1233–1234)
Established or subclinical diabetes insipidus (DI) may worsen in pregnancy due to increased vasopressinase production by the placenta, or decreased vasopressinase breakdown by the liver. Extended fluid-deprivation tests should be avoided in pregnancy and close observation with paired urine and plasma osmolality measurements may be sufficient to exclude DI. Desmopressin is safe for use in pregnancy for diagnosis or treatment of DI. Transient DI may occur in pregnancy and is often associated with acute fatty liver of pregnancy and, more rarely, with pre-eclampsia and HELLP syndrome (see p. 1303).

Hypopituitarism
Hypopituitarism (see pp. 1188–1190) is rare in pregnancy but may be caused by the following:
- pituitary surgery
- radiotherapy
- pituitary or hypothalamic tumours
- pituitary haemorrhage
• postpartum pituitary infarction (Sheehan syndrome)
• lymphocytic hypophysitis.

Sheehan syndrome usually presents after delivery following postpartum haemorrhage and may lead to partial or complete pituitary failure. There may be a delay in diagnosis, as the symptoms may be attributed to the postpartum state. Lymphocytic hypophysitis is an uncommon autoimmune disorder due to extensive infiltration of the anterior pituitary by chronic inflammatory cells, predominantly lymphocytes, causing pituitary expansion. Anti-pituitary antibodies have been described and this condition is associated with autoimmune thyroiditis or adrenalitis in 20% of cases. It is most common in late pregnancy and the postpartum period. It presents with features suggestive of an expanding pituitary tumour and 85% of cases have endocrine hypofunction.

## Adrenal disease

See also page 1224.

### Conn syndrome and hyperaldosteronism

This is rare in pregnancy but hypertension, particularly in the absence of a positive family history, and hypokalaemia are indications for screening. High levels of progesterone in pregnancy may antagonize aldosterone and ameliorate the hypokalaemia. Renin and aldosterone levels are increased in pregnancy, and diagnosis requires the use of pregnancy-specific normal ranges. Hypertension is controlled in the usual way with labetalol, methyldopa or nifedipine, and hypokalaemia is treated with potassium supplementation or potassium-sparing diuretics. Amiloride is safe to use in pregnancy and high doses (e.g. 20 mg) may be needed. Spironolactone, which is used as a potassium-sparing diuretic in Conn syndrome outside pregnancy, should be avoided, as it may cause feminization of a male fetus because it is an antiandrogen. Surgery for adrenal adenomas can usually be safely deferred until after delivery.

### Phaeochromocytoma and paraganglioma

Phaeochromocytoma and paraganglioma (see pp. 1231–1232) are a rare but dangerous cause of hypertension in pregnancy. Women with hypertension associated with unusual features of palpitations, anxiety, sweating or headache should be screened. Management involves adequate α-blockade with phenoxybenzamine to control hypertension, followed by β-blockade, if required, to control tachycardia. Alpha-blockade is imperative prior to delivery. Surgical removal is the only cure, and optimal timing of tumour resection depends on the point of gestation at which the diagnosis is made. There is an increasing vogue to delay tumour resection until the puerperium.

## Renal disease
**Urinary tract infection**

See pages 762–767.

**Bacteriuria in pregnancy**

The urine of all pregnant women must be cultured, as 2–6% have asymptomatic bacteriuria. While asymptomatic bacteriuria in the non-pregnant female seldom leads to acute pyelonephritis and often does not require treatment, acute pyelonephritis frequently occurs in pregnancy under these circumstances. Failure to treat may thus result in severe symptomatic pyelonephritis later in pregnancy, with the possibility of preterm labour. Therefore, *bacteriuria must always be treated and be shown to be eradicated*. Re-infection may require prophylactic therapy. Tetracycline, sulphonamides and 4-quinolones must be avoided in pregnancy. Trimethoprim should be avoided in the first trimester. Amoxicillin, nitrofurantoin and cephalosporins may safely be used in pregnancy.

**Chronic kidney disease**

Women with chronic kidney disease (CKD) are at increased risk of pre-eclampsia, fetal growth restriction (FGR), preterm delivery and caesarean section; the perinatal mortality rate is increased. These obstetric complications and the risk of permanent deterioration in renal function are increased by the presence and severity of any renal impairment or hypertension.

In women with *moderate or severe renal impairment* (CKD stage 3–5), GFR 45 to 15 mL/min/1.73 m²), 60–90% of infants are born preterm and there is a risk of accelerated decline in renal function of 20–50% in the mother.

An increase in the degree of proteinuria is very common in pregnancy and does not necessarily imply pre-eclampsia or worsening renal disease.

**Management**

Management should include regular monitoring of blood pressure, renal function and fetal wellbeing. In view of the increased risk of pre-eclampsia, treatment with low-dose aspirin (75 mg daily from week 12 to delivery) is used, especially in those with hypertension and renal impairment or a previous poor obstetric history.

**Renal transplantation**

If graft function is normal, pregnancy outcome is excellent and there is no adverse long-term effect on renal allograft function or survival. The chance of successful pregnancy outcome is reduced and the risk of long-term deterioration in graft function increased with poor baseline graft function. Pregnancy outcome is optimal in those without hypertension, proteinuria or recent episodes of graft rejection.

The doses of immunosuppressive drugs are maintained at pre-pregnancy levels.
Prednisolone, azathioprine, ciclosporin and tacrolimus are safe for use in pregnancy without any reported increase in the risk of congenital malformations. Mycophenolate mofetil and sirolimus are contraindicated. Prophylactic antibiotics should be given for recurrent UTIs and to cover any surgical procedure. The risks of pre-eclampsia, graft rejection, fetal growth restriction (FGR), preterm delivery and infection are increased. Caesarean section is only required for obstetric indications but the rate is increased.

### Acute kidney injury

Because serum creatinine falls in pregnancy, acute kidney injury (AKI) is defined as an abrupt deterioration in renal function with a serum creatinine >90 µmol/L. Mild degrees of AKI are not uncommon, particularly immediately postpartum. The most common underlying causes are:

- **Infection**: septic abortion, puerperal sepsis, acute pyelonephritis.
- **Blood loss**: postpartum haemorrhage, placenta abruption.
- **Volume contraction**: pre-eclampsia, eclampsia, hyperemesis gravidarum, diarrhoea.
- **Post-renal failure**: ureteric damage or obstruction.
- **Drugs**: NSAIDs, antibiotics (e.g. aminoglycosides).

Women with pre-eclampsia are particularly prone to pulmonary oedema and therefore management protocols include fluid restriction, even in the presence of oliguria. If these patients develop AKI, this is usually rapidly reversible upon recovery and less dangerous than pulmonary oedema, which may result if the AKI is treated with repeated fluid challenges. In this respect, therefore, the management of AKI differs from that outside pregnancy.

### Skin disorders in pregnancy

Common skin changes that occur in pregnancy include striae (see p. 1378), spider naevi, melasma (pigmentation on the face) and linea nigra (midline pigmentation on the abdomen). A shift in maternal immune profile from predominantly Th1 to Th2 may underlie the tendency for atopic dermatitis to develop or worsen during pregnancy. Psoriasis usually improves.

The specific dermatoses of pregnancy have recently been reclassified as follows:

- **Atopic eruption of pregnancy**:
  - **Atopic eczema** (see pp. 1349–1351).
  - **Prurigo of pregnancy** usually starts on the abdomen in the third trimester but may persist for some months after delivery. Clustered excoriated papules (prurigo-like lesions) occur on the abdomen and extensor surfaces of the limbs. The cause is unknown but pregnancy-related itch (pruritus gravidarum) may be due to cholestasis (see p. 1304). Rarely, liver biochemical tests are abnormal and urinary HCG levels may be elevated. Prurigo can recur in subsequent pregnancies. Treatment is with topical steroids and oral antihistamines.
  - **Pruritic folliculitis of pregnancy** is characterized by an itchy folliculitis, which looks
similar to steroid-induced ‘acne’. It is not associated with any increased maternal or fetal risk. Treatment is with topical benzoyl peroxide, and hydrocortisone cream helps to relieve symptoms.

- **Polymorphic eruption of pregnancy** (pruritic urticated papules of pregnancy) is a relatively common, intensely itchy rash that starts on the abdomen, often within striae, in the last trimester; it is associated with multiple births. It is uncomfortable but harmless. Symptomatic topical therapy and antihistamines are helpful until after delivery, when the rash resolves.

- **Pemphigoid gestationis** is a rare disease that is analogous to bullous pemphigoid (see pp. 1369–1370). It is associated with prematurity and stillbirth, and transplacental passage of pathogenic immunoglobulin G (IgG) antibodies can lead to transient blistering in the neonate. It often starts around the umbilicus with itchy, inflamed papules; then blistering appears and the eruption may become generalized. Onset may be in the first or second trimester, and it typically flares postpartum. The diagnosis is confirmed with direct immunofluorescence (see p. 1368). Systemic steroid therapy is required. Recurrences may occur with subsequent pregnancies and with the oral contraceptive pill, which should be avoided.

---

**Rheumatoid arthritis in pregnancy**

50–80% of women with rheumatoid arthritis usually go into remission in pregnancy. However, about 90% will flare during the postpartum period. Disease-modifying anti-rheumatic drugs (DMARDs) are contraindicated in pregnancy. Women should take advice from their rheumatologist and obstetrician prior to conception. **Box 29.10** shows the use of drugs in pregnancy.

**Box 29.10**

**Drug use during pregnancy in treatment of rheumatoid arthritis**

- **Paracetamol**: the oral analgesic of choice
- **Oral NSAIDs and selective COX-2 inhibitors**: can be used after implantation up until the last trimester if symptoms justify their use
- **Corticosteroids**: may be used to control disease flares (main maternal risks are hypertension, glucose intolerance and osteoporosis)
- **DMARDs**:
  - **May be used**: sulfasalazine, hydroxychloroquine, azathioprine or ciclosporin if required
to control inflammation

- **Must be avoided**: methotrexate, leflunomide and cyclophosphamide; women should not conceive while taking methotrexate or leflunomide

- **Biological agents**: safety during pregnancy is currently unclear

  - **Contraindicated in breast-feeding**: methotrexate, leflunomide, cyclophosphamide
    COX-2, cyclo-oxygenase 2; DMARDs, disease-modifying anti-rheumatic drugs; NSAIDs, non-steroidal anti-inflammatory drugs.

**Prescribing in Pregnancy**

Many clinicians are understandably reluctant to prescribe drugs for pregnant women. This relates mainly to concern regarding teratogenic risk. The following general principles should be remembered:

- **Older generic drugs.** Use older generic drugs within each class, since there are likely to be more data on use in pregnancy.

- **Dosages.** Resist the temptation to prescribe lower doses. Pregnant women usually need **higher** doses because of increased renal and liver clearance.

- **Disease control.** Control of underlying diseases, such as arthritis, inflammatory bowel disease, epilepsy, asthma and thyrotoxicosis, with appropriate drug therapy is likely to reduce adverse fetal and neonatal outcomes such as preterm birth and growth restriction.

- **Treatment for unfamiliar diseases.** When considering treatment for these, always ask the specialist physician, ‘What would you do if this woman was not pregnant?’ Then assess the risks of this strategy in pregnancy.

- **Risks to the fetus.** These must be balanced against potential benefits to the mother (and therefore indirectly the fetus).

  The **teratogenic potential** of some drugs classified as ‘absolutely contraindicated’ (see **Box 2.6**, p. 22) is sufficiently high to justify termination of a pregnancy following inadvertent exposure, e.g. methotrexate (see p. 680) or thalidomide. For others, there are theoretical reasons to avoid their use in pregnancy, but they carry a low risk of teratogenesis and therefore there is no justification for termination (e.g. rubella vaccine, simvastatin, ACE inhibitors).

  For drugs that are ‘relatively contraindicated’, there are situations in which use is appropriate and where no safer alternative exists: for example, warfarin in women with prosthetic heart valves or AEDs in women with epilepsy.

  - Beta-blockers should not be used as first-line treatment of hypertension, but may be indicated to control tachyarrhythmias, for migraine prophylaxis, thyrotoxicosis and mitral stenosis, and in those at risk of aortic dissection.

  - Diuretics should be avoided in the treatment of hypertension but are appropriate in the treatment of pulmonary oedema.

Disorders of the Ear

Anatomy and Physiology

The ear can be divided into three parts: outer, middle and inner (Fig. 30.1).
The outer ear consists of the pinna and external auditory meatus, and funnels sound energy to the middle ear, selectively amplifying sounds in the 2–4 kHz range by 15 decibels (dB, speech sounds). When sound energy passes from air in the outer ear to fluid in the inner ear, it loses 30 dB due to energy that is reflected at the interface of the two mediums. The middle ear acts as a transformer, increasing the pressure of the acoustic wave to account for the energy lost at this air–fluid interface. As the acoustic wave moves across the tunnel of the inner ear, passing from the oval window to the round window, it causes maximal vibration of the basilar membrane in a location that is specific to its resonant frequency. This vibration causes the hair cell to open its ion gates and an action potential to be propagated along a fibre of the cochlear nerve. The location of the nerve fibre and the strength of its action potential allow the central nervous system to construct meaning from the sound we hear.

The outer ear has a skin-lined tube 2.5 cm long leading down to the tympanic membrane (the ear drum). Its outer third is cartilaginous and contains hair and sebaceous and ceruminous glands, but the walls of the inner two-thirds are bony. The outer ear is self-cleaning, as the skin is migratory so there are no indications to use cotton wool buds. Wax should only be seen in the outer third.

The middle ear is an air-containing cavity derived from the branchial clefts. It communicates with the mastoid air cells superiorly, and the Eustachian tube connects it to the nasopharynx medially. The Eustachian tube ventilates the middle ear and maintains equal air pressure across the tympanic membrane. It is normally closed but opens via the action of the palatal muscles to allow air entry when swallowing or yawning. A defect in this mechanism, such as with a cleft palate, will prevent air entering the middle ear cleft, which may then fill with fluid. Lying within the middle ear cavity are the three ossicles (malleus, incus and stapes), which transmit sound from the tympanic membrane (Fig. 30.2) to the inner ear. On the medial wall of the cavity is the horizontal segment of the facial nerve, which can be damaged during surgery or by direct extension of infection in the middle ear.
The inner ear contains the cochlea for hearing and the vestibule and semicircular canals for balance. There is a semicircular canal arranged in each body plane and these canals are stimulated by rotatory movement. The facial, cochlear and vestibular nerves emerge from the inner ear and run through the internal acoustic meatus to the brainstem (see Fig. 21.8).

**Physiology of hearing**

The ossicles, in the middle ear, transmit sound waves from the tympanic membrane to the cochlea. They amplify the waves by about 18-fold to compensate for the loss of sound waves moving from the air-filled middle ear to the fluid-filled cochlea. Hair cells in the basilar membrane of the cochlea detect the vibrations and transduce these into nerve impulses, which pass to the cochlear nucleus and then eventually to the superior olivary nuclei of both sides; thus lesions central to the cochlear nucleus do not cause unilateral hearing loss.

If the ossicles are diseased, sound can also reach the cochlea by vibration of the temporal bone (bone conduction).

**Clinical Approach to the Patient with a Disorder of the Ear**

**Examination**

The pinna and post-auricular region should first be examined for erythema, scars or swellings. An auroscope is used to examine the external ear canal whilst the pinna is retracted backwards and upwards to straighten the canal. Look for wax, discharge or foreign bodies. The tympanic membrane should always be seen with a light reflex anteroinferiorly. Previous repeated
infections may cause a thickened, whitish drum but fluid in the middle ear may show as dullness of the drum. Perforations can be described as marginal if they involve the annulus, subtotal if the pars tensa is absent, and total if both pars tensa and the annulus are absent.

**Rinne test**

*(Fig. 30.3.)*

- Normally, a tuning fork, 512 Hz, will be heard as louder if held next to the ear (i.e. air conduction) than it will if placed on the mastoid bone *(Rinne-positive).*
- If the tuning fork is perceived louder when placed on the mastoid (i.e. via bone conduction), then a defect in the conducting mechanism of the external or middle ear is present (true *Rinne-negative*).

![Rinne test](image)

**Figure 30.3** Rinne test. Comparing conduction of sound. A. Air conduction. B. Bone conduction.

**Weber test**

*(Fig. 30.4.)* A tuning fork placed on the forehead or vertex of a patient with normal hearing (or with symmetrical hearing loss) should be perceived centrally by the patient. A patient with unilateral conductive hearing loss will hear the sound loudest in the affected ear, whereas a patient with unilateral sensorineural hearing loss will report the sound to be loudest in the unaffected ear.
Pure-tone audiometry

The patient is asked to respond when they hear sounds presented as pure tones at varying sound intensities and frequencies. Sounds are presented to each ear (representing air conduction) and then to each mastoid in turn (representing bone conduction). An audiogram is produced by the lowest sound intensity that is reliably perceptible at each frequency tested at both ears and mastoids (Fig. 30.5).

Common Disorders of the Ear

There are four main symptoms related to ear pathology: pain (otalgia), discharge (otorrhoea), hearing loss and dizziness (vertigo). The sequence and combination of symptoms can differentiate between most conditions and therefore history is often the most useful diagnostic
The painful ear (otalgia)

A painful ear is a common complaint but, due to the complex innervation, may be referred from distant sites and can thus on occasion have an obscure aetiology.

Otitis externa

When the natural barriers to infection are overcome, the skin of the ear canal can become infected. Discharge and itch are the initial presenting symptoms, followed by pain and then reduction in hearing as the ear canal closes off. Infection can spread to the pinna, causing cellulitis. Although the causative organism is most commonly bacterial (pseudomonal species, followed by staphylococcal species), it can also be fungal. There may be swelling of the pre-auriculacural or post-auricular lymph nodes that can be mistaken for mastoiditis.

**Examination** often reveals debris in the canal, which needs to be removed either by gentle mopping or preferably by suction, viewed directly under a microscope. The tympanic membrane is normal, when visible. In severe cases, the canal may be swollen and a view of the tympanic membrane impossible. Any foreign body seen should be removed with great care by trained personnel.

**Treatment** is with topical antibiotics in the first instance: drops such as dexamethasone 0.05%, framycetin sulphate 0.5%, gramicidin 0.005% drops, hydrocortisone acetate 1% or gentamicin 0.3%, or a spray such as dexamethasone 0.1%, neomycin sulphate 3250 units. If it does not resolve in 3–4 days, then microsuction in an Ear, Nose and Throat (ENT) department is necessary.

Finafloxacin ear drops are used if there is a perforation, to reduce ototoxicity.

Otitis media

Otitis media is an infection of the middle ear seeded from the upper respiratory tract through the Eustachian tube. Therefore most commonly encountered pathogens are similar to those that cause upper respiratory tract infections: respiratory syncytial virus (RSV), *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Moraxella catarrhalis*. Otitis media most commonly affects children under the age of 10. Infection causes inflammation of the middle ear mucosa and inflammatory exudate in the middle ear space. Due to the middle ear fluid, otitis media presents with otalgia and hearing disturbance. If it does not resolve, it can lead to tympanic membrane perforation and discharge. There are no mucous glands in the external ear canal. If the discharge is serous, then middle ear pathology is unlikely. Otitis media classically presents with otalgia followed by discharge, whereas otitis externa presents with discharge followed by otalgia. Rare complications of otitis media include mastoiditis as the middle ear inflammatory fluid escapes from the middle ear into the mastoid, or meningitis as the infection spreads through the tegmen into the intracranial cavity. Examination shows a healthy ear canal.
with an erythematous and occasionally bulging tympanic membrane.

**Treatment** of the acute case is initially with non-steroidal anti-inflammatory drugs. Otitis media is often viral in origin – for example, following a cold – and will settle within 72 hours without antibacterial treatment. In people with systemic features or after 72 hours, a systemic antibiotic, such as amoxicillin, should be given, particularly in children under 2 years old. Topical therapy is of no value. If there is tenderness and swelling over the mastoid, then an urgent ENT opinion should be obtained.

---

**Referred otalgia**

Pain may be referred from:

- the teeth and temporomandibular joint from the auriculotemporal nerve (a branch of the mandibular (Vth cranial) nerve)
- cervical spinal problems from C1 to C3
- tonsil and tongue base problems from the glossopharyngeal (Jacobson's) nerve
- the larynx and pharynx from the vagus (Arnold's) nerve
- Ramsay Hunt syndrome, causing vesicles along the distribution of the VIIth cranial nerve.

The innervation of the pinna is from the auriculotemporal branch of the trigeminal and the first two cervical nerves (**Fig. 30.6**). Therefore, dental pain, temporomandibular joint dysfunction and upper cervical osteoarthritis can all present as otalgia. The ear canal is innervated by the above-mentioned nerves, and also by the facial and vagus nerves (**Fig. 30.6**). Hence Ramsay Hunt syndrome (varicella reactivation along the sensory division of the facial nerve) causes otalgia with ear canal vesicles, whereas cancer of the larynx and pharynx can occasionally present as otalgia due to referred pain along the vagus nerve. The middle ear is innervated by the glossopharyngeal nerve and therefore infections of the pharynx are associated with otalgia.
The discharging ear (otorrhea)

Discharge from the ear is usually due to infection of the outer or middle ear. The most common cause is otitis externa, followed by otitis media with a perforated tympanic membrane (see above).

Cholesteatoma

Although cholesteatoma is a rarer cause of the otorrhea, it has severe implications if missed and should be considered in any non-resolving or recurrent case of otorrhea. Cholesteatoma is defined as keratinizing squamous epithelium within the middle ear cleft and can present with foul-smelling otorrhea. Examination shows a defect in the tympanic membrane full of white, cheesy material. Mastoid surgery is required to remove this sac of squamous debris, as it can erode local structures such as the ossicles or facial nerve, or even extend intracranially to cause meningitis or an intracranial abscess.

Hearing loss
Deafness can be conductive or sensorineural and these can be differentiated at the bedside by the Rinne and the Weber tests (Box 30.1) or with pure-tone audiometry. **Conductive hearing loss** has many causes (Box 30.2) but wax is the most common.

**Box 30.2**

**Causes of deafness**

**Conductive**

**External meatus**
- Wax
- Foreign body
- Otitis externa
- Chronic suppuration

**Drum**
- Perforation/trauma

**Middle ear**
- Otosclerosis
- Ossicular bone problems
- Suppuration (otitis media)

**Sensorineural**

**Congenital**
- Pendred syndrome (see p. 1202)
- Long QT syndrome
- Björgnstad syndrome (pili torti)

**End-organ**
- Advancing age
- Occupational acoustic trauma
• Ménière's disease
• Drugs (e.g. gentamicin, furosemide)

**VIIIth nerve lesions**
• Acoustic neuroma
• Cranial trauma
• Inflammatory lesions:
  • Tuberculous meningitis
    – Sarcoidosis
    – Neurosyphilis
    – Carcinomatous meningitis
**Brainstem lesions (rare)**
• Multiple sclerosis
• Infarction

---

**Perforated tympanic membrane**
This arises from trauma or chronic middle ear disease when recurrent infection results in a permanent defect. Surgical repair is indicated only if the patient is symptomatic with recurrent discharge. The larger the perforation, the greater the impact on hearing.

**Otitis media and otitis externa**
As discussed above, both of these infections lead to hearing loss but the sequence of events will help differentiate the conditions: hearing loss is common and early in otitis media, but rare and late in otitis externa.

**Secretory otitis media with effusion (‘serous otitis media’ or ‘glue ear’)**
This is common in children because Eustachian tube dysfunction may lead to poorly ventilated middle ears. The vacuum created by poor ventilation leads to a non-inflammatory effusion. The effusion resolves naturally in the majority of cases but can persist or recur, causing a hearing loss that impacts on speech and language skills and on educational progress. The presenting complaint is hearing loss or speech delay but little association with otalgia.

*Examination* shows a dull tympanic membrane with loss of light reflex *(Fig. 30.7)* and occasionally fluid with air bubbles visible in the middle ear. Children with glue ear frequently have adenoidal hypertrophy and nasal blockage.
**Management** involves insertion of a grommet (tymanostomy tube) into the tympanic membrane, which ventilates the middle ear cavity, if the symptoms are persistent and troublesome. Antibiotic–glucocorticoid ear drops are more effective than oral antibiotics. Adenoidectomy can be added to the procedure if there is a strong history of complete nasal blockage or recurrent upper respiratory tract infections. Grommets are extruded from the tympanic membrane as it heals (over 6 months to 2 years). Developmental outcomes are not improved by grommet insertions. In most children, the middle third of the face grows around the age of 7–14 years and Eustachian tube dysfunction is rare after this.

**Otosclerosis**

This is usually a hereditary disorder, in which new bony deposits occur within the stapes footplate and the cochlea. Characteristically seen in the second and third decades, it is more common in females and can become worse during pregnancy. The hearing loss may be mixed, and management includes a hearing aid or replacement of the fixed stapes with a prosthesis (stapedectomy). The choice of treatment is dependent on the patient. Surgery is an excellent option, with very good success rates in regular stapedectomists' hands, but it always carries a small risk of a complete hearing loss. Hearing aids, whilst safe, require the patient's compliance if they are to afford benefit.

**Presbycusis**

This is the most common cause of deafness. It is a degenerative disorder of the cochlea and is typically seen in old age. It can be due to the loss of outer hair cells (sensory), loss of the ganglion cells (neural) or strial atrophy (metabolic), or there can be a mixed picture. Ageing itself does not cause outer hair cell loss but environmental noise toxicity over the years is a major factor. The onset is gradual and the higher frequencies are affected most (see Fig. 30.5). Speech has two components: low frequencies (vowels) and high frequencies (consonants).
When the consonants are lost, speech loses its intelligibility. Increasing the volume merely increases the low frequencies and the characteristic response of ‘Don’t shout. I'm not deaf!’
A high-frequency-specific hearing aid will do much to ease the frustrations of both the patients and their close contacts.

### Noise trauma

Cochlear damage can occur, for example, from shooting without ear protectors or from industrial noise (see p. 59), and characteristically has a loss at 4 kHz.

### Acoustic neuroma

This is a slow-growing benign schwannoma of the vestibular nerve (see p. 868), which can present with progressive sensorineural hearing loss. Any patient with an asymmetric sensorineural hearing loss or sudden sensorineural hearing loss should be investigated: for example, with a magnetic resonance imaging (MRI) scan.

### Dizziness/vertigo

Vertigo is usually rotatory when it arises from the ear. The presence of otalgia, otorrhoea, tinnitus or hearing loss suggests an otologic aetiology. Vestibular causes can be classified according to the duration of the vertigo. Common causes are summarized below.

- seconds (<1 minute) – benign paroxysmal positional vertigo
- minutes to hours – Ménière's disease
- hours to days – labyrinthine or central pathology.

### Benign paroxysmal positional vertigo

Benign paroxysmal positional vertigo (BPPV) is thought to occur when otoconia (tiny crystals of calcium carbonate) are dislodged from the utricle into the semicircular canals, commonly the posterior canal. Positional vertigo is precipitated by head movements, usually to a particular position, and often occurs when turning in bed or on sitting up. The onset is typically sudden and distressing. The vertigo lasts seconds (<1 minute) and the phenomenon becomes less severe on repeated movements (fatigue). There is no serious underlying cause but it sometimes follows vestibular neuronitis (see p. 810), head injury or ear infection. It occurs in 50% of older people and is the most common cause of head injury in those under 50 years of age.

### Diagnosis

Diagnosis is made on the basis of the history and by the **Hallpike manoeuvre (Fig. 30.8)**. A positive Hallpike test confirms BPPV, which can be cured in over 90% of cases by the Epley
manoeuvre. This involves gentle but specific manipulation and rotation of the patient's head to shift the loose otoliths from the semicircular canals.

![Figure 30.8 Hallpike manoeuvre for diagnosis of benign paroxysmal positional vertigo. This can be done in the outpatient department. (a) The patient sits on a couch, his head turned towards one ear. (b) The head is supported by the examiner while the patient lies down so that his head is just below the horizontal. Nystagmus (following a latent interval of a few seconds) is commonly noted when the head has been turned towards the affected ear. This can be repeated with the patient's head turned towards the other ear.](image)

The differential diagnosis includes a cerebellar mass, but in that case positional nystagmus (and vertigo) is immediately apparent (no latent interval) and does not fatigue.

### Ménière's disease

This is a rare condition characterized by recurring, episodic, rotatory vertigo lasting 30 minutes to a few hours; attacks are recurrent over months or years. Classically, it is associated with a low-frequency sensorineural hearing loss, a feeling of fullness in the affected ear, loss of balance, tinnitus and vomiting. There is a build-up of endolymphatic fluid in the inner ear, although its precise aetiology is still unclear.

### Management

Vestibular sedatives, such as cinnarizine, are used in the acute phase. Preventative measures, such as a low-salt diet, betahistine and avoidance of caffeine, are useful. If the disease cannot be controlled, then a chemical labyrinthectomy, perfusing the round window orifice with ototoxic drugs such as gentamicin, is used. Gentamicin destroys the vestibular epithelium; therefore the patient has severe vertigo for around 2 weeks until the body compensates for the lack of vestibular input on that side. The patient will happily trade occasional mild vertigo
when the balance system is challenged against the unpredictable, severe and disabling attacks of vertigo involved in Ménière's disease. There is a risk of sensorineural hearing loss and complete vestibular failure if Ménière's starts in the previously unaffected side. The final option is surgical decompression of the endolymphatic compartment of the inner ear to relieve the endolymphatic hydrops.

### Labyrinthine or central causes of vertigo

(See Box 21.13.) These are managed with vestibular sedatives in the acute phase. Most patients will settle over a few days but continuous true vertigo with nystagmus suggests a central lesion. A patient with a deficit of vestibular function due to viral labyrinthitis or neuronitis should be able to cease vestibular sedatives within 2 weeks; long-term use can give parkinsonian side-effects, delay central compensation and thus prolong the vertigo. Vestibular rehabilitation by a physiotherapist or audiological scientist can speed up the compensation process, although most patients will be able to do this themselves with time.

### Tinnitus

This is a sensation of a sound when there is no auditory stimulus. It can occur without hearing loss and results from heightened awareness of neural activity in the auditory pathways. Patients describe a hissing or ringing in their ears and this can cause much distress. It usually does not have a serious cause but vascular malformation, such as aneurysms, or vascular tumours can be associated. In these cases, the tinnitus is pulsatile and most commonly unilateral.

### Management

This is difficult. A tinnitus masker (a mechanically produced, continuous soft sound) can help. Cognitive behavioural therapy through audiological services are of use and rehabilitate patients well.

### Further reading

### Disorders of the Nose

**Anatomy and physiology**

*(Fig. 30.9.)* The function of the nose is to facilitate smell and respiration:

- Smell is a sensation conveyed by the olfactory epithelium in the roof of the nose. The
olfactory epithelium is supplied by the 1st cranial nerve (see p. 802).

- The nose also filters, moistens and warms inspired air and, in doing so, assists the normal process of respiration.

![FIGURE 30.9 The anatomy of the nose in longitudinal section. IT, inferior turbinate; MT, middle turbinate; ST, superior turbinate; a, internal ostium; b, respiratory region; c, choanae.]

The external portion of the nose consists of two nasal bones attached to the rest of the facial skeleton and to the upper and lower lateral cartilages. The internal nose is divided by a midline septum that comprises both cartilage and bone. This divides the internal nose in two, from the external nostril to the posterior choanae. The posterior choanae are in continuity with the nasopharynx posteriorly. The paranasal sinuses open into the lateral wall of the nose and form a system of aerated chambers within the facial skeleton.

The blood supply of the nose is derived from branches of both the internal and external carotid arteries. The internal carotid artery supplies the upper nose via the anterior and posterior ethmoidal arteries. The external carotid artery supplies the posterior and inferior portion of the nose via the superior labial artery, greater palatine artery and sphenopalatine artery. On the anterior nasal septum there is an area of confluence of these vessels (Little's area; Fig. 30.10A).
Clinical Approach to the Patient with a Disorder of the Nose

Examination

The anterior part of the nose can be examined using a nasal speculum and light source. Endoscopes are required to examine the nasal cavity and postnasal space.

Common Disorders of the Nose

Epistaxis

Nose bleeds vary in severity from minor to life-threatening. Little's area (Fig. 30.10A) is a frequent site of nasal haemorrhage. First aid measures should be administered immediately, including external digital compression of the anterior lower portion of the external nose, ice packs and leaning forward. The patient should be asked to avoid swallowing any blood running posteriorly, as this causes nausea.

Not infrequently, small, recurrent epistaxes occur and these may require a visit to the emergency clinic for an examination and simple local anaesthetic cautery with a silver nitrate stick. If the bleeding continues profusely, then resuscitation in the form of intravenous access, fluid replacement or blood, and oxygen can be administered. If further intervention is necessary, consideration should be given to intranasal cautery of the bleeding vessel, or intranasal packing using a variety of commercially available nasal packs (Fig. 30.10B). In addition to direct treatment of the epistaxis, a cause should be sought and treated appropriately (Box 30.3). If the above treatments fail, surgical ligation of the sphenopalatine artery can be undertaken endoscopically or an interventional arterial embolization can be performed for the problematic vessel.
### Aetiology of epistaxis

#### Local

- Idiopathic
- Trauma – foreign bodies, nose-picking and nasal fractures
- Iatrogenic – surgery, intranasal steroids
- Neoplasm – nasal, paranasal sinus and nasopharyngeal tumours

#### General

- Anticoagulants/antiplatelet agents
- Coagulation disorders
- Severe hypertension
- Osler–Weber–Rendu syndrome (familial haemorrhagic telangiectasia)

### Rhinitis

See pages 1076–1077.

### Nasal obstruction

Nasal obstruction is a symptom and not a diagnosis. It can significantly affect a patient's quality of life. Causes include:

- **Rhinitis** (see pp. 1076–1077). The most common aetiology is allergy-based. Rhinitis results in erythema of the nasal mucosa and hypertrophy of inferior turbinates. If an allergen is identified, then allergen avoidance is the mainstay of treatment. Topical steroids and/or antihistamines can be tried. If rhinitis is severe, then referral to an allergy clinic for immunotherapy is warranted. Short-term benefit can be gained in severe nasal blockage by surgically reducing the inferior turbinate.

- **Septal deviation.** Correction can be undertaken surgically.

- **Nasal polyps.** This condition occurs with inflammation and oedema of the sinus nasal mucosa. This oedematous mucosa prolapses into the nasal cavity and can cause significant nasal obstruction. In allergic rhinitis (see p. 1075), the mucosa lining the nasal septum and inferior turbinates are swollen and a dark-red or plum colour. Nasal polyps can be identified as glistening swellings, which are insensate. Treatment with intranasal steroids helps, but if polyps are large or unresponsive to medical treatment, then surgery is necessary.

- **Foreign bodies.** These are usually seen in children who present with unilateral nasal discharge. Clinical examination of the nose with a light source often reveals the foreign body,
which requires removal, either in clinic or in theatre, with a general anaesthetic.

• **Sinonasal malignancy.** This is extremely rare. The diagnosis must be considered if unusual unilateral symptoms are seen, including nasal obstruction, epistaxis, pain, epiphora (watery eye), cheek swelling, paraesthesia of the cheek, unilateral serous otitis media and proptosis of the orbit.

## Sinusitis

Sinusitis is an infection of the paranasal sinuses that is bacterial (mainly *Streptococcus pneumoniae* and *Haemophilus influenzae*) or occasionally fungal. It is most commonly associated with an upper respiratory tract infection and can occur with asthma. Symptoms include frontal headache, purulent rhinorrhea, facial pain with tenderness, and fever. Sinusitis can be confused with a variety of other conditions, such as migraine, trigeminal neuralgia and cranial arteritis.

## Management

Treatment for a bacterial sinusitis includes nasal decongestants, such as xylometazoline; broad-spectrum antibiotics, such as co-amoxiclav because *H. influenzae* can be resistant to amoxicillin; anti-inflammatory therapy with topical corticosteroids, such as fluticasone propionate (nasal spray) to reduce mucosal swelling; and steam inhalations.

If the symptoms of sinusitis are recurrent (**Box 30.4**) or complications such as orbital cellulitis arise, then an ENT opinion is appropriate and a computed tomography (CT) scan of the paranasal sinuses is undertaken. Plain sinus X-rays are now rarely used to image the sinuses.

CT scan of the sinuses (**Fig. 30.11**) or an MRI scan can demonstrate bony landmarks and soft tissue planes.
FIGURE 30.11 CT of the sinuses. An inverting papilloma (P) can be seen obstructing the right nostril, and there is mucosal thickening (M) of the right maxillary sinus.

**Functional endoscopic sinus surgery (FESS)** is used for ventilation and drainage of the sinuses.

### Anosmia

Olfaction is mainly under the control of cranial nerve I, although irritant, unpleasant nasal sensations are carried by cranial nerves V, IX and X. Anosmia is a complete loss of the sense of smell and **hyposmia** is a decreased sense of smell:

- A **conductive deficit** of smell occurs if odorant molecules do not reach the olfactory epithelium high in the nose.
- A **sensorineural loss** of smell is incurred if the neural transmission of smell is affected.
- Some conditions predispose to a mixed (conductive and sensorineural) loss of smell.

The main cause of a loss of smell is nasal obstruction due to upper respiratory infection or nasal polyps. Other causes include sinonasal disease, old age, drug therapy and head injury/trauma. It is difficult to predict the speed and extent of recovery in the latter causes. In many, anosmia is idiopathic, but before this diagnosis is accepted, an assessment of the patient for the possibility of an intranasal tumour or intracranial mass should be undertaken.

### Fractured nose

People with a fractured nose present with epistaxis, bruising of the eyes and nasal bridge swelling. Initially, it is often difficult to assess whether the bones are deviated, particularly if there is significant swelling. Reduction of the fracture should be undertaken in the first 2 weeks after injury and can be achieved by manipulation. However, if the fracture sets, a more formal rhinoplasty may have to be undertaken at a later stage. The patient should be examined for a head injury and the nose should also be checked for a septal haematoma (**Fig. 30.12**). This is painful, can cause nasal obstruction, is fluctuant to touch on the nasal septum, and requires
immediate drainage to prevent destruction of the septal cartilage.

**FIGURE 30.12** Septal haematoma.

**Disorders of the Throat**

**Anatomy and Physiology**

The throat can be considered as the oral cavity, the pharynx and the larynx (*Fig. 30.13*). The oral cavity extends from the lips to the tonsils. The pharynx can be divided into three areas:

- **The nasopharynx** extends from the posterior nasal openings to the soft palate
- **The oropharynx** extends from the soft palate to the tip of the epiglottis
- **The hypopharynx** extends from the tip of the epiglottis to just below the level of the cricoid cartilage, where it is continuous with the oesophagus.

**FIGURE 30.13** Normal anatomy of the throat.

Lying within the hypopharynx is the larynx. This consists of cartilaginous, ligamentous and muscular tissue that has the primary function of protecting the distal airway. The pharynx is
innervated from the pharyngeal plexus.

In the larynx, there are two vocal cords that abduct (open) during inspiration and adduct (close) to protect the airway and for voice production (phonation). The main nerve supply of the vocal cords comes from the recurrent laryngeal nerves (branches of the vagus nerve), which arise in the neck, but on the left side pass down around the aortic arch and then ascend in the tracheo-oesophageal groove to the larynx.

Normal vocal cords in phonation vibrate between 90 (male) and 180 (female) times per second, giving the voice its pitch or frequency. A healthy voice requires full closure of the vocal cords with a smooth, regular pattern of vibration, and any pathology that prevents full closure will result in air escaping between the vocal cords during phonation and a ‘breathy’ voice.

**Clinical Approach to the Patient with a Disorder of the Throat**

**Examination**

Good illumination is essential. Look at the teeth, gums, tongue, floor of mouth and oral cavity. The tonsils, soft palate and uvula are easily seen, and a gag reflex (see p. 810) is present. The remainder of the pharynx and larynx can be inspected with a laryngeal mirror or flexible nasendoscope.

Examination of the neck for lymph nodes and other masses is also performed.

**Common Disorders of the Throat**

**Hoarseness (dysphonia)**

There are three essential components for voice production: an air source (the lungs); a vibratory source (the vocal cords); and a resonating chamber (the pharynx and nasal and oral cavities). Although chest and nasal disorders can affect the voice, the majority of hoarseness is due to laryngeal pathology.

Inflammation that increases the ‘mass’ of the vocal cords will cause the vocal cord frequency to fall, giving a much deeper voice. Thus listening to a patient's voice can often give a diagnosis before the vocal cords are examined.

**Nodules**

Nodules (always bilateral and more common in females) and polyps (Fig. 30.14A) are found on the free edge of the vocal cord, preventing full closure and giving a ‘breathy, harsh’ voice. They are commonly found in professionals who rely on their voice for their livelihood, such as teachers, singers and lawyers. They are usually related to poor technique of voice production and can usually be cured with speech therapy. If surgery is needed, great care must be taken to
remain in the superficial layers of the vocal cord in order to prevent deep scarring, which leaves the voice permanently hoarse.

**FIGURE 30.14** Disorders of the vocal cords. A. Vocal cord polyp. B. Reinke's oedema of the vocal cords.

**Reinke's oedema**

This is due to a collection of tissue fluid in the subepithelial layer of the vocal cord (**Fig. 30.14B**). The vocal cord has poor lymphatic drainage, predisposing it to oedema. Reinke's oedema is associated with irritation of the vocal cords by smoking, voice abuse, acid reflux and, very rarely, hypothyroidism. Treatment is to remove the irritation in most cases, but surgery to incise the cords and reduce the oedema will also allow the voice to return to its normal pitch.

**Acute-onset hoarseness**

Hoarseness, in a smoker, is a danger sign. Any patient with a hoarse voice for over 6 weeks should be seen by an ENT surgeon. Other red flag symptoms will require urgent laryngoscopy (**Box 30.5**). The voice may be deep, harsh and breathy, indicating a mass on the vocal cord (**Fig. 30.15**), or it can be weak, suggesting a paralysed left vocal cord secondary to mediastinal disease, such as bronchial carcinoma.

**Box 30.5**

Red flags for hoarseness requiring urgent laryngoscopy

- Heavy smoking
- High alcohol intake
- Haemoptysis
- Dysphagia
- Pain, including otalgia
- Increasing dyspnoea
Early squamous cell carcinoma of the larynx has a good prognosis. Treatment is with carbon dioxide laser resection or radiotherapy. Spread and growth of the tumour can lead to referred otalgia, and, if the tumour is significant in its size, requires a laryngectomy (removal of the voicebox), with a neck dissection to remove the affected glands in the neck. A patient with a paralysed left vocal cord must have a CT of the neck and chest. Medialization of the paralysed cord to allow contact with the opposite cord can return the voice and give a competent larynx. This can be done under local or general anaesthesia, producing an immediate result whatever the long-term prognosis of the chest pathology.

**Stridor**

Stridor, or noisy breathing, can be divided into the following types:

- **Inspiratory**: obstruction is at the level of the vocal cords or above.

- **Mixed** (both inspiratory and expiratory): obstruction is in the subglottis or extrathoracic trachea.

- **Expiratory**: obstruction is in the intrathoracic trachea or distal airways.

All people with stridor, both paediatric and adult, are potentially at risk of asphyxiation and should be investigated fully. Severe stridor may be an indication for either intubation or a tracheostomy (*Box 30.6*).

---

**Box 30.6**

**Indications for tracheostomy**

- Upper airway obstruction (real or anticipated)
- Long-term ventilation
- Bronchial lavage
- Incompetent larynx with aspiration
Tracheostomy tubes (Fig. 30.16) are:

- **Cuffed or uncuffed.** A high-volume, low-pressure cuff is used to prevent aspiration and to allow positive-pressure ventilation.

- **Fenestrated or unfenestrated.** A fenestrated cuff has a small hole on the greater curvature of the tube (both outer and inner), allowing air to escape upwards to the vocal cords; the patient can therefore speak. This tube often has a valve that allows air to enter from the stoma but closes on expiration, directing the air through the fenestration.

Most long-term tracheostomy tubes have an inner and an outer tube. The inner tube fits inside the outer tube and projects beyond its lower end. A major problem with a tracheostomy tube is crusting of its distal end with dried secretions, and this arrangement allows the inner tube to be removed, cleaned and replaced as frequently as required, without disrupting the outer tube.

When to decannulate a patient is often a difficult issue if laryngeal competence is unclear. Movement of the vocal cords requires an ENT examination and a speech therapist's involvement. The tracheostomy tube itself can also produce problems due to compression of the oesophagus with a cuffed tube and prevention of the larynx from rising during normal swallowing.

**Tonsillitis and pharyngitis**

Viral infections of the throat are common and, although many practitioners may be under pressure from the patient to give antibiotics, they should not be used. The vast majority of infections are usually self-limiting, settling with bed rest, analgesia and encouragement of fluid intake. Fungal infections, usually candidiasis, are uncommon and may indicate an
immunocompromised patient or undiagnosed diabetes.

**Tonsillitis**

Tonsillitis, with a good history of pyrexia, dysphagia, lymphadenopathy and severe malaise, is usually bacterial; β-haemolytic streptococcus is the most common organism, which responds to penicillin V.

**Glandular fever**

Glandular fever (see p. 258) can also present with tonsillitis. Although, clinically, the tonsils have a confluent white exudate, there is often a petechial rash on the soft palate and an accompanying lymphadenopathy.

**Quinsy (peritonsillar abscess)**

Quinsy is a collection of pus outside the capsule of the tonsil, usually located adjacent to its superior pole. The patient often has trismus, making examination difficult, but the pus pushes the uvula across the midline to the opposite side. The area is usually hyperaemic and smooth but unilateral tonsil ulceration is more likely to be a malignancy. In either case, urgent referral to an ENT specialist is essential.

Indications for a **tonsillectomy** are shown in **Box 30.7**. This is carried out under a general anaesthetic and current surgical techniques include diathermy dissection, laser excision and coblation (using an ultrasonic dissecting probe). There are strong advocates for each technique and much will depend on the individual surgeon's preference. Some departments carry out tonsillectomy as a day-case procedure, as most reactionary bleeding will occur within the first 8 hours postoperatively.

**Box 30.7**

**Indications for tonsillectomy**

- Suspected malignancy
- Obstructive sleep apnoea due to tonsillar hypertrophy
- Recurrent tonsillitis: 5 attacks a year for at least 2 years
- Quinsy in a patient with a history of recurrent tonsillitis

**Snoring**

Snoring is caused by high-pressure airflow, resulting in vibration of soft tissue above the level of the larynx. It is a common symptom (50% of 50-year-old males will snore to some extent) and can be considered to be related to obstruction of three potential areas: the nose, the palate or and the hypopharynx (see **Fig. 24.26**). There is a strong association between snoring and sleep-disordered breathing, such as in obstructive sleep apnoea (see pp. 1085–1086).
The Epworth questionnaire (see Box 24.17) can assist in identification of sleep apnoea. People with a history of habitual, non-positional, heroic snoring (can be heard through a wall) require a full ENT examination and can be investigated by sleep nasendoscopy, in which a sedated, snoring patient has a flexible nasendoscope inserted to identify the source of vibration.

Nasal pathology, such as polyps, can be removed surgically with good results and most patients will benefit from lifestyle changes, such as weight loss. Stiffening or shortening the soft palate via surgery, often using a laser, can help for palatal snorers but hypopharyngeal snorers require either a dental prosthesis at night to hold the mandible forwards or continuous positive airway pressure (CPAP) via a mask (see p. 1086).

**Dysphagia**

Dysphagia (see pp. 365–366) occurs because of any lesion between the throat and stomach. The two conditions described here are the ones usually dealt with by ENT departments. Gastroenterology departments see causes further down the gullet.

**Pharyngeal pouch**

A pharyngeal pouch is a herniation of mucosa through the fibres of the inferior pharyngeal constrictor muscle (cricopharyngeus) (Fig. 30.17A). An area of weakness known as Killian's dehiscence allows a pulsion diverticulum to form. Patients present with a neck swelling following a failed swallow attempt. They can occasionally compress the swelling to allow food particles to be pushed back into the oesophagus. They may also complain that a gurgling sound is heard in the neck following a swallow as liquid and food collect in the pouch. Occasionally, patients present with recurrent pneumonia following aspiration of food into the trachea. Diagnosis is made with a barium swallow (Fig. 30.18) and treatment is surgical, either via an external approach through the neck where the pouch is excised or, more commonly, via endoscopy with stapling of the party wall (Fig. 30.17B).
Foreign bodies

Foreign bodies in the pharynx can be divided into three general categories: soft food bolus, coins (smooth) and bones (sharp). Soft food bolus can be initially treated conservatively with muscle relaxants for 24 hours. Impacted coins should be removed at the earliest opportunity but sharp objects require emergency removal to avoid perforation of the muscle wall.

If the patient perceives the foreign body to be to one side, then it should be above the cricopharyngeus and an ENT examination will locate it; common areas are the tonsillar fossae, base of tongue, posterior pharyngeal wall and valleculae. Radiology will identify coins, and a clinical decision can be made to see whether a coin will pass down to the stomach; in this case
no further treatment, is required as it will exit naturally. Some departments advocate the use of a metal detector to monitor the position of the coin in the patient, who is usually a child or has a mental disorder. Fish can be divided into those with a bony skeleton (teleosts) and those with a cartilaginous skeleton (elasmobranchs), and therefore radiology is useful only in some cases. Radiology can also identify air in the cervical oesophagus, indicating a radiolucent foreign body lying distally. A soft tissue lateral neck radiograph is the investigation of choice to delineate some of the features above.

**Globus pharyngeus**

This is a functional disorder and is not a true dysphagia. It is a condition with classic symptoms of an intermittent sensation of a lump in the throat. This is perceived to be in the midline at the level of the cricoid cartilage and is worse when swallowing saliva; indeed, it often disappears when ingesting food or liquids. ENT examination is clear and normal laryngeal mobility can be felt when gently rocking the larynx across the postcricoid tissues. A contrast swallow will not only show the structures below the pharynx but also assess the swallowing dynamically. Treatment is with explanation and reassurance. Antidepressants may be tried. Any suspicious area will require an endoscopy with biopsy.

**Disorders of the Eye**

Most of the major and common types of eye disease are covered below. However, diabetic eye disease (pp. 1265–1269) and hypertensive eye disease (p. 1046) are discussed elsewhere.

**Applied Anatomy and Physiology**

The average length of the human eye is 24 mm. It is essentially made up of two segments:

- The smaller anterior segment is transparent and coated by the cornea; its radius is approximately 8 mm.
- The larger posterior segment is coated by the opaque sclera; its radius is approximately 12 mm.

It is the cornea and the sclera that give the mechanical strength and shape to the exposed surface of the eye.

*The cornea* occupies the central aspect of the globe and is one of the most richly innervated
tissues in the body. This clear, transparent, avascular structure, measuring 12 mm horizontally and 11 mm vertically, provides 78% of the focusing power of the eye. The eyelids prevent the cornea from drying and becoming an irregular surface by distributing the tear film over the surface of the globe with each blink.

Anatomically, the cornea is made up of five layers:

- epithelium
- Bowman's layer (membrane)
- stroma
- Descemet's membrane
- endothelium.

The endothelial cells lining the inner surface of the cornea are responsible for maintaining the clarity of the cornea by continuously pumping fluid out of the tissue. Any factor that alters the function of these cells will result in corneal oedema and cause blurred vision.

*The sclera* is an opaque white structure covering four-fifths of the globe and is continuous with the cornea at the limbus. The six extraocular muscles responsible for eye movements are attached to the sclera, and the optic nerve perforates it posteriorly.

*The conjunctiva* covers the anterior surface of the sclera. This richly vascularized and innervated mucous membrane stretches from the limbus over the anterior sclera (where it is called the bulbar conjunctiva) and is then reflected on to the undersurface of the upper and lower lids (the tarsal conjunctiva). The area of conjunctival reflection under the lids makes up the upper and lower fornix.

*The anterior chamber* is the space between the cornea and the iris, and is filled with aqueous humour (*Fig. 30.19*). This fluid is produced by the ciliary body (2 µL/min) and provides nutrients and oxygen to the avascular cornea. The outflow of aqueous humour is through the trabecular meshwork and canal of Schlemm adjacent to the limbus. Any factor that impedes its outflow will increase the intraocular pressure. The upper range of normal for intraocular pressure is 21 mmHg.
The uveal tract is made up of the iris anteriorly, the ciliary body and the choroid. The iris is the coloured part of the eye under the transparent cornea. The muscles of the iris diaphragm regulate the size of the pupil, thereby controlling the amount of light entering the eye. The muscles of the ciliary body control the accommodation of the lens, and the secretory epithelium produces the aqueous humour (see above). The highly vascular choroid lines the inner aspect of the sclera and upon this lies the retina.

The lens lies immediately posterior to the pupil and anterior to the vitreous humour. It is a transparent biconvex structure and is responsible for 22% of the refractive power of the eye. By changing its shape, it can alter its refractive power and help to focus objects at different distances from the eye. By the fourth decade of life, this ability to change shape starts to decline and, with time, the lens starts to become less transparent and cataracts begin to develop.

The vitreous humour fills the cavity between the retina and the lens.

The retina is a multilayered structure. The metabolically active region of the retina is represented in Figure 30.20. There are two types of photoreceptors in the retina: rods and cones. There are approximately 6 million cones, mainly confined to the macula, and these are responsible for detailed central vision and colour vision. The peripheral retina has around 125 million rods that are responsible for peripheral vision. The axons of the ganglion cells form the optic nerve (or disc) of the eye (Fig. 30.21).
The blood supply to the eye is via the ophthalmic artery; in particular, the central retinal artery is responsible for supplying the inner retinal layers. Venous return is through the central retinal and ophthalmic veins. Local lymphatic drainage is to the pre-auricular and submental nodes.

The sensory innervation of the eye is through the trigeminal (Vth) nerve. The six extraocular muscles are supplied by different nerves (see pp. 805–806):

- oculomotor (IIIrd) nerve: medial, superior, inferior rectus and inferior oblique
- trochlear (IVth) nerve: superior oblique
- abducens (VIth) nerve: lateral rectus.
The oculomotor (IIIrd) nerve also supplies the upper lid and, indirectly, the pupil (parasympathetic fibres are attached to it). The facial (VIIth) nerve supplies the orbicularis and other muscles of facial expression.

**Clinical Approach to the Patient with a Disorder of the Eye**

**History and examination**

A detailed history gives most of the facts needed to make a working diagnosis. The eye has limited mechanisms by which it can convey a diseased state. Common symptoms include alteration in visual acuity, redness, pain, discharge and photophobia.

It is essential to adopt a systematic approach to the examination of the eye. Different approaches and instruments (including direct ophthalmoscope, slit lamp with or without Goldman or Volk lens) are necessary for examination of the lids and anterior and posterior segments, as well as extraocular movements.

**Visual acuity**

It is vital for an accurate assessment of visual acuity to be recorded in all people with an eye problem. The visual acuity of each eye is recorded in two ways: distance visual acuity and near visual acuity. Distance vision is measured in Snellen letters or, ever more commonly, in LogMAR letters or figures of different sizes (see below). The recording is given as an expression of the line of letters that can be discerned at a particular distance, usually 6 metres (20 feet): for example 6/60, where 6 equals the distance of the chart from the eye in metres and 60 equals the distance at which the letter subtends 5′ at the nodal point.

The Snellen visual acuity chart (**Fig. 30.22**) is most commonly employed, but use of the LogMAR chart (**logarithm of the Minimum Angle of Resolution; Fig. 30.23**) is increasing, largely due to its necessity in studies or research, since it allows better statistical analysis of results. Unlike the Snellen and other visual acuity charts, the LogMAR chart has equal graduation between the letters on a line, as well as the space between lines. There is also a fixed number of letters – five – on each line. Research conducted using a logarithmic progression in size of letters on a test chart provides the most accurate visual acuity measurement. Snellen equivalents can be calculated from the LogMAR charts if necessary (**Fig. 30.24**).
FIGURE 30.22  Snellen chart.
Common Disorders of the Eye

Refractive errors

The eye projects a sharp and focused image on to the retina. Refractive errors refer to any abnormality in the focusing mechanism of the eye and not to any opacity in the system, such as a corneal or retinal scar.

The refraction of light in emmetropic (normal), myopic (short-sighted; negative lenses will correct) and hypermetropic (long-sighted; positive lenses will correct) eyes is shown in Figure 30.25.
**Astigmatism** is a refractive error of the eye in which there is a different degree of refraction in the different meridians of curvature. It may be myopic in one plane and hypermetropic or emmetropic in the other plane. In this situation, the front surface of the eye is shaped more like a rugby ball than a football.

**Presbyopia** is the term used to describe the normal ageing of the lens, which leads to a change in the refractive state of the eye. As the lens ages, it becomes less able to alter its curvature and this causes difficulty with near vision, especially reading.

### Management

Errors of refraction can be corrected by using spectacles or contact lenses. The latter often result in better-quality vision but carry the risk of infection. They may be the only option in some refractive states such as keratoconus, a degenerative disorder of the eye in which structural changes within the cornea cause it to thin and to take on a more conical shape than its normal gradual curve. A number of surgical techniques can correct these errors of refraction, with varying degrees of accuracy. Phakic intraocular lenses may be used to treat high degrees of myopia but the most popular method remains the excimer laser to re-profile the corneal curvature (using PRK, LASIK and LASEK techniques). The laser either removes corneal tissue centrally to flatten the cornea in myopia or it removes tissue from the peripheral cornea...
to steepen it in hypermetropia.

**Disorders of the lids**

The lids afford protection to the eyes and help to distribute the tear film over the front surface of the globe. Excess tears are drained via the puncta and lacrimal system to the nose (Fig. 30.26). Malposition of the lids, factors that affect blinking and lacrimal drainage can all cause problems.

![Image of the right eye](image)

**Entropion**

The lid margin rolls inwards so that the lashes are against the globe (Fig. 30.27A). The lashes act as a foreign body and cause irritation, leading to a red eye that can mimic conjunctivitis. Occasionally, the constant rubbing of lashes against the cornea causes an abrasion. The most common cause is ageing and surgery is usually required.

![Disorders of the eyelid. A. Lid entropion. The lower lid appears inverted. B. Acute dacryocystitis, showing a lump on the side of the nose.](image)

**Ectropion**

The lid margin rolls outwards and is not apposed to the globe. As a result, the lacrimal
punctum is not in the correct anatomical position to drain tears and patients usually complain of a watery eye. Underlying factors include age, VIIth nerve palsy and cicatricial skin conditions. Surgery is usually required.

### Dacryocystitis

Patients who have inflammation of the lacrimal sac usually present with a painful lump at the side of the nose adjacent to the lower lid *(Fig. 30.27B)*. This should be treated with oral broad-spectrum antibiotics such as a cephalosporin, and patients should be watched carefully for signs of cellulitis. All patients should be referred to the ophthalmologist, as some have an underlying mucocele or dilated sac, and will require surgery.

### Blepharitis

This is an extremely common condition in which inflammation of the lid margins may involve the lashes and lash follicles *(Fig. 30.28A)*, resulting in styes, or inflammation and blockage of meibomian glands *(Fig. 30.28B)* leading to chalazion *(Fig. 30.28C)*. Common underlying causes of blepharitis include meibomian gland dysfunction, seborrhoea and *Staphylococcus aureus* infection. Patients can be asymptomatic or complain of itchy, burning eyes because of tear film instability resulting from meibomian gland dysfunction. *Staph. aureus* is frequently responsible for chronic blepharo-conjunctivitis and some patients may develop keratitis in the cornea *(Fig. 30.29)*.

**FIGURE 30.28** Blepharitis. A. Crusty and scaly deposits on the lashes and lash bases. B. Upper lid showing meibomian glands plugged with oily secretions. C. Blockage of the meibomian glands leads to swelling of the lid (chalazion).
Management

Lid hygiene is the mainstay of treatment for blepharitis, as it helps to reduce the bacterial load and unblock meibomian glands. A short course of topical chloramphenicol or fusidic acid is useful in chronic cases, but in severe cases or cases where acne rosacea is suspected, oral doxycycline is used. Some patients are left with a lump once the acute inflammatory phase has subsided. Most of these patients find the lump, or chalazion, cosmetically unacceptable and require incision and curettage. People with keratitis should be referred to the ophthalmologist for topical steroids.

Conjunctivitis

The most common cause of a red eye, inflammation of the conjunctiva can arise from a number of causes, viral, bacterial and allergic being the most frequently encountered. Common features in all types include soreness, redness and discharge; in general, the visual acuity is good. History should include the speed of onset of the inflammation, the colour and consistency of the discharge, whether the eye is itchy, and if there has been a recent history of a cold or sore throat. In the neonate, it is vital to exclude gonococcal or chlamydial conjunctivitis associated with maternal sexually transmitted infection. The differential diagnosis of conjunctivitis is shown in Box 30.8.

Bacterial conjunctivitis

Bacterial conjunctivitis is uncommon, making up 5% of all cases of conjunctivitis. In the vast majority of patients, it causes a sore or gritty eye in the presence of good vision. Bacterial conjunctivitis is invariably bilateral and should be suspected when conjunctival inflammation is associated with a purulent discharge.

Clinical features

Gonococcal conjunctivitis should be suspected when the onset of symptoms is rapid, the discharge is copious, and ocular inflammation includes chemosis (conjunctival oedema) and lid oedema. Gonococci are a cause of conjunctivitis, giving rise to a palpable pre-auricular node. Less acute or subacute purulent conjunctivitis with moderate discharge can be attributed to organisms such as Haemophilus influenzae and Streptococcus pneumoniae. Chronic conjunctivitis is usually associated with mild conjunctival injection and scant purulent discharge. Common organisms include Staphylococcus aureus and Moraxella lacunata.

Management

Prompt treatment with oral and topical penicillin is given in gonococcal conjunctivitis to ensure a reduced rate of corneal perforation. A Gram stain of the conjunctival swab can quickly confirm the presence of diplococci. Gonococcal conjunctivitis is a notifiable disease in the UK. Empirical treatment for both subacute and chronic conjunctivitis involves a topical broad-spectrum antibiotic, such as chloramphenicol. Swabs should be taken if these cases do not respond to this initial treatment. Antibiotic resistance is increasing.

Chlamydial conjunctivitis

Chlamydia trachomatis (see pp. 321–322) in developed countries causes a sexually transmitted infection that is most prevalent in sexually active adolescents and young adults. Direct or indirect contact with genital secretions is the usual route of infections but shared eye cosmetics can also be involved. Neonatal chlamydial conjunctivitis is a notifiable disease in the UK and should be suspected in newborns with a red eye. Mothers should be asked about sexually transmitted infections.

Clinical features

The onset of symptoms is slow, and patients may complain of mild discomfort for weeks. In these cases, the red eye is associated with a scanty mucopurulent discharge and a palpable pre-auricular lymph node. In chronic cases, it is not unusual to see superior corneal vascularization. In neonates, the onset of the red eye is typically around 2 weeks after birth,
whereas gonococcal conjunctivitis occurs within days of birth. Conjunctival swabs should be taken and a nucleic acid amplification test (NAAT; see p. 321) performed prior to commencement of treatment.

Management

Topical erythromycin twice daily is commenced and patients referred to the genitourinary physician. Neonates should be started on topical erythromycin and referred to the paediatrician, as there may be associated otitis media or pneumonitis.

Trachoma

See Box 30.9.

Box 30.9

Trachoma

- A very common cause of blindness worldwide (see p. 288)
- Found mainly in the tropics and the Middle East
- Caused by Chlamydia trachomatis but not usually sexually transmitted
- Chronic conjunctival inflammation causes progressive scarring, trichiasis, entropion and subsequent corneal scarring
- The result may be severe visual impairment or blindness from corneal opacification or ulceration

Viral conjunctivitis

Adenoviral conjunctivitis

This is highly contagious and can cause epidemics in communities. Transmission is through direct or indirect contact with infected individuals. The onset of symptoms may be preceded by a cold or influenza-like symptoms. Inflammation is commonly associated with chemosis, lid oedema and a palpable pre-auricular lymph node. Some patients develop a membrane on the tarsal conjunctiva (Fig. 30.30) and haemorrhage on the bulbar conjunctiva. Viral conjunctivitis can cause deterioration in visual acuity owing to corneal involvement (focal areas of inflammation). In 50% of these patients, the conjunctivitis is unilateral.
The condition is largely self-limiting in the majority of cases. Lubricants, together with a cold compress, can be a soothing element of management for patients. Adhering to strict hygiene and keeping towels separate from those of the rest of the household go a long way towards reducing the spread of the infection. In people with corneal involvement or intense conjunctival inflammation, topical steroids are indicated.

**Herpes simplex conjunctivitis**

Primary ocular herpes simplex conjunctivitis is typically unilateral. It usually causes a palpable pre-auricular lymph node, and cutaneous vesicles develop on the eyelids and the skin around the eyes in the majority. Over 50% of these patients develop a dendritic corneal ulcer (*Fig. 30.31*). The organism responsible for this condition is the herpes simplex virus (HSV), usually HSV-1, although HSV-2 can give rise to ocular infection.

Primary ocular HSV infection is self-limiting but most clinicians choose treatment with topical aciclovir in order to limit the risk of corneal epithelial involvement.

**Molluscum contagiosum conjunctivitis**

This is typically unilateral; it produces a red eye that generally goes unrecognized and comes to the forefront because patients fail to improve and the cornea starts to become involved. On close inspection, pearly, umbilicated nodules, filled with the DNA poxvirus, can be seen on the lid margin.

*Management* includes curetting the central portion of the lesion, freezing the centre or completely excising the lesion. If the corneal involvement is severe or the eye is very inflamed, a short course of topical steroids, such as prednisolone 0.5% or dexamethasone 0.1%, is helpful.
**Phthiriasis palpebrarum**

Phthiriasis palpebrarum (*Fig. 30.32*) is an eyelid infestation caused by *Phthirus pubis*, or the crab louse. Infestation of the cilia and eyelid is rare. It leads to blepharitis with marked conjunctival inflammation, pre-auricular lymphadenopathy and, rarely, secondary infection at the site of louse bite.

![Phthiriasis palpebrarum image](image)

**FIGURE 30.32** Phthiriasis palpebrarum. The lice (L) and the nits (eggs) can be seen on the lid margins. E, empty egg.

**Management**

Mechanical removal of the lice with fine forceps, physostigmine 1.25% and pilocarpine gel 4% are all effective treatments.

**Allergic conjunctivitis**

There are five main types of allergic conjunctivitis: seasonal, perennial, vernal, atopic and giant papillary. Both seasonal and perennial allergic conjunctivitis are acute allergic conjunctival disorders. Symptoms include itching and pink to reddish eyes. These two eye conditions are mediated by mast cells and can be treated easily with cold compresses, eye washes with tear substitutes, and avoidance of allergens. The last three are difficult to treat; they are chronic and can be sight-threatening, so should be referred to an ophthalmologist.

**Seasonal/perennial conjunctivitis**

Seasonal allergic conjunctivitis and perennial conjunctivitis, affecting 20% of the general population in the UK, are allergic reactions to grass and tree pollen and fungal spores. Seasonal allergic conjunctivitis occurs mainly in spring and summer. Perennial allergic conjunctivitis occurs all year round but peaks in the autumn; causes include allergens, such as house-dust mites.

The main symptoms include itching, redness, soreness, watering and a stringy discharge.
Occasionally, the conjunctiva may become so hyperaemic that chemosis results. This is usually associated with swollen lids.

Lowering the allergen load (reducing dust; see p. 1077) is helpful. Medical treatment includes the use of antihistamine drops such as azelastine and emedastine, together with topical mast-cell-stabilizing agents such as sodium cromoglicate and nedocromil. Olopatadine (twice daily) has dual action and is very effective. Corticosteroid drops should be avoided. Oral antihistamines help the itching.

**Corneal disorders**

**Trauma**

**Corneal abrasions**

Trauma resulting in the removal of a focal area of epithelium on the cornea is very common. Abrasions usually occur when the eye is accidentally poked with a finger, a foreign body flies into the eye or something brushes against the eye.

**Symptoms** include severe pain, due to exposure of the corneal nerve endings, lacrimation and inability to open the eye (blepharospasm). Blinking and eye movement can aggravate the pain and foreign body sensation. The visual acuity is usually reduced. Most cases will need topical anaesthetic drops such as oxybuprocaine or tetracaine to be administered before it is possible to examine the eye. The cornea should be inspected with a blue light after instillation of fluorescein drops. The orange dye will stain the area of the abrasion. Under blue light, the abrasion lights up as green. Occasionally, foreign bodies can lodge on the undersurface of the upper lid and give rise to linear vertical abrasions. Eversion of the upper lid is necessary in all cases of abrasions (**Fig. 30.33**).

![Linear corneal abrasion](https://via.placeholder.com/150)

**FIGURE 30.33** Linear corneal abrasion. A. Stained with fluorescein. B. Stained with fluorescein and viewed with blue light.

**Treatment** consists of a broad-spectrum topical antibiotic, such as chloramphenicol drops or ointment four times a day for 5 days. The role of padding is controversial but common practice is to pad the affected eye for 24 hours once chloramphenicol ointment has been applied to the eye.

**Corneal foreign body**
Occasionally, when something flies into the eye, it sticks on the cornea (Fig. 30.34A). It may be associated with lacrimation and photophobia. Examination is best attempted following instillation of a topical anaesthetic and should include eversion of the upper lid (Fig. 30.34B). Corneal foreign bodies can usually be seen directly with a white light.

The corneal foreign body should be removed. Treatment involves a topical antibiotic, such as chloramphenicol four times a day for 5 days, or fusidic acid twice a day for 5 days.

**High-velocity trauma**

In cases of high-velocity trauma, corneal perforation or an intraocular foreign body should be suspected. Examination may show a corneal laceration and a foreign body may also be embedded in the cornea. The foreign body may be present on the iris or in the lens or vitreous. Other clues pointing towards a penetrating injury include a large subconjunctival haemorrhage, a flat anterior chamber with low intraocular pressure, and the presence of blood in the anterior chamber (hyphaema). Urgent referral to the ophthalmologist is mandatory, ensuring that no drops are instilled into the eye and that a plastic shield is placed over the eye to minimize further risk of trauma.

Blunt trauma usually results in periorbital bruising and gross lid oedema, which can make examination to exclude perforating injury difficult. These patients should be referred to the ophthalmologist for a detailed ocular examination to exclude a perforation, retinal detachment or a traumatic hyphaema (Fig. 30.35).
Keratitis

This is a general term used to describe corneal inflammation. Common causes include herpes simplex virus, contact lens-associated infection and blepharitis. Symptoms include the sensation of a foreign body or pain (depending on the size and depth of the ulcer), photophobia and lacrimation. Vision is reduced if the ulcer affects the visual axis.

Herpes simplex keratitis

Corneal epithelial cells infected with the virus eventually undergo lysis and form an ulcer, which is typically dendritic in shape (see Fig. 30.31). The ulcer stains with fluorescein and can be observed easily with a blue light. Topical immunosuppression, such as with steroid drops, or systemic immunosuppression, such as in AIDS, can lead to the centrifugal spread of the virus, such that the ulcer increases in area and is referred to as a geographic ulcer. Recurrent attacks of HSV keratitis can be triggered by ultraviolet light, stress and menstruation. All these factors are responsible for activating the virus, which normally lies dormant in the ganglion of the Vth nerve.

**Treatment** consists of aciclovir ointment five times a day for 2 weeks; this is usually very effective.

Contact lens-related keratitis

A small number of contact lens wearers develop infective corneal ulcers, which are potentially sight-threatening (Fig. 30.36). The organisms usually responsible include Gram-positive and Gram-negative bacteria. Patients should be referred to an ophthalmologist for scraping of the ulcer and commencement of antibiotic treatment.

![Contact lens-related keratitis](image)

**FIGURE 30.36** Contact lens-related keratitis. A. Corneal ulcer. B. Severe keratitis with a corneal abscess and a hypopyon.

Keratoconus

Keratoconus is an eye condition in which the normally round, dome-shaped cornea progressively thins and causes a cone-shaped bulge to develop. Aetiology is uncertain but genetic factors play a role, and the condition is more common in people with allergic diseases such as asthma, in Down syndrome and in some disorders of collagen such as Marfan's disease. Keratoconus affects up to 1 in 1000 people and is more common in individuals of
Asian heritage. It is usually diagnosed in teenagers and young people.

**Management**

In the early stages, spectacles or soft contact lenses may be used to correct vision. As the cornea becomes thinner and steeper, rigid gas-permeable contact lenses may be necessary.

Corneal cross-linking is a new treatment that can stop keratoconus becoming worse. It is effective in more than 9 out of 10 patients, with a single 30-minute day-case procedure, but is only suitable when the corneal shape is continuing to deteriorate. In very advanced cases, where contact lenses fail to improve vision, a corneal transplant may be needed.

### Corneal dystrophy

Corneal dystrophies may be classified anatomically as consisting of:

- epithelial and subepithelial dystrophies
- epithelial–stromal *TGFBI* corneal dystrophies
- stromal dystrophies
- endothelial dystrophies.

The most common endothelial dystrophy, Fuchs' corneal dystrophy, is a genetically associated degenerative disorder leading to corneal oedema and vision loss. The gene involved is *TCF4*. The condition affects both eyes; it is more common in females and is of gradual onset, leading to blindness in the 40–60 age group. There is an accumulation of deposits (guttae) in the cornea with thickening of Descemet's membrane. Treatment is by corneal transplantation.

### Cataracts

Cataract (Fig. 30.37) is by far the most common cause of preventable blindness in the world, having an effective surgical treatment. In the UK, approximately 250 000 cataract operations are performed each year, making it the most common surgical procedure.
Aetiology

Age-related opacification of the lens (cataract) is the commonest cause of visual impairment, with 30% of people over 65 years having visual acuities below that required for driving (Snellen acuity less than 6/12). The common causes of cataracts are summarized in Box 30.10.

Box 30.10

Cataracts: aetiology

Congenital
- Maternal infection
- Familial

Age
- Elderly

Metabolic
- Diabetes
- Galactosaemia
- Hypocalcaemia
- Wilson's disease

Drug-induced
- Corticosteroids
In young patients, familial or congenital causes should be excluded. Any history of ocular inflammation is noted. Cataracts diagnosed in infants demand urgent referral to the ophthalmologist in order to minimize the subsequent development of amblyopia.

### Clinical features
Gradual painless deterioration of vision is the most common symptom. Other symptoms are dependent on the type of cataract: for example, a posterior capsular type would lead to glare and problems with night driving. Early changes in the lens are correctable by spectacles but eventually the opacification needs surgical intervention.

### Investigations
Blood glucose, serum calcium and liver biochemistry should be measured to diagnose metabolic disorders.

### Management
Small-incision extracapsular or phacoemulsification cataract extraction with the insertion of an intraocular lens is the treatment of choice (Fig. 30.37C). Recent advances have enabled surgeons to perform multiple steps in the surgical process with the Excimer laser to enhance visual outcomes. Lens technology has also improved and Toric lenses are available to treat astigmatism, and multifocal or accommodative lenses to overcome intraocular lens-induced presbyopia.

### Glaucoma
Glaucoma is due to increased pressure inside the eye, which is sufficiently elevated to cause optic nerve damage and result in visual field defects, with loss of sight (Fig. 30.38). Normal intraocular pressure (IOP) is 10–21 mmHg. Some types of glaucoma can result in an IOP exceeding 70 mmHg. Glaucoma is the second most common cause of blindness worldwide and the third most common cause of blind registration in the UK.

![Image](image1)

**FIGURE 30.38** The optic disc. A. Normal optic disc. B. Glaucomatous optic disc. The central cup is enlarged and deepened.

### Primary open-angle glaucoma

Primary open-angle glaucoma (POAG) is the most common form of glaucoma. High intraocular pressures result from reduced outflow of aqueous humour through the trabecular meshwork (Fig. 30.39A). Common risk factors include age (0.02% of 40-year-olds versus 10% of 80-year-olds), race (black Africans are at five times greater risk than whites), positive family history and myopia.

![Image](image2)

**FIGURE 30.39** Glaucoma. A. Primary open-angle glaucoma. B. Angle-closure glaucoma.

### Clinical features

POAG causes a gradual, insidious, painless loss of peripheral visual field, causing loss of vision. It is initially asymptomatic and the central vision remains good until the end-stage of the disease. Usually, glaucoma is identified during a routine ophthalmic examination.
Diagnosis is only made if the IOP is measured. The optic disc is inspected and shows an enlarged cup with a thin neuroretinal rim. Visual fields are assessed and show a normal blind spot with scotomas.

Management

Treatment aims to reduce the IOP, either by reducing aqueous production or by increasing aqueous drainage:

- **Beta-blockers**, such as timolol, carteolol and levobunolol, reduce aqueous production and are the most commonly prescribed topical agents. These drugs are contraindicated in people with chronic obstructive pulmonary disease, asthma or heart block.

- **Prostaglandin analogues**, such as latanoprost, bimatoprost and travoprost, increase aqueous outflow and are also used (alone or in combination with beta-blockers) for POAG, as they can reduce IOP by 30%.

- **Carbonic anhydrase inhibitors**, such as dorzolamide and acetazolamide, reduce aqueous production and are available in topical preparations. Acetazolamide is also available orally and, in this form, is the most potent drug for reducing IOP. It should not be used in patients who have a sulphonamide allergy.

- **Selective laser trabeculoplasty (SLT)** is a form of laser surgery that can lower the IOP by about 30% when used as initial therapy. It is useful when eye-drop medications are not lowering the eye pressure enough or are causing significant side-effects. It may sometimes be used as initial treatment in glaucoma, although effects commonly last 1–5 years only.

**Acute angle-closure glaucoma**

Acute angle-closure glaucoma (AACG) is an ophtalmic emergency. There is a sudden rise in intraocular pressure to levels over 50 mmHg. This occurs due to reduced aqueous drainage when the ageing lens pushes the iris forwards against the trabecular meshwork (Fig. 30.39B). People most at risk of developing AACG are those with shallow anterior chambers, such as hypermetropes and women. The attack is more likely to occur under reduced light conditions when the pupil is dilated.

Clinical features

AACG causes sudden onset of a red, painful eye and blurred vision. Patients become unwell, with nausea and vomiting, and complain of headache and severe ocular pain. The eye is injected and tender, and feels hard. The cornea is hazy and the pupil is semi-dilated (Fig. 30.40). Box 30.11 shows the differential diagnosis of the acute red eye. Box 30.12 shows features that require urgent referral to an ophthalmologist.
**Box 30.11**

**Box 30.12**

**Red flags for a red eye**

The following symptoms require **urgent** referral:

- Severe pain
- Photophobia
- Reduced vision, particularly if sudden
- Coloured halos around point of light in a patient's vision
- Proptosis
- Smaller pupil in affected eye

*Plus* on medical assessment:

- High intraocular pressure
• Corneal epithelial disruption
• Shallow anterior chamber depth
• Ciliary flush

Management

Prompt treatment is required to preserve sight and includes:

- i.v. acetazolamide 500 mg (provided there are no contraindications) to reduce IOP, and
- instillation of pilocarpine 4% drops to constrict the pupil to improve aqueous outflow and prevent iris adhesion to the trabecular meshwork.

Other topical drops, such as beta-blockers and prostaglandin analogues, can also be instilled if available, provided there are no contraindications. Analgesia and antiemetics are given as required.

Patients must be referred to an ophthalmologist immediately so that reduction in IOP can be monitored and other agents, such as oral glycerol or i.v. mannitol, can be administered to non-responding patients. Definitive treatment involves making a hole in the periphery of the iris of both eyes either by laser or by surgical means.

Uveitis

Uveitis is inflammation of the uveal tract, which includes the iris, ciliary body and choroid. It is classified according to the part of the uveal tract that the inflammation affects:

- **Anterior uveitis** is inflammation that affects the anterior part of the uveal tract. This can include the iris (iritis), or both the iris and the ciliary body (iridocyclitis). It is the most common type of uveitis.

- **Intermediate uveitis** is inflammation that affects the middle part of the uveal tract or eye, mainly the vitreous. It can also affect the underlying retina.

- **Posterior uveitis** is inflammation that affects the posterior part of the eye. It can affect the choroid, optic nerve head and the retina (or any combination of these structures). It includes chorioretinitis, retinitis and neuroretinitis.

- **Panuveitis** is inflammation affecting the whole of the uveal tract.

  The most common symptoms of uveitis are blurred vision, pain, redness, photophobia and floaters. Each symptom is determined by the location of the inflammation, such that photophobia and pain are common features of iritis whilst floaters are commonly seen with posterior uveitis.

**Anterior uveitis (iritis)**

The classic presentation entails a triad of eye symptoms: redness, pain and photophobia. Vision can be normal or blurred, depending on the degree of inflammation. The eye can be
generally red or the injection can be localized to the limbus. The anterior chamber shows features consistent with inflammation, including cells, keratic precipitates on the corneal endothelium, fibrin or hypopyon (pus), and the pupil may have adhered to the lens (posterior synechiae) (Fig. 30.41). The IOP may be normal or raised, either due to cells clogging up the trabecular meshwork, or due to posterior synechiae causing aqueous humour to build up behind the iris and force the iris against the trabecular meshwork and so reduce aqueous drainage.

**Management**

This consists of reducing inflammation with the use of topical steroids such as dexamethasone 0.1% and dilating the pupil with cyclopentolate 1% to prevent formation of posterior synechiae. Dilatation also allows fundoscopy to exclude posterior segment involvement. If the IOP is raised, this is treated with topical beta-blockers, prostaglandin analogues, or oral or i.v. acetazolamide. Referral should be made to the ophthalmologist.

**Intermediate uveitis**

This usually causes painless blurred vision, most commonly associated with floaters. It is unusual to experience photophobia and redness. Both eyes are commonly affected in intermediate uveitis.
Management

This consists of a combination of treatment for anterior and posterior uveitis depending on the degree of anterior and posterior involvement.

Posterior uveitis

This commonly causes painless, blurred vision and can progress to severe visual loss. It is commonly associated with floaters and scotomata, or blind spots in the visual field.

Posterior uveitis is often found with systemic autoimmune diseases or infections; appropriate investigations should be performed and treatment given that is aimed at the cause.

Autoimmune diseases associated with uveitis include rheumatoid arthritis and Behçet's disease, ankylosing spondylitis and positive HLA-B27 (see p. 683), reactive arthritis, sarcoidosis, psoriasis and inflammatory bowel disease (Crohn's disease and ulcerative colitis; see p. 407). Infections, a rare cause of uveitis, include herpes simplex, herpes zoster, toxoplasmosis, cytomegalovirus, syphilis, tuberculosis, HIV infection and Lyme disease. In a number of patients, no cause is found (idiopathic uveitis).

Management

Steroids are commonly given orally, or more locally by injection into or around the eye. If steroid treatment is needed to treat uveitis in the longer term, second-line immunosuppressive drugs, such as mycophenolate mofetil, ciclosporin or azathioprine, are used. Biological agents, such as rituximab or adalimumab, are showing increasing promise in more severe cases.

Disorders of the retina

Central retinal vein occlusion

Central retinal vein occlusion (CRVO) usually leads to profound, sudden, painless loss of vision with thrombosis of the central retinal vein at or posterior to the lamina cribrosa, where the optic nerve exits the globe. The thrombus causes obstruction to the outflow of blood, leading to a rise in intravascular pressure. This results in dilated veins, retinal haemorrhage, cotton wool spots and abnormal leakage of fluid from vessels, causing retinal oedema (Fig. 30.42). In severe cases, an afferent papillary defect (p. 804) is present and this suggests the ischaemic variant.
Predisposing factors include increasing age, hypertension and cardiovascular disease, diabetes, glaucoma and, in the younger age group, blood dyscrasias and vasculitis.

**Management**

Treatment of any underlying medical condition is mandatory. Referral to an ophthalmologist is essential to monitor the eye, as some patients can develop retinal ischaemia with resulting neovascularization of the retina and iris. Panretinal photocoagulation should be commenced if there is neovascularization, and intravitreal steroid or anti-vascular endothelial growth factor (anti-VEGF) therapy is also used if there is macular oedema. Patients who develop iris neovascularization – rubeosis – where these new blood vessels block the drainage angle are at risk of developing rubeotic glaucoma.

**Central retinal artery occlusion**

Central retinal artery occlusion (CRAO) results in sudden, painless severe loss of vision. Retinal arterial occlusion results in infarction of the inner two-thirds of the retina. The arteries become narrow and the retina becomes opaque and oedematous. A cherry-red spot is seen at the fovea because the choroidal vasculature shows up through the thinnest part of the retina (Fig. 30.43). An afferent papillary defect is usually present.

Arteriosclerosis-related thrombosis is the most common cause of CRAO. Emboli from atheromas and diseased heart valves are other causes. Giant cell arteritis (see pp. 700–701) must be excluded.
Management

CRAO is an ophthalmic emergency since studies have shown that irreversible retinal damage occurs within 90 minutes of onset. Ocular massage and 500 mg i.v. acetazolamide help to reduce ocular pressure and may assist in dislodging the emboli. Breathing into a paper bag allows a build-up of carbon dioxide, which acts as a vasodilator and so helps dislodge the emboli. Other options include making a corneal paracentesis to drain off some aqueous humour, thereby reducing the IOP.

People with CRAO should have a thorough medical evaluation to determine the aetiology of the emboli or thrombus. Some patients may present with transient loss of vision or amaurosis fugax (see p. 832). All people with CRAO and amaurosis fugax should be started on oral aspirin if it is not medically contraindicated.

Retinal detachment

This causes a painless, progressive visual field loss. The shadow corresponds to the area of detached retina. If the detachment affects the macula, central vision will be lost. Following a tear in the retina, fluid collects in the potential space between the sensory retina and the pigment epithelium (Fig. 30.44). Patients usually report a sudden onset of floaters, often associated with flashes of light (photopsia) prior to the detachment. These individuals should be referred to an ophthalmologist for a detailed fundal examination.

![FIGURE 30.44 Retinal tear leading to detachment.](image)

Retinitis pigmentosa

This is a common chronic, inherited, degenerative disease of the retina, which can be primary or part of a syndrome, and leads to blindness. There is constriction of the peripheral vision, leading to tunnel vision and progressive loss of night vision.

Ophthalmoscopy shows bone spicule deposits and attenuated retinal vessels. Several genes
are implicated.

There is no treatment but high-dose vitamin A supplementation may slow progression. Gene therapy is being investigated.

**Age-related macular degeneration**

Age-related macular degeneration (AMD) is the most common cause of visual impairment in patients over 50 years in the Western world, and the most common cause of blind registration in this age group. It affects 10% of people over 65 years and 30% over 80 years. Mutations in various genes have been reported: fibulin 5, complement factor H, and the Arg 80 Gly variant of complement C3.

The cause is unknown but suggested risk factors include increasing age, smoking, hypertension, hypercholesterolaemia and ultraviolet exposure.

There are two types:

- **Non-exudative (dry) macular degeneration** describes a painless and progressive loss of central vision. With age, lipofuscin deposits (drusen) are found between the retinal pigment epithelium (RPE) and Bruch's membrane (Fig. 30.45A; see Fig. 30.20). Drusen may be hard or soft, and there may be focal RPE detachment. Not all people with these changes will be affected visually but some develop distortion and blurring of their central vision. Extensive atrophy of RPE can occur (geographic atrophy).

- **Exudative (wet) AMD** (10% of cases) occurs with the development of abnormal subfoveal choroidal neovascularization in the region of the macula and causes severe central visual loss (Fig. 30.45B).

![FIGURE 30.45 Age-related macular degeneration. A. With deposition of material (drusen) over the macula. B. With choroidal neovascularization.](image)

**Management**

The Age-Related Eye Disease Study (AREDS) has shown that vitamins C and E, β-carotene, zinc and copper slow progression of the disease. The subsequent study, AREDS 2, suggests that adding lutein, zeaxanthin and omega 3 does not improve the original AREDS formula overall, unless subjects had little of the supplements in their diets.
People with central distortion or with frank macular pathology should be referred *urgently* to the ophthalmologist for assessment of treatment. Anti-VEGF, such as ranibizumab, aflibercept and bevacizumab, are given by intravitreal injections with great success; the last of these is unlicensed yet less expensive. The treatment course should be commenced *as a matter of urgency*, as vision is maintained in up to 95% of patients and improves in approximately one-third. Initial monthly monitoring with optical coherence tomography (OCT) is recommended (Fig. 30.46). Laser treatment and photodynamic therapy with verteporfin constituted the treatment of choice in the past for wet AMD but now have limited roles.

Severe visual loss is possible and low-vision aids, such as magnifying glasses, may help to improve a patient's independence.

**Visual loss**

Every patient with unexplained sudden visual loss requires ophthalmic referral. The initial history and examination are summarized in *Box 30.13*.

---

**Box 30.13**

**The initial history and examination in the patient presenting with sudden loss of vision**
RAPD, relative afferent papillary defect.

The common causes of blindness are similar across the world (Box 30.14). In developing countries, trachoma due to *Chlamydia trachomatis* (see p. 288) is also a major cause, accounting for 10% of global blindness; onchocerciasis (river blindness, due to *Onchocerca volvulus*; see p. 309) accounts for blindness in about 1 million people, although this figure is decreasing with treatment. In leprosy, 70% of patients have ocular involvement, and blindness occurs in 5–10% of these. Ocular involvement is common in cerebral malaria (see p. 299), although loss of vision is rare.

**Box 30.14**

Causes of loss of vision
**Painless loss of vision**
- Cataract
- Open-angle glaucoma
- Retinal detachment
- Central retinal vein occlusion
- Central retinal artery occlusion
- Diabetic retinopathy
- Vitreous haemorrhage
- Posterior uveitis
- Age-related macular degeneration
- Optic nerve compression
- Cerebral vascular disease

**Painful loss of vision**
- Acute angle-closure glaucoma
- Giant cell arteritis
- Optic neuritis
- Uveitis
- Scleritis
- Keratitis
- Shingles
- Orbital cellulitis
- Trauma

HIV infection can produce uveitis but the major problem is severe opportunistic infection of the eye when the CD4 count falls (see pp. 338–339) and anti-retroviral therapy is not available.

Vitamin A deficiency and xerophthalmia affect millions each year; the World Health Organization (WHO) classification of xerophthalmia by ocular signs is shown in Box 10.15.

The WHO lists the most common causes of blindness across the world as cataract, glaucoma, acute macular degeneration, corneal opacity, diabetic retinopathy, and infections from bacteria or parasites.

Introduction

Skin diseases are common throughout the world. In the UK, they account for about 1 in 10 consultations in primary care. In tropical and often poorer areas, infections such as leprosy and onchocerciasis predominate, while in more affluent temperate countries, chronic inflammatory disorders such as atopic eczema occur most commonly. Skin disorders can be an isolated complaint, part of an inherited disorder such as Ehlers–Danlos syndrome, or a feature of systemic disease such as systemic lupus erythematosus (SLE).

The common presenting symptoms of a rash or lesion(s) are itch, pain, disturbed sleep and anxiety/psychological upset. Because of their visibility, skin diseases can affect self-esteem and quality of life. They may also impair the ability to work: for example, hand eczema in a chef. Skin disease is rarely life-threatening, although, for example, malignant melanoma, toxic epidermal necrolysis and pemphigus can be fatal.

Structure and Function of the Skin

With an average surface area of 2 m² in the adult, the skin is the largest organ in the human body. It consists of three main layers:

1. the epidermis
2. the dermis
3. the subcutis (Fig. 31.1).
The functions of the skin are summarized in Box 31.1.

Box 31.1
Functions of the skin

- Physical barrier against friction and shearing forces
- Protection against infection (immune and innate), chemicals, ultraviolet irradiation
- Prevention of excessive water loss or absorption
- Ultraviolet-induced synthesis of vitamin D
- Temperature regulation
- Sensation (pain, touch and temperature)
- Antigen presentation/immunological reactions/wound healing
- Hormonal, e.g. testosterone synthesis
The epidermis

The epidermis is a *stratified squamous epithelium* of ectodermal origin. It varies in thickness according to body site (from 0.05 to 1.5 mm) and provides an essential barrier against the environment and pathogens. Downward projections of the epidermis into the dermis are called the rete ridges. The epidermis is mainly composed of keratinocytes, which originate from a proliferating *basal layer* and differentiate as they migrate outwards to the surface, where they are shed. This process involves a carefully autoregulated sequence of protein and lipid synthesis. In the basal layer, keratinocytes synthesize a variety of keratin filaments and desmosomal proteins (desmoglein and desmoplakin), which make up the ‘cytoskeleton’ and give cells their strength and cohesion. Higher up in the *granular layer*, lipid and lipid hydrolases are synthesized, then secreted by lamellar bodies to form a water-tight intercellular lipid bilayer. These lamellar bodies also produce abundant quantities of pro-filaggrin, which is converted to filaggrin in the outer layer of cells or *stratum corneum*. Filaggrin has a dual role, holding moisture within cells – so-called ‘natural moisturizing factor’ – and as a component of the tough protein cell envelope. As the cells migrate outwards, they die, lose their nuclei and flatten into squames. The *outer stratum corneum* is tissue-paper thin but provides most of the barrier function of the epidermis. Filaggrin deficiency leads to a ‘leaky’ skin that loses water and allows entry of allergens that trigger an immunological response. Loss-of-function mutations in the filaggrin gene cause the dry, scaly skin complaint, ichthyosis vulgaris, and are a major risk factor for atopic eczema and associated allergies. Changes in lipid metabolism and protease activity in the outermost layers cause skin shedding (desquamation). It takes approximately 30 days for keratinocytes to migrate from the basal layer to the skin surface in normal skin, but is considerably faster in, for example, psoriasis.

*Keratinocytes* secrete a variety of cytokines (e.g. interleukins, interferon-gamma (IFN-γ), tumour necrosis factor-alpha (TNF-α)) in response to tissue injury, which stimulate wound healing and protect the body against microbial invasion. They also produce antimicrobial peptides (β-defensins and cathelicidins) that are part of the innate immune system. A deficiency of these peptides may underline the increased susceptibility to certain infections in people with atopic eczema.

Other cells in the epidermis

*Melanocytes* originate from the neural crest and reside in the basal layer in a ratio of approximately 1 per 10 keratinocytes. They synthesize the pigment melanin, which is transferred into surrounding keratinocytes to give protection against ultraviolet (UV) radiation. Racial differences in skin colour are due to variation in melanin production, not melanocyte numbers.

*Merkel cells* are also found in the basal layer. They are numerous on fingertips and in the oral cavity, and play a role in sensation.

*Langerhans cells* are dendritic cells derived from the bone marrow. They form a network
across the supra-basal layer and play a role in antigen presentation and in immunoregulation.

The epidermis is anchored to the dermis by a complex meshwork of proteins that link the keratin intermediate filaments of basal keratinocytes to collagen fibres in the superficial dermis. This area is called the *basement membrane zone* (see Fig. 31.34). Inherited or autoimmune-induced deficiencies of these proteins can cause skin fragility and a variety of blistering diseases (see pp. 1368–1371).

The dermis

The dermis is of mesodermal origin and is a matrix of collagen and elastin fibres, surrounded by an extracellular gel-like substance (ground substance). These fibres give skin its strength and elasticity. The dermis contains a range of cells: fibroblasts, mast cells, lymphocytes and dermal dendritic cells. It also contains blood and lymphatic vessels, nerves, muscle and appendages (sweat glands, sebaceous glands and hair follicles). In the upper *papillary dermis*, there are finger-like projections that contain terminal capillary networks. The lower *reticular dermis* is thicker and denser.

Eccrine sweat glands are found throughout the skin, except at the mucosal surfaces, and are responsible for most thermoregulatory sweating. Apocrine sweat glands are found in the axillae and anogenital area, and do not function until puberty. Sebaceous glands are also inactive until puberty, when they excrete an oily substance called sebum under the influence of androgens. Sebum passes on to the skin surface via the pilosebaceous duct (hair follicle). Its lipids contribute to the skin barrier and have antimicrobial actions. Sebaceous glands are found in the highest density on the face, scalp and upper torso.

The skin is richly innervated. Sensory *nerve fibres* transmit stimuli of touch, pain, itch, vibration, pressure and temperature. Innervation of dermal autonomic structures, including sweat glands, blood vessels and arrectores pilorum muscles, control the skin's thermoregulatory mechanisms.

Hair

The skin surface is covered with hair, except for the mucous membranes and the glabrous skin of the palms and soles. Hairs arise from modified downgrowth of epidermal keratinocytes into the dermis. The hair shaft has an inner and outer root sheath, a cortex and sometimes a medulla. The lower portion of the hair follicle consists of an expanded bulb (which also contains melanocytes) surrounding a richly innervated and vascularized dermal papilla. The hair regrows from the bulb after shedding. All hair follicles go through a cycle of anagen (growth), catagen (involution) and telogen (shedding). At any one time, most hairs (>90%) will be in the anagen phase, which is usually 3–5 years for scalp hair. Grey hair is due to decreased tyrosinase activity in the hair bulb melanocytes. White hair is due to a total loss of these melanocytes. There are three types of hair:

- *terminal*: medullated coarse hair, e.g. scalp, beard, pubic
- *vellus*: non-medullated fine, downy hairs seen on the face of women and in pre-pubertal
• **lanugo**: non-medullated fetal hair, seen in premature babies and occasionally in malnourished people, e.g. those with anorexia nervosa.

**Nails**

Nails are tough plates of hardened keratin, which arise from the nail matrix (just visible as the moon-shaped lunula) under the nail fold. It takes 6 months to grow a fingernail and 1 year to grow a toenail.

**The subcutis**

The subcutaneous layer consists predominantly of adipose tissue arranged into lobules and separated by fibrous septa. It also contains blood vessels and nerves. This layer provides insulation and cushioning against trauma; in non-obese subjects, it contains about 80% of all body fat.

**Clinical Approach to the Patient with Skin Disease**

**Dermatological history and examination**

The **history** should include the following:

• time course and distribution of rash/lesion(s)
• symptoms (e.g. itch or pain)
• family history (e.g. atopy and psoriasis)
• drug/allergy history (oral and topical medication)
• general medical history
• provoking factors (e.g. sunlight or medication)
• occupational, recreational and travel history.

**Examination** entails careful inspection of the whole skin – looking and feeling (for terminology, see **Box 31.2**) – and should include nails, hair and mucosal surfaces. The following terms are used to describe distribution: flexural, extensor, acral (hands and feet), symmetrical, localized, widespread, facial, unilateral, linear, centripetal (trunk more than limbs), annular and reticulate (lacy network or mesh-like).

**Box 31.2**

Investigations

Many rashes and lesions can be diagnosed by their appearance. Laboratory tests are useful if the diagnosis is uncertain, to reach a prognosis and to identify pathogens (Box 31.3).

Infections

The skin's surface is covered with an array of microbes that protect against pathogens. This natural flora or ‘microbiome’ may be disturbed by a range of factors, including altered host immunity, impaired skin barrier function or trauma, and this can lead to infection. Nasal carriage of bacteria can also be a source of infection.

Bacterial infections
Impetigo

Impetigo is a highly infectious skin disease that usually affects children (Fig. 31.2) and is spread by direct contact. Infected areas appear as inflamed plaques with a golden, crusted surface, typically around the mouth and nose. It is caused by *Staphylococcus aureus* or *Streptococcus pyogenes*. Toxin-producing strains of staphylococcus can also cause blisters (bullous impetigo; see below). Skin and nasal swabs should be taken if the complaint is extensive or recurrent, or constitutes a suspected outbreak.

![Impetigo. Crusted, blistering lesions on the chin.](image)

**Management**

Localized impetigo may be treated with topical fusidic acid. Mupirocin should be reserved for cases caused by meticillin-resistant *Staphylococcus aureus* (MRSA). The new topical antibiotic retapamulin is also effective but is considered a second-line treatment due to its expense. Widespread infection or bullous impetigo should be treated with oral antibiotics for 7 days (flucloxacillin 500 mg four times daily, or erythromycin or clarithromycin if the patient is penicillin-allergic). Five days' treatment with once-daily co-trimoxazole is also an option. Affected individuals should avoid school or work until the lesions are dry or for 48 hours after starting antibiotics.

**Staphylococcal scalded skin syndrome**

Certain strains of staphylococci secrete exfoliative toxins (ETs) that can cause widespread areas of desquamation – staphylococcal scalded skin syndrome (SSSS; Fig. 31.3) – or the localized blistering of bullous impetigo (see Fig. 31.2). ETs are serine proteases that
hydrolyse desmosomal proteins in the granular layer, leading to detachment of the superficial epidermis. In SSSS, ETs spread haematogenously from a source of infection and can cause septic shock and pneumonia. SSSS is more common in newborns than adults. However, in adults, it is often associated with underlying illness such as renal disease or immunosuppression, and has a higher mortality rate of up to 50%.

SSSS can resemble toxic epidermal necrolysis (TEN; see pp. 1383–1384) but the mucous membranes are not involved in SSSS and the level of epidermal detachment is higher. Histology therefore shows a more superficial split in SSSS (intra-epidermal) than in TEN (sub-epidermal). Frozen section processing can expedite the diagnosis. SSSS requires systemic treatment with anti-staphylococcal antibiotics (e.g. flucloxacillin) and full supportive care.

**Cellulitis and erysipelas**

Cellulitis and erysipelas are caused by superficial and deeper infection of the dermis and subcutaneous tissues, respectively. It is not always possible to make a clear distinction. Both complaints present with tender confluent areas of inflamed skin and are often associated with fever and malaise. Cellulitis typically affects the lower leg or arm and may spread proximally. Other sites that may be affected include the abdomen and perianal and periorbital areas. Erysipelas is more common on the face and is more sharply demarcated. Localized blistering (clear or blood-stained), necrosis, abscess formation, lymphangitis and lymphadenopathy may occur. The most common infective organisms are β-haemolytic streptococcus and *Staph. aureus*. Gram-negative or anaerobic bacteria may cause infection in those with diabetes or the immunocompromised.

Lymphoedema, leg ulcer, toe-web intertrigo and traumatic wounds are risk factors for cellulitis and erysipelas, and the skin should be carefully examined to look for any broken
areas that act as an entry point for infection. Skin swabs are usually negative unless taken from broken skin. Serological tests can be used to confirm a streptococcal infection (antistreptolysin O titre, ASOT) and anti-DNase B titre.

Management

Systemic antibiotics (flucloxacillin or erythromycin, both 500 mg four times daily) are usually the drugs of choice; depending on the patient’s age, disease severity and co-morbidities; options range from high-dose oral therapy at home to urgent hospital admission for intravenous therapy. Toe-web fungal infection should be treated, as this may reduce the risk of recurrent infection.

About 25% of patients suffer from recurrent episodes of cellulitis and it is not clear whether prophylactic treatment with low-dose antibiotics (e.g. phenoxybenzaminepenicillin 500 mg twice daily) is beneficial.

Necrotizing fasciitis

This is a rapidly spreading, deeper bacterial infection of the subcutaneous tissues that may complicate surgical or traumatic wounds. It is characterized by severe pain that is out of proportion to the degree of skin inflammation and systemic upset. Urgent medical and surgical intervention is required for this severe, life-threatening infection (see pp. 270–271).

Folliculitis

Folliculitis is an inflammatory disorder of the hair follicle, which presents as itchy or tender small papules and pustules. It may be caused by a range of microbes, most commonly Staph. aureus. Predisposing factors include humid climates, occlusive clothing, obesity and diabetes. A localized variant affecting the beard area (‘sycosis barbae’) is more common in black African men and is caused by ingrowth of curly hairs. Extensive, itchy folliculitis of the upper trunk and limbs may be a manifestation of human immunodeficiency virus (HIV) infection. The Gram-negative bacterium, Pseudomonas aeruginosa, may cause outbreaks of folliculitis from inadequately disinfected hot tubs and pools.

Treatment is with topical antiseptics, topical antibiotics or oral antibiotics, and management of underlying predisposing factors.

Boils (furuncles)

Boils or furuncles are deeper infections of hair follicles and are painful, red, pus-filled swellings. They are usually caused by Staph. aureus. Boils are most common in young men and may spread from person to person due to poor hygiene or overcrowding. They may also be a manifestation of diabetes or malnutrition. Multiple coalescing boils are sometimes called ‘carbuncles’. The rapid emergence of highly pathogenic strains of Staph. aureus that secrete a
toxin called **Panton–Valentine leukocidin (PVL)** (pp. 269–270) is causing concern. It is associated with outbreaks of severe recurrent boils and skin abscesses in healthy adults. MRSA is also involved in an increasing number of cases of furunculosis in some parts of the world, such as the USA. Skin swabs should be taken from all patients with severe or recurrent folliculitis to determine antibiotic sensitivities and screen for PVL toxin-producing strains of staphylococci.

### Management

Isolated boils can be treated with hot bathing alone. Antistaphylococcal oral antibiotics (flucloxacillin, erythromycin 500 mg four times daily or clarithromycin 250 mg twice daily) for 10–14 days are required for widespread infection or facial involvement. PVL-positive strains require more prolonged therapy with a combination of antibiotics such as rifampicin and clindamycin. Larger boils and abscesses may need incision and drainage. Screening of family contacts, nasal decolonization and use of antiseptic washes (e.g. chlorhexidine) are recommended.

### Ecthyma

Ecthyma is also caused by streptococci (group A β-haemolytic), *Staph. aureus*, or occasionally both. It presents as chronic, well-demarcated, deep ulcers with a necrotic crust and exudate. It is associated with malnutrition and poor hygiene: for example, in intravenous drug users. **Management** is with systemic antibiotics, phenoxymethylpenicillin 500 mg four times daily and flucloxacillin 500 mg four times daily for 10–14 days, and improved nutrition.

### Erythrasma and pitted keratolysis

**Erythrasma** is an orange–beige rash that affects the large flexures (axillae and groin) and is caused by *Corynebacterium minutissimum* (Fig. 31.4). It is often misdiagnosed as a fungal infection. Corynebacteria are part of the normal skin microbiome but can also act as pathogens. They can be identified by their characteristic coral-pink fluorescence when examined with Wood's light (UVA). Corynebacteria are also implicated in pitted keratolysis.
Management is with topical or oral erythromycin 500 mg four times daily. Antiperspirants may also be helpful.

Pitted keratolysis is a superficial infection of the horny layer of the skin. It frequently involves the soles of the forefoot and appears as numerous small, punched-out, circular lesions of rather macerated skin (e.g. as seen after prolonged immersion). There may be associated hyperhidrosis of the feet and a prominent odour.

Management is with topical antibiotics (e.g. sodium fusidate or clindamycin, applied three times daily for 2–4 weeks) and topical antiperspirants, which are effective therapies.

Further reading

Mycobacterial infections

Leprosy (Hansen's disease)
Leprosy (see pp. 285–286) usually involves the skin and nerves, and the clinical features depend on the host's immune response to the infecting organism, Mycobacterium leprae.

Indeterminate leprosy is the most common clinical type, especially in children. It presents as small, hypopigmented or erythematous, circular, scaly macules with reduced sensation. It
may resolve spontaneously or progress to one of the other types. Biopsy reveals a perineural granulomatous infiltrate and scant acid-fast bacilli.

**Tuberculoid leprosy** presents with a few larger, hypopigmented (see Fig. 11.32) or erythematous plaques with an inflamed border. Sensation is absent within lesions, which are dry and hairless, due to nerve damage. Nerves may be enlarged and palpable. Biopsy shows a granulomatous infiltrate around nerves but no organisms.

**Lepromatous leprosy** presents with multiple inflammatory papules, plaques and nodules. Loss of the eyebrows (‘madarosis’) and nasal stuffiness are common. Skin thickening and severe disfigurement may follow. Anaesthesia is much less prominent. Biopsy shows numerous acid-fast bacilli.

**Diagnosis and management** are discussed on page 286.

### Skin manifestations of tuberculosis

Tuberculosis can occasionally cause skin manifestations:

- **Lupus vulgaris** usually arises as a post-primary infection. It commonly presents on the head or neck with red–brown nodules that look like apple jelly when pressed with a glass slide (‘diascopy’). They heal with scarring, and new lesions slowly spread out to form a chronic solitary, erythematous plaque. Chronic lesions are at high risk of developing into squamous cell carcinoma.

- **Tuberculosis verrucosa cutis** arises in people who are partially immune to tuberculosis but who suffer a further direct inoculation in the skin. It presents as warty lesions on a ‘cold’ erythematous base.

- **Scrofuloderma** arises when an infected lymph node discharges onto the skin with ulceration and scarring.

- **The tuberculides** are a group of rashes caused by hypersensitivity reactions within the skin to underlying *Mycobacterium tuberculosis* infection. Erythema nodosum is the most common and is discussed on page 1363. Erythema induratum (‘Bazin’s disease’) is a similar rash with deep red nodules on the calves rather than the shins; lesions can ulcerate.

### *Mycobacterium marinum* infection (‘fish tank/swimming pool granuloma’)

This atypical/non-tuberculous mycobacterial infection presents with one or more painless granulomatous nodules on a hand or upper limb, which usually follow mild trauma. Local lymphadenopathy may also be present. Infection is usually acquired by coming into contact with non-chlorinated water or by cleaning out a fish tank without gloves. The diagnosis is usually made from the occupational or recreational history and clinical features. A skin biopsy shows granulomatous inflammation in the dermis and *Mycobacterium marinum* may be isolated from prolonged culture at low temperature. Polymerase chain reaction (PCR) of tissue
can also confirm the diagnosis but this is not widely available.

**Treatment** is with combination oral antibiotics (e.g. clarithromycin and ciprofloxacin) for 4–8 weeks. Other antibiotics, such as tetracyclines, trimethoprim–sulfamethoxazole and antituberculous drugs, can be used. Occasionally, mild infections will clear themselves without treatment.

### Viral infections

#### Viral exanthem

An exanthem is the most common cutaneous manifestation of viral infection and is an erythematous maculopapular rash that predominantly affects the torso and proximal limbs. It is probably caused by deposits of immune complexes of antibody and viral antigen within dermal blood vessels. Many different viruses can cause exanthems, e.g. echovirus (see p. 260), erythrovirus (see p. 252), human herpesvirus 6 (see pp. 252–253), Epstein–Barr virus (see p. 258). The rash resolves spontaneously in 7–10 days.

#### Slapped cheek syndrome (erythema infectiosum, fifth disease)

See page 252.

#### Herpes simplex virus

Herpes simplex virus (HSV; see also pp. 247–249) occurs as two genomic subtypes. Most people are affected in early childhood with HSV type 1 but the infection is usually subclinical. Occasionally, it can present with either clusters of painful blisters on the face (**Fig. 31.5**) or a painful gingivostomatitis. In some individuals, cell-mediated immunity is poor and they experience recurrent attacks of HSV, often manifest as cold sores. Immunosuppression can also cause a recrudescence of HSV. HSV can also autoinoculate into sites of trauma and present as painful blisters or pustules that may be seen, for example, on the fingers of healthcare workers (‘herpetic whitlow’).

![Primary herpes simplex infection.](image)
HSV type 2 infections are discussed on page 249. Other rare complications of HSV infection include corneal ulceration, eczema herpeticum, chronic perianal ulceration in acquired immunodeficiency syndrome (AIDS) patients, and erythema multiforme.

**Management**

Oral valaciclovir (500 mg twice daily for 5 days) is used for primary HSV and painful genital HSV. Cold sores are treated with aciclovir cream but this must be used early to shorten an attack; frequent recurrences can be treated with prophylactic oral therapy. Attacks of herpes become less frequent with time. Intravenous aciclovir must be used in immunosuppressed patients.

**Varicella zoster virus**

Varicella zoster virus (VZV) causes the common childhood infection, chickenpox. It is discussed on pages 249–250. It also causes herpes zoster.

**Herpes zoster (shingles)**

‘Shingles’ results from reactivation of latent VZV infection. It may be preceded by a prodromal phase of tingling or pain, which is followed by a painful, unilateral, blistering eruption in a dermatomal distribution (Fig. 31.6; see also Fig. 11.16). The blisters occur in crops and may become purulent before crusting. The rash lasts 2–4 weeks and is usually more severe in the elderly. Occasionally, more than one dermatome is involved.

![Herpes zoster in an African male](https://example.com/herpes-zoster-african-male.jpg)

**FIGURE 31.6** Herpes zoster in an African male. (Courtesy of Dr P Matondo, Lusaka, Zambia)

Complications of shingles include severe, persistent pain (post-herpetic neuralgia), ocular disease (if the ophthalmic nerve is involved) and, rarely, a motor neuropathy.

**Management**
Herpes zoster requires adequate analgesia and antibiotics (if secondary bacterial infection is present). Valaciclovir 1 g or famciclovir 250 mg three times daily for 7 days is used; alternatively, oral aciclovir 800 mg five times daily for 7 days helps shorten the attack if given early in the illness.

High-dose intravenous aciclovir is used in immunosuppressed patients. A live-attenuated varicella zoster virus vaccine is available to boost immunity against VZV in the elderly and reduce the risk of developing herpes zoster.

### Human papillomavirus

Human papillomavirus (HPV) is responsible for the common cutaneous infection of ‘viral warts’ (see also p. 265).

**Common warts** are papules with a coarse, roughened surface, often seen on the hands and feet but also on other sites. Small black dots (thrombosed vessels) are often seen within the lesion (*Fig. 31.7*). Warts on the face may become elongated (‘filiform’). Children and adolescents are usually affected. Spread is by direct contact and can be facilitated by trauma.

![Viral wart.](image)

**Plantar warts** (*verrucae*) affect the soles of the feet. They are flattened due to pressure but still have a characteristic warty (papillomatous) surface. Black dots can be seen if the skin is pared down (unlike callosities). Warts may be tender if they affect pressure points or are sited around nail folds.

**Plane warts** are much less common and are caused by certain HPV subtypes. They are clinically different and appear as very small, flesh-coloured or pigmented, flat-topped lesions (best seen with side-on lighting) with little surface change and no black dots. They are usually multiple and are frequently found on the face or the backs of the hands.

**Anogenital warts** (see p. 326).

### Management

There is no definitive cure and warts may persist for months or years before spontaneously clearing. They are often recalcitrant in those with impaired immunity (e.g. transplant
recipients).

Regular use of a topical keratolytic agent (e.g. 10–26% salicylic acid) after removal of hyperkeratotic skin may hasten resolution and is the mainstay of treatment. Liquid nitrogen cryotherapy can also be effective. Other destructive treatments include cantharadin, curettage and cautery, and laser therapy, but these may cause considerable pain and scarring.

**Molluscum contagiosum**

Molluscum contagiosum is a common cutaneous infection of childhood and is caused by a pox virus. Lesions are multiple small (1–3 mm) translucent, firm papules, which may look as though they contain fluid – ‘water blisters’ – but in fact contain soft, white matter that can be extruded through a central (umbilicated) depression and on squeezing. Mollusca may exhibit the Köbner phenomenon (see p. 1353). They can affect any body site, including the genitalia, and are transmitted by contact. Occasionally, lesions may be up to 1 cm in diameter (‘giant molluscum’).

Lesions usually recur in crops over 6–12 months before resolving spontaneously. Treatment is not required, but localized trauma, such as cryotherapy or curettage, may be helpful in older children. Hydrogen peroxide 1% cream or 5% imiquimod cream can be used in younger children. Mollusca are usually sexually transmitted in adults, and giant lesions or widespread involvement should raise the possibility of immunosuppression, especially HIV infection.

**Orf**

Orf is a pox virus infection of sheep and goats that causes a vesicular and pustular rash around the mouths of young offspring. People who handle the infected animal may become infected. Orf has long been recognized in farm workers but has recently been reported in children who catch the infection at ‘petting stations’ in city farms. Lesions appear as 1–2 cm red papules on the hands with an inflamed border that blisters; alternatively, they turn into pustules and resolve spontaneously after 4–6 weeks, conferring life-long immunity. Occasionally, orf is complicated by erythema multiforme (see p. 1363).

Fungal infections

Fungal skin diseases have a high prevalence in humans, ‘thrush’ and ‘athlete’s foot’ being two extremely common examples. In most cases, infection is confined to the stratum corneum (superficial mycoses), which elicits no inflammation, or the deeper layers of the epidermis, including hair and nails (cutaneous mycoses), where inflammation may be triggered by the fungus or its products. Subcutaneous mycoses include a range of infections of the subcutaneous tissues, usually following traumatic inoculation. The inflammatory response may extend upwards to the epidermis.

There are three groups of pathogenic fungi that commonly affect the outer layer of skin or keratinizing epithelium: dermatophytes, Candida albicans and Malassezia (formerly pityrosporum).

Dermatophyte infection

Dermatophyte (tinea) fungi invade and grow in dead keratin. The three main genera that affect humans are Trichophyton, Microsporum and Epidermophyton. They tend to form an expanding annular lesion due to lateral growth: hence the name ‘ringworm’. Tinea may be transmitted to humans by other people (anthropophilic), from animals (zoophilic) or from soil (geophilic). The clinical appearance depends on the infecting organism, the site affected and the host reaction.

Tinea of the body usually presents with asymmetrical, scaly, inflamed patches with clearer centres and a scaly, raised border. Occasionally, vesicles or pustules may be seen. Treatment with topical steroids will modify the appearance, reducing scaling and erythema due to the anti-inflammatory effect and thereby masking some of the clinical signs – ‘tinea incognito’. However, the rash typically flares when steroids are stopped. Tinea infections are classified according to body site: tinea corporis (body), tinea facei (face), tinea barbae (beard), tinea cruris (groin), tinea manuum (hand), tinea pedis (foot), tinea capitis (scalp) and tinea unguium (nails). Multiple sites may be affected, and skin, hair and nails should be examined.

Asymmetrical scaly rashes should be investigated for fungal infection by mycology of skin scrapings.

Tinea cruris is more common in men than women and presents with an intensely itchy rash in the groin, with a scaly border that extends on to the thighs (Fig. 31.8).
**Tinea pedis** (athlete's foot) is extremely common in adults and is often confined to the toe webs, where the skin looks white, macerated and fissured. It may extend more widely on to the soles and sides of the feet, causing dryness, scaling and erythema, and the toenails are also often affected. Tinea pedis frequently flares in hot weather, causing pustules or blisters, and this can be misdiagnosed as eczema. Infection may also spread to the palm (*tinea manuum*), especially in manual workers. Annular lesions are rarely seen on palmoplantar skin.

**Tinea capitis** is the most common dermatophyte infection in young children, especially those of black African origin, whose hair and scalp seem more susceptible to fungal invasion. Adults and the elderly are rarely affected. Fungus may confine itself to within the hair shaft (endothrix) or spread out over the hair surface (ectothrix). The latter may fluoresce under a Wood's lamp (UV light). Scalp ringworm is spread by close contact (especially in schools and households) and by sharing of brushes or clippers. Immigration has led to changing patterns of fungal infections in Europe (e.g. *Trichophyton tonsurans* from Central America, *Trichophyton violaceum* from India and Pakistan). The majority of UK cases are due to *T. tonsurans* (which does not fluoresce).

The clinical appearance of scalp ringworm varies from mild diffuse scaling with no hair loss (similar to dandruff) to the more typical appearance of bald, scaly patches with broken hairs. An increased host response causes pustules and an inflammatory exudate, and certain types of tinea can trigger a severe inflammatory reaction with a swollen purulent mass or ‘kerion’. This may be mistaken for a bacterial infection and inappropriately treated with an antibiotic. Extensive infection is occasionally accompanied by a widespread papulopustular rash on the trunk. This is a so-called ‘id reaction’ and probably relates to the host immune response to the fungus. It resolves when the infection is treated.

**Tinea unguium and onychomycosis**

Onychomycosis is a broad term for fungal nail infection. Tinea unguium refers to a dermatophyte infection of the fingernails or toenails (*Fig. 31.9*). Tinea toenail infection is a common finding in the elderly and is usually asymptomatic. Fingernail infection is less
common. Affected nails are dystrophic, thick (subungual hyperkeratosis) and discoloured (white–yellow–beige). Infection usually starts at the distal or lateral nail edges, then spreads proximally. The whole nail plate may be destroyed with advanced disease. The **differential diagnoses** include nail psoriasis and traumatic nail dystrophy (which may coexist with fungal infection). Diseased nails should be clipped back and the crumbly white nails analysed by microscopy and mycological culture to confirm the diagnosis and identify the organism. *Trichophyton rubrum* is the most common pathogen.

![Dermatophyte infection of the nail. White, crumbling dystrophy is shown.](image)

**FIGURE 31.9**

**Management**

Localized tinea of the body or flexures is treated with an antifungal cream (clotrimazole, miconazole or terbinafine applied three times daily for 1–2 weeks). Nystatin is ineffective. More widespread infection, tinea pedis, tinea manuum and tinea capitis require oral antifungal therapy with itraconazole (100 mg daily) or terbinafine (250 mg per day) for 1–2 months. Griseofulvin is a less effective drug, but is still used for childhood tinea capitis.

Tinea unguium of the toenails requires prolonged oral antifungal therapy. Itraconazole (as a continuous or pulsed regimen) or terbinafine for 3–6 months can clear up to 80% of cases but relapses are common.

**Candida albicans**

*Candida albicans* (see also p. 295) is a commensal yeast within the gastrointestinal tract. It can overgrow on occluded moist skin, causing nappy rash, intertrigo of the large flexures in obese people (*Fig. 31.10*), and vulvovaginal candidiasis or ‘thrush’. The glans penis may be affected in uncircumcised males (candidal balanitis).
Candidal intertrigo causes irritation and soreness; affected areas are glazed and inflamed, with a ragged peeling edge that may contain a few small pustules. Spotty erythema may extend beyond the affected border (satellite lesions).

*Candida* may also affect the moist interdigital clefts of the toes and mimic tinea pedis. In people who frequently immerse their hands in water (e.g. cleaners, caterers), *Candida* may cause chronic infection of the nail folds (‘paronychia’) and nail infection (candidal onychomycosis). *Candida* can also infect the oral mucosa, especially in those who have taken broad-spectrum antibiotics and in the immunosuppressed and elderly. Affected mucosal surfaces are inflamed with superficial white or creamy pseudomembranous plaques, which can easily be scraped away.

**Management**

Predisposing factors should be treated. Diabetes should be excluded. Topical therapy (azoles or nystatin) is usually adequate, except for nail infection, and may take the form of creams, pessaries, lozenges or powder, depending on body site. Recurrent vulvovaginal candidiasis (see p. 325) is a common complaint in women and may require oral azole antifungal therapy.

**Malassezia**

This lipophilic yeast family (formerly called pityrosporum; see p. 297) form part of the normal skin microbiome. Colonization is prominent in the scalp, flexures and upper trunk. At least 10 different species have been identified and there is increasing evidence of their causal role in three common dermatoses:
• pityriasis versicolor
• seborrheic eczema (see pp. 1351–1352)
• Pityrosporum folliculitis.

**Pityriasis versicolor** is a common complaint in young adults and *Malassezia globosa* appears to be the causative agent; in fair-skinned people, it typically causes pink–beige scaly macules on the torso. Pale areas may be prominent after suntanning and in darker-skinned individuals as the yeast impairs melanin synthesis.

The **diagnosis** is usually made clinically but can be confirmed by microscopy of skin scrapings, which shows the characteristic ‘meatballs and spaghetti’ appearance of spherical yeast and short pseudohyphae.

**Management** is with topical azoles or oral itraconazole for resistant cases. Antifungal shampoos containing selenium sulphide or ketoconazole may also be used as a body wash. The pigment changes can take months to resolve and recurrences are common.

**Pityrosporum folliculitis** is also common in young men and causes small, itchy, monomorphic papules and pustules on the upper back, shoulders and face. It may be confused with acne. Topical and oral azole antifungals can be effective but the complaint often relapses quickly.

### Subcutaneous mycoses

Subcutaneous mycoses (see p. 297) are a rare group of localized infections of the skin and subcutaneous tissues that follow traumatic implantation of the fungal agent, a soil saprophyte. The causative organisms vary geographically and disease examples include sporotrichosis (worldwide), chromoblastomycosis and mycotic mycetoma (tropical and subtropical). Sporotrichosis or ‘rose gardener’s disease’ usually causes a slowly growing, inflamed nodule at the site of skin inoculation, with new lesions developing along lymphatics and blood vessels – ‘sporotrichoid spread’. Treatment is with oral itraconazole.

### Infestations

#### Scabies

Scabies is an ectoparasite infestation with the mite *Sarcoptes scabiei*. It can affect all races and people of any social class. It is most common in children and young adults but can affect any age group. There are 300 million cases of scabies in the world each year. It is more common in poorer countries with social overcrowding, especially sub-Saharan Africa. At any
time there are approximately 130 million untreated cases. Although scabies is a trivial complaint, the infectious complications include neonatal septicaemia, post-streptococcal nephritis and rheumatic fever, and cause considerable morbidity. Scabies is spread by close or prolonged contact, such as within households or institutions, and by sexual contact. It presents with an intensely itchy, excoriated rash that resembles eczema. Pruritus is usually worse at night and disturbs sleep. Small, red papules, vesicles and occasionally pustules occur anywhere on the body but rarely on the face, except in neonates. The distribution of lesions is helpful in making a diagnosis (Fig. 31.11). Sites of predilection are the finger webs, palms, soles, wrists, axillae, the male genitalia, and around the nipples and umbilicus.

![Fig. 31.11 Scabies. Itchy papules and pustules centred on the web spaces of the hand.](image)

The diagnostic sign is fine linear or curved burrows but these are not always visible. Dermoscopy may help. The rash may be complicated by secondary bacterial infection. Scabies can be confirmed by microscopy of potassium hydroxide-treated skin scrapings from the tip of a burrow, which reveal the mite and/or its eggs.

Management

A topical scabicide (e.g. 5% permethrin) is applied overnight. For the treatment to be successful, the following should be noted:

- Treat all skin below the neck, including the genitalia, palms and soles, and under the nails. Treat the head and neck regions in infants (up to age 2 years).
- All close contacts should be treated at the same time, even if asymptomatic.
- Reapply scabicide to the hands if they are washed during the treatment period.
- Wash or clean recently worn clothes (preferably at 60°C) to avoid re-infection.
• Advise that pruritus may persist for up to 4 weeks after successful treatment.
• The application should be repeated after 1 week.

Malathion can be used if permethrin is unavailable; benzyl benzoate is employed occasionally but is very irritant and should not be used in children. Lindane is a cheap therapy but there are concerns about resistance to this drug and neurotoxicity. Oral ivermectin 200 µg/kg, as 2 doses 2 weeks apart, is effective, especially for use in institutions, but remains unlicensed for this indication.

**Crusted scabies (Norwegian scabies)**

Crusted scabies is a variant that occurs in immunosuppressed individuals when huge numbers of mites are carried in the skin *(Fig. 31.12)*. Pruritus may be mild or absent. Individuals are highly infectious and may be the source of outbreaks if the diagnosis is delayed. Hyperkeratotic crusted lesions characteristically affect the hands and feet. This may progress to a widespread erythema with irregular crusted plaques, mimicking infected eczema or psoriasis.

![Crusted scabies](image)

**FIGURE 31.12** Crusted scabies in a patient with chronic myeloid leukaemia.

*Management* is with careful barrier nursing, repeated applications of a scabicide and oral ivermectin (200 µg/kg – at least 2 doses 1 week apart).

**Lice infection**

Lice are blood-sucking ectoparasites that cause three patterns of infection in humans.

**Head lice (pediculosis capitis)**

Head lice infestation is an extremely common problem in schoolchildren, especially young girls. Lice spread by close contact and cause pruritus, leading to excoriations and papules
around the hairline of the neck and ears.

**Diagnosis** can be confirmed by identifying the eggs (‘nits’), which are firmly stuck to the hair shaft, or the adult lice, which can be caught between the teeth of a fine comb.

**Management** aims at eradication but this is difficult because of the time-consuming nature of treatment and frequent re-infestations. Lotions containing traditional topical insecticides, such as malathion, carbaryl and phenothrin, are used less widely because of resistance and are being replaced with physical treatment (wet combing). This involves use of a fine-toothed comb to remove young lice before they mature and needs to be repeated meticulously until all eggs have hatched. Oral ivermectin is an option in recalcitrant infestations but is unlicensed in the UK.

**Body lice (pediculosis corporis)**

Infestation with body lice is a disease of poverty and neglect. It is rarely seen in developed countries except in homeless individuals and vagrants. It is spread by direct contact or by sharing of infested clothing. The lice and eggs are rarely seen on the patient but are commonly found on the clothing. Infestation with body lice presents with itch, excoriations and, sometimes, post-inflammatory hyperpigmentation of the skin.

**Management** consists of malathion or permethrin for the patient and high-temperature washing and drying of clothing.

**Pubic lice (crabs, Phthiriasis pubis)**

Pubic lice are transmitted by direct contact, usually sexual (see p. 331). Infestation presents with itching, especially at night. Lice can be seen near the base of the hair with eggs somewhat further up the shaft. Occasionally, eyebrows, eyelashes and the beard area are affected.

**Management** is as for head lice but all sexual contacts should be treated and the patient screened for other sexually transmitted diseases. Eyelash infestation is treated with white soft paraffin three times daily for 1–2 weeks.

**Arthropod-borne diseases (‘insect bites’ or papular urticaria)**

These depend on contact with an animal (e.g. dog, cat, bird) that is infested with fleas (*Cheyletiella*) or on bites from flying insects (e.g. midges, mosquitoes). In the case of flea bites, the animal itself may be itchy with scaly and thickened skin. Flea eggs can lie dormant in soft furnishings (e.g. carpets) for many months. Bites present as itchy, urticated lesions, which are often grouped in clusters or lines. The legs are most commonly affected and lesions can blister in hot weather. It is not unusual for an individual to react badly to bites when other family members seem unaffected. Anti-flea treatment of the animal and furnishings is required. Insect repellents and appropriate clothing help lessen bites from flying insects.

Infestations with bed bugs have increased enormously in the past decade in the developed world. Bed bugs are small, brown/black, lentil-sized insects, which emerge from the seams of bedding at night-time when attracted to the warmth of sleeping humans and the carbon dioxide
they produce. Their bites cause clustered, itchy papules on exposed areas, including the eyelids, face and neck. Infestations require professional insecticide treatment of properties. Advice can be obtained from the National Pest Technicians Association in the UK (see ‘Further reading’).

Further reading

Tropical dermatoses
Skin diseases feature among a group of ‘neglected tropical diseases’ defined by the World Health Organization WHO: leprosy, leishmaniasis, dracunculiasis (guinea worm), lymphatic filariasis and onchocerciasis. These are endemic in poor countries and constitute a huge physical and financial burden. Travellers returning to the West from tropical or subtropical countries may also be affected by skin diseases, especially cutaneous leishmaniasis, cutaneous larva migrans and myiasis. In addition, rashes may be a feature of systemic infections such as dengue, schistosomiasis and rickettsial diseases.

Leishmaniasis (see pp. 303–305) is an infection with the protozoon *Leishmania*, and is acquired from the bite of a sandfly vector. Cutaneous, mucocutaneous and visceral disease (kala azar) may occur, depending on the infecting organism and host response. *Cutaneous leishmaniasis* (see p. 304) is the most common form and presents as a chronic ulcer (oriental sac), which heals slowly over many months with scarring.

*Cutaneous larva migrans* is caused by direct contact with the larvae of hookworm from animal faeces – usually acquired by walking or lying on sandy beaches. Larvae penetrate the skin and cause an intensely itchy serpiginous lesion, which migrates as the larva burrows within the epidermis.

*Myiasis* is an infestation of the skin with developing fly larvae (maggots). Species that can penetrate intact skin to cause boil-like lesions include botfly and tumbu fly.

Papulo-Squamous/Inflammatory Rashes

Eczema

The terms eczema and dermatitis are used interchangeably to describe a common group of inflammatory skin diseases. In the developed world, eczema may affect about 10% of the
population at any one time, with up to 40% experiencing an episode of eczema during their lifetime. Eczema is classified as constitutional or endogenous, and contact or exogenous (Box 31.4). It can also be classified according to duration (acute, subacute or chronic).

### Box 31.4

**Classification of eczema**

**Endogenous**
- Atopic eczema
- Seborrhoeic eczema
- Discoid eczema
- Chronic hand/food eczema
- Venous (‘gravitational’) eczema
- Asteatotic eczema
- Lichen simplex/nodular prurigo

**Exogenous**
- Irritant contact eczema
- Allergic contact eczema

The inflammation common to all forms of eczema causes erythema and surface change (dryness, scaling), as well as itch, which ranges from mild to intolerable. In acute eczema, tiny vesicles or larger bullae may be seen within oedematous, inflamed skin. Scratching leads to sero-sanguinous exudate and crusts. In subacute eczema, there is less oedema and some flaking and scaling. Chronic eczema is thickened and dry with prominent skin creases (lichenification). Secondary bacterial infection may occur and cause crusts, papules and pustules. The histology of eczema correlates with the clinical signs: in acute eczema the keratinocytes are swollen with increased intercellular fluid (‘spongiosis’), while in chronic disease there is little oedema but prominent thickening of the epidermis (acanthosis) and scaling (hyperkeratosis). Inflammatory cells are present around the upper dermal vessels in all patterns.

**Atopic eczema**

This type of constitutional eczema is extremely common affecting up to 20% of children. It usually starts under the age of 2 years and is often associated with other atopic diseases, which present in a sequence described as the ‘atopic march’.
Aetiology

Atopic eczema is a genetically complex, familial disease with a strong maternal influence. A positive family history of atopic disease is often present: there is a 90% concordance in monozygotic twins but only 20% in dizygotic twins. If one parent has atopic disease, the risk of a child developing eczema is about 20–30%. If both parents have atopic eczema, the risk is greater than 50%.

The exact pathophysiology is not fully understood but abnormalities in skin barrier function, combined with abnormalities in both adaptive and innate immunity, seem to be crucial. In at least 80% of cases, there is a raised serum total immunoglobulin E (IgE) level, but it is not clear whether this is of primary importance or a secondary effect.

Genetic studies have shown a primary problem of skin barrier function. Loss-of-function mutations in the epidermal barrier protein filaggrin cause ichthyosis vulgaris but also strongly predispose to atopic eczema. This work has been reproduced in different ethnic groups around the world. Filaggrin is coded by the FLG gene in the epidermal differentiation complex on chromosome 1q21.

Filaggrin deficiency leads to poor barrier function and dry skin, and allows antigen penetration into the epidermis. There is an initial selective activation of Th2-type CD4 lymphocytes in the skin, which drives the inflammatory process (adaptive immunity). This causes an increase in the cytokines interleukin (IL)-4, IL-5 and IL-13, as well as high IgE levels. During the chronic phase of the disease, both Th1 and Th2 cells are involved.

There are also defects in the innate immune system in atopic eczema. There is a decrease in epidermal antimicrobial peptides, Toll-like receptor 2 expression and epidermal tight junctions, and this, in turn, may explain why cutaneous infection (Staphylococcus and herpes simplex) is common in eczema (but rare in psoriasis).

Recent research shows the IL-4/IL-13 pathway is critical in Th2 activation. Blockade of this pathway is now being used as a new treatment for both eczema and asthma. IL-31 (which is induced by IL-4) may be a key player in ‘itch’.

Exacerbating factors

Infection, either in the skin or systemically, can lead to an exacerbation, possibly by a superantigen effect. Paradoxically, lack of infection (in infancy) may cause the immune system to follow a Th2 pathway and allow eczema to develop (the so-called ‘hygiene hypothesis’). Soap, bubble bath and woollen fabric can irritate and aggravate eczema. Teething is another factor in young children. Severe anxiety or stress appears to exacerbate eczema in some individuals. Cat and dog dander can aggravate eczema. The role of house dust mites and diet is less clear-cut. Immediate/type 1 hypersensitivity to food allergens (cow’s milk, egg, soya, wheat, fish and nuts) are common in young children with severe eczema. It causes urticaria (hives) and gastrointestinal symptoms (reflux, vomiting and diarrhoea) but not eczema. Rarely, there may be a delayed reaction to foods such as cow’s milk that cause an eczema flare after 12–24 hours. Delayed food hypersensitivity cannot be investigated with prick tests or blood
tests and the mechanism is unknown. The diagnosis is made by taking a careful dietary history, followed by oral food challenge tests. There is some evidence that food allergens may play a role in triggering atopic eczema and that dairy products or eggs cause exacerbation of eczema in a minority of infants under 12 months of age.

**Clinical features**

Atopic eczema has a variable clinical presentation. The most common involves itchy, erythematous, scaly patches, especially in the flexures of the elbows, knees, ankles and wrists ([*Fig. 31.13*]), and around the neck. In infants, eczema often starts on the cheeks before spreading to the body. Very acute lesions may weep or exude and can show small vesicles. Scratching can produce excoriations, and repeated rubbing produces skin thickening (lichenification) with exaggerated skin markings.

![Atopic eczema behind the knees.](image)

In people with pigmented skin, eczema may be more prominent on the extensor surfaces of the sites mentioned above, and the follicles can be prominent. Lichenification is common. Pigmentary changes – hyper- and hypopigmentation – may follow the inflammatory phase of eczema and are often slow to resolve.

**Associated features**

In some atopic individuals, the skin of the upper arms and thighs may feel roughened due to follicular hyperkeratosis (‘keratosis pilaris’). The palms may show very prominent skin creases (‘hyperlinear palms’). There may be an associated dry, ‘fish-like’ scaling of the skin, which is non-inflammatory and often prominent on the lower legs (‘ichthyosis vulgaris’).

**Complications**

Broken skin can become secondarily infected by bacteria, usually *Staph. aureus*, although
streptococci may be involved, especially in macerated flexural areas such as the neck and groin. Pustules, crusted papules with exudate and impetigo-like lesions suggest secondary infection. Cutaneous viral infections (e.g. viral warts and molluscum) may be more widespread in atopic eczema. HSV can cause a widespread infection of the skin, *eczema herpeticum (Kaposi's varicelliform eruption)*. It appears as multiple small blisters or monomorphic, painful, punched-out crusted papules *(Fig. 31.14)* associated with malaise and pyrexia. Very rarely, infection may become disseminated and life-threatening. Eczema herpeticum needs urgent treatment with systemic aciclovir. An unusually extensive form of hand, foot and mouth disease has been recently described in children with eczema, in which blistering, crusted lesions may extend to involve large areas of the limbs and face (‘eczema coxsackium’). This resolves spontaneously but secondary bacterial infection may require antibiotics.

![Eczema herpeticum. Multiple punched-out crusted erosions are shown.](image)

Ocular complications of atopic eczema include conjunctival irritation and, less commonly, keratoconjunctivitis and cataract.

### Investigations

Atopic eczema is diagnosed by the history and clinical features. About 80% of patients also have laboratory features of atopy (raised total serum IgE and allergen-specific IgE and mild eosinophilia).

### Prognosis

The majority (80–90%) of children with early-onset atopic eczema will spontaneously improve and ‘clear’ before the teenage years, 50% being clear by the age of 6. A few will experience a recurrence as adults, even if just in the form of hand eczema. However, if the onset of eczema is late in childhood or in adulthood, the disorder follows a more chronic
remitting/relapsing course.

Management
(See Box 31.5.)

Box 31.5
Management of atopic eczema

- Education and explanation
- Avoidance of irritants/allergens
- Emollients
- Bath oils/soap substitutes
- Topical therapies:
  - Steroids
  - Immunomodulators
- Adjunct therapies:
  - Oral antibiotics
  - Sedating antihistamines
  - Bandaging
- Phototherapy
- Systemic therapy, e.g. oral prednisolone, ciclosporin

General measures
These include avoiding irritants (especially soaps or furry animals), wearing cotton clothes and not getting too hot. Manipulating the diet (e.g. following a dairy-free or egg-free diet) may be helpful in a minority of infants with moderate to severe eczema. However, dietary modification should only be made with expert supervision, to ensure adequate intake of nutrients such as calcium.

Topical therapies
Topical therapies (see pp. 1385–1386) are sufficient to control atopic eczema in most people. The three components are usually a topical steroid, bland moisturizer and soap substitute/bath oil. Moisturizers should be used liberally on all dry skin areas and reapplied as often as needed (see Box 31.26). Dermatology nurse-led education of eczema sufferers and their families can help provide psychological support and improve adherence to treatment.

Topical steroids
Topical corticosteroids remain the mainstay of eczema treatment. Selecting an appropriate
dose and potency of steroid according to the body site, surface area and age of the patient is necessary to minimize the risk of adverse effects and allow safe, long-term intermittent treatment. Unfortunately, ‘steroid phobia’ is common among patients or their carers and leads to under-use of an otherwise effective treatment. Steroids should only be used on inflamed skin. Potent steroids should only be used for short periods. Regular use of emollients may lessen steroid usage. Topical steroids are classified into four main groups according to potency (Box 31.6). They are usually applied once or twice a day to inflamed areas.

### Box 31.6

**Classification of topical steroids by potency**

**Very potent**
- 0.05% clobetasol propionate
- 0.3% diflucortolone valerate

**Potent**
- 0.1% betamethasone valerate
- 0.025% fluocinolone acetonide

**Moderately potent**
- 0.05% clobetasone butyrate
- 0.05% alclometasone dipropionate

**Mild**
- 2.5% hydrocortisone
- 1% hydrocortisone

While mild steroids rarely cause atrophy, this is a significant risk with potent and superpotent steroids, especially if used under occlusion or with keratolytics such as salicylic acid. Milder steroids should be used on the face and flexures, especially in the periocular area and in young children. The palmoplantar skin usually requires potent steroid therapy due to the thicker stratum corneum. The ‘fingertip unit’ can be used to guide topical steroid dosage. The **adverse effects of topical steroids** include:
- cutaneous atrophy and telangiectasia
- striae
- steroid-induced rosacea, perioral dermatitis and folliculitis
- tinea incognito (a tinea infection modified by a topical steroid applied inappropriately)
- ocular adverse effects – cataract, glaucoma.
Topical calcineurin inhibitors

Tacrolimus ointment (0.1% and 0.03%) and the less potent 1% pimecrolimus cream, applied twice daily, are licensed for the treatment of atopic eczema in children over 2 and adults. They do not cause skin atrophy and are a good option for treating eczema on delicate areas such as the face and eyelids. They are less effective on thicker, lichenified skin due to poorer penetration. The main adverse effect is a burning or prickling sensation when first used, which improves with continued treatment. Alcohol-induced flushing can affect a minority. Initial concerns that the immunosuppressant effects of topical calcineurin inhibitors (TCIs) would increase the risk of skin cancer have not materialized, but patients using these preparations are advised to avoid sun exposure and vaccinations. Tacrolimus ointment is also used twice weekly to prevent eczema flares.

Antibiotics

These are needed for bacterial infection and are usually given orally for 7–10 days. Flucloxacillin (500 mg four times daily) is effective against *Staphylococcus*, and phenoxyethylpenicillin (500 mg four times daily) acts against *Streptococcus*. Erythromycin (500 mg four times daily) is useful if there is allergy to penicillin. Topical antiseptics are used in cases of recurrent infection but they can be irritant. They are usually added to the bath water rather than applied directly to the skin.

Sedating antihistamines

These (e.g. oral hydroxyzine hydrochloride 10–25 mg) are useful at night-time.

Bandaging

Paste bandaging can be useful for resistant or lichenified eczema of the limbs. It helps absorption of treatment and acts as a barrier to prevent scratching. Wet tubular gauze bandages are used for inpatient therapy but are difficult and time-consuming to apply at home.

Second-line agents

These are used in severe, unresponsive eczema, especially if it is significantly interfering with an individual's life (e.g. growth, sleeping, school work or job). Ultraviolet phototherapy (see p. 1362), ciclosporin (3–5 mg/kg daily), azathioprine (1–3 mg/kg daily) and methotrexate can be helpful. Short, tapering courses of oral prednisolone usually give rapid disease control but relapse is common on withdrawal. The risks and benefits of long-term systemic therapy require careful evaluation and should be discussed with the patient.

New drugs

The new anti-IL-4/IL-13 monoclonal antibody dupilumab has been shown to have great efficacy and speed of action in atopic eczema. A new anti-IL-31 drug is in phase 3 trials in adults with eczema.

Omalizumab (anti-IgE monoclonal antibody) is already licensed for use in resistant asthma
and chronic urticaria. There are conflicting reports as to whether it helps eczema, especially in those with very high IgE levels, but it may act via a non-anti-IgE mechanism. It is currently under trial in the UK in children with eczema. Apremilast (a phosphodiesterase-4 inhibitor) is also being studied in both eczema and psoriasis.

Seborrhoeic eczema

Clinical features

Seborrhoeic eczema is extremely common in adults of all ages and in its mildest form is often overlooked. As the name implies, it occurs in greasy body areas. On the face, it presents with scaling and erythema around the nose (Fig. 31.15), medial eyebrows, hairline and ear canals. Itch is variable. Dandruff is thought to be the mildest manifestation of scalp seborrhoeic dermatitis. More severe scalp involvement can look like psoriasis. The pre-sternal area may be affected in men and other sites include the large flexures and anogenital area. A generalized form of seborrhoeic eczema presents as erythroderma in the elderly (see pp. 1362–1363). Children are not affected until puberty, but a self-limiting infantile form is recognized, with scalp scaling/cradle cap and a non-itchy napkin dermatitis.

Aetiology

There is increasing evidence that the lipophilic commensal yeast, Malassezia (see p. 297), plays a role in triggering the inflammatory skin changes of seborrhoeic dermatitis in susceptible individuals. Host immunity is also involved, and seborrhoeic dermatitis is one of the earliest skin manifestations of HIV infection (see p. 337). Its prevalence is also increased in Parkinson's disease.
Management
Seborrhoeic dermatitis usually runs a chronic course with relapses, and treatment is suppressive rather than curative. Topical azole antifungal creams, with short-term use of mild-to moderate-potency steroids according to body site, are usually helpful. Topical calcineurin inhibitors (TCIs) are an effective option but are unlicensed in the UK for this form of dermatitis. A ketoconazole shampoo is useful to treat scalp involvement and as maintenance therapy.

Venous eczema (varicose eczema, stasis, gravitational eczema)
Venous eczema usually affects the elderly and those with varicose veins or a history of venous thrombosis. The inner calf is involved and there are usually coexistent signs of venous hypertension (see pp. 1375–1376), including haemosiderin deposition, lipodermatosclerosis and varicose ulceration. The eczematous changes range from mild erythema and scaling to an acute exudative inflammatory rash. It may be complicated by allergic contact dermatitis to medicated creams or bandages, and patch tests should be used if there is an inadequate response to treatment.

Management
This should include bland emollients, such as a liquid paraffin and white soft paraffin mix, and short-term use of a moderately potent topical steroid. Underlying venous hypertension may also benefit from compression hosiery or surgical intervention (see p. 1376).

Discoid eczema (nummular eczema)
Discoid eczema is characterized by well-demarcated, inflamed scaly patches, sometimes with tiny vesicles. It usually affects the limbs and torso, and is intensely itchy, which helps differentiate it from psoriasis. Lesions may be secondarily infected with *Staph. aureus*. The cause is unknown. Potent topical steroids are usually required to clear individual lesions.

Asteatotic eczema (winter eczema, eczema craquelé)
This form of eczema often affects the elderly in wintertime and can be intensely pruritic. It involves the lower legs, lower back and other areas that have few sebaceous glands. These areas are particularly vulnerable to the drying effects of soap and water. The skin resembles crazy paving with dry scales and inflamed cracks. Frequent use of a bland moisturizer and soap substitute is usually all that is needed.

Hand eczema
Hand eczema is a common problem in adults ([Fig. 31.16](#)) and has different patterns and causes. The causes are broadly classified as:

- **Contact dermatitis/eczema** – due to an external harsh substance (irritant) or allergy-provoking substance (allergen).
- **Endogenous dermatitis/eczema** – where no external factors can be identified. There may also be involvement of the feet.

In reality, it is often a mixed complaint with an underlying endogenous eczema tendency and an additional irritant and/or allergic component.

Mild **irritant hand eczema** in the finger webs and backs of the hands, with dry, sore, chapped skin, is extremely common in cold, dry weather and in those who wash their hands frequently, either at home (especially those who care for young children) or in occupations such as catering, healthcare and hairdressing. Hand eczema can also occur as part of **atopic eczema** and it is sometimes the only site in which this complaint persists beyond the teens. A **hyperkeratotic** form of eczema is characterized by dry, scaly plaques and cracks on the palms and soles, and shares similarities with psoriasis at these sites. In other cases, the features are non-specific and the complaint lasts for months – chronic hand eczema. Localized eczema of the finger pads is called ‘pulpitis’. Even mild and localized hand eczema can be debilitating, as it affects the ability to do manual tasks.

**Patch testing** should be used in anyone with chronic hand eczema to investigate contact allergies, as it is not possible to identify which patients have an allergic contact dermatitis by clinical features alone. A careful history of occupation and hobbies may indicate the need to test with extra allergens: for example, plants in a gardener or garlic in a chef.

---

**Allergic contact and irritant contact eczema**

The most common causes of allergic contact dermatitis are as follows:
• fragrance – e.g. perfume (*Fig. 31.17*), toiletries, soap and moisturizers

![Image](image)

*FIGURE 31.17 Contact eczema secondary to perfume allergy.*

• rubber chemicals – in household and examination gloves and footwear
• metals – in jewellery, buckles and gadgets, including mobile phones
• chemical hair dye – in permanent and semi-permanent colorants
• preservative chemicals – in cosmetics, toiletries, and household and occupational products
• other ingredients in medicated creams, such as lanolin, hydrocortisone and topical antibiotics.

Allergic contact dermatitis is an example of a delayed-type hypersensitivity reaction and the rash does not usually appear until at least 12–24 hours after skin contact. Other areas of the body that are prone to allergic contact dermatitis include the face (due to cosmetics and toiletries) and the lower leg, outer ear and anogenital area (due to medicaments).

**Management** involves managing eczema actively (as for atopic eczema; see pp. 1350–1351), minimizing contact with irritants and avoiding exposure to allergens. This may include wearing protective clothing such as gloves or, in extreme cases, even changing occupation or hobbies. The oral retinoid, alitretinoin, is an effective treatment for severe chronic hand eczema and can clear or significantly improve eczema in over half of all patients over a 6-month course. Like all oral retinoids, it is a teratogen, and a pregnancy prevention programme (see p. 897) must be followed.

**Lichen simplex**

This is a chronic form of eczema in which the skin is thickened and lined (lichenified) in response to repeated rubbing and scratching (*Fig. 31.18*). Common sites are the nape of the neck, outer calves and anogenital area. Topical antipruritics, short-term treatment with a potent topical steroid, and advice about habit reversal are usually helpful. There may be underlying emotional stress: hence the alternative name ‘neurodermatitis’.
Nodular prurigo

This is a very persistent and itchy nodular eruption that is also perpetuated by picking and scratching. It may develop on a background of atopic eczema. Scattered eroded and hyperkeratotic nodules are typically found on the upper trunk and the extensor surfaces of the limbs. Unfortunately, topical corticosteroids, sedating antihistamines and antipruritics usually give temporary relief at best, and the complaint runs a chronic course.

The diagnosis is made by exclusion of other pathologies and may require a skin biopsy. General medical causes of pruritus should be excluded, including HIV infection (see p. 335).

Further reading

Psoriasis

Psoriasis is a common papulo-squamous disorder affecting 2% of the population and is characterized by well-demarcated, red, scaly plaques. The skin becomes inflamed and hyperproliferates at about ten times the normal rate. It affects males and females equally and can involve all races. The age of onset occurs in two peaks. Early onset (age 16–22) is more common and is often associated with a positive family history. Late-onset disease peaks at age
Aetiology

The condition appears to be polygenic but is also dependent on certain environmental triggers. Twin studies show 73% concordance in monozygotic twins compared with 20% in dizygotic pairs. Nine genetic psoriasis susceptibility loci have been identified (PSORS 1–9). Some loci seem shared with other diseases: atopic eczema (1q21, 3q21, 17q25, 20p), rheumatoid arthritis (3q21, 17q24–25) and Crohn's disease (16). The most studied locus, PSORS1 (which accounts for 35–50% of the heritable component), lies in the major histocompatibility (MHC) region of chromosome 6 (human leucocyte antigen (HLA) Cw6).

The exact aetiology is unknown but evidence suggests that psoriasis is a T-lymphocyte-driven disorder that is a response to an unidentified antigen(s). Figure 31.19 shows the trigger factors that activate the antigen-presenting cell (dendritic/Langerhans). This activation results in upregulation of Th1-type T-cell cytokines, such as IFN-γ, IL-1, 2 and 8, growth factors (tumour growth factor alpha (TGF-α) and TNF-α) and adhesion molecules (ICAM-1). The pro-inflammatory cytokine TNF-α is also produced by keratinocytes and this may be involved in both initiation and maintenance of psoriatic lesions. TNF-α-blocking drugs have proved highly effective in treatment (Fig. 31.19). IL-17 and IL-22 are thought to work together to produce clinical psoriasis (see p. 1356).
Pathogenesis

Trigger factors activate the dendritic cell and, in turn, Th1 and Th17 via IL-12 and IL-23. These T cells secrete mediators to activate keratinocytes to produce antimicrobial peptides, cytokines and chemokines. These maintain the inflammation and feedback to activate the dendritic cell.

(a) Site of action of ustekinumab and briakinumab. (b) Site of action of infliximab, etanercept and adalimumab. IFN-γ, interferon-gamma; IL, interleukin; TNF-α, tumour necrosis factor-alpha; UV, ultraviolet.

Pathology

Skin biopsy shows epidermal acanthosis and parakeratosis, reflecting the increase in skin turnover, and the granular layer is often absent. Polymorphonuclear abscesses may be seen in the upper epidermis. The epidermal rete ridges appear elongated and clubbed as they fold down into the dermis. Dermal changes include capillary dilatation surrounded by a mixed neutrophilic and lymphohistiocytic perivascular infiltrate.

Clinical features

Different patterns of psoriasis are recognized and can occur together. Certain drugs can make psoriasis worse: notably, lithium, antimalarials and beta-blockers.

Chronic plaque psoriasis

This is the most common type of psoriasis. It is characterized by pink–red, well-demarcated plaques, with a silver scale seen especially on extensor surfaces of the knees (Fig. 31.20A) and elbows (Fig. 31.20B). The lower back, ears and scalp are also commonly involved. New plaques of psoriasis occur at sites of skin trauma: the so-called ‘Köbner phenomenon’. The lesions can become itchy or sore.
Flexural psoriasis

This tends to occur in later life. It is characterized by well-demarcated, red, glazed plaques with little, if any, scaling affecting the large flexures of the groin, natal cleft and sub-mammary area. The rash is often misdiagnosed as candida intertrigo but the latter usually shows satellite lesions.

Guttate psoriasis

‘Raindrop-like’ psoriasis is a variant most commonly seen in children and young adults (Fig. 31.20C). An explosive eruption of very small circular or oval plaques appears over the trunk about 2 weeks after a streptococcal sore throat.

Erythrodermic and pustular psoriasis

These are the most severe types of psoriasis, reflecting a widespread, intense inflammation of the skin. They can occur together (‘Von Zumbusch’ psoriasis) and may be associated with malaise, pyrexia and circulatory disturbance. This form can be life-threatening. The pustules are not infected but are sterile collections of inflammatory cells. There is also a more localized variant of pustular psoriasis that confines itself to the hands and feet (palmoplantar psoriasis) and is not associated with severe systemic symptoms. This latter type is more common in heavy cigarette smokers.
Associated features

**Nails**

Up to 50% of individuals with psoriasis develop nail changes ([Fig. 31.21](#)) and, rarely, these can precede the onset of skin disease. There are five types of nail change:

- pitting of the nail plate
- distal separation of the nail plate (onycholysis)
- yellow–brown discoloration
- subungual hyperkeratosis
- rarely, a damaged nail matrix and lost nail plate.

![FIGURE 31.21 Psoriasis of the nail. Yellowish brown discoloration and distal nail plate separation (onycholysis).](image)

Topical therapy is usually ineffective, but systemic medication and biologics can improve nail dystrophy.

**Arthritis and enthesitis**

Some 5–10% of individuals develop psoriatic arthritis and most of these will have nail changes (see pp. 685–686). Asymptomatic enthesitis may be an early manifestation.

**Metabolic syndrome**

(See p. 209.) Psoriasis patients have a higher prevalence of cardiometabolic diseases and these may reflect a common underlying chronic, systemic inflammatory state.

**Management**

There is no curative treatment and the choice of therapy will be determined on an individual basis, according to the site and severity of disease, its psychological impact, co-morbidities such as cardiovascular or liver disease, and the individual's wishes ([Box 31.7](#)).
Management of psoriasis

- Education and explanation
- Emollients
- Topical therapies:
  - Mild to moderate steroids
  - Vitamin D analogues
  - Tazarotene
  - Tacrolimus
  - Purified coal tar
  - Salicylic acid
  - Dithranol
- Topical therapy in combination with UVB or PUVA
- Systemic therapy if conventional treatments have failed (monitoring for toxicity is required):
  - Methotrexate
  - Ciclosporin
  - Mycophenolate
  - Hydroxyxarbamide
  - Acitretin
- Cytokine modulators if systemic therapy has failed:
  - Etanercept
  - Adalimumab
  - Infliximab
  - Ustekinumab

PUVA, psoralens + ultraviolet A; UVB, ultraviolet B.

Chronic plaque psoriasis

Localized disease is usually managed with a vitamin D analogue (calcipotriol, calcitriol, tacalcitol) and an emollient to reduce scaling. Moderate to potent corticosteroids may also be used. Other topical therapy includes tazarotene (a retinoid), purified coal tar and dithranol, though these are less popular due to irritancy. Salicylic acid can be a useful adjunct for removing scales. Topical therapy is applied once or twice daily to palpable lesions. Once lesions have flattened, therapy can be discontinued. Vitamin D analogues used in extensive psoriasis may lead to hypercalcaemia if more than 100 g is given per week.

Dithranol stains the skin and clothes and has become less popular, as treatment is messy and time-consuming. Short-contact dithranol therapy is applied in increasing concentrations for 10–30 minutes and then washed off. Topical therapies are sometimes used in combination with
UVB or psoralens + ultraviolet A (PUVA; see p. 1362) phototherapy. The ‘Goeckerman regimen’ consists of tar and UVB; the ‘Ingram regimen’ consists of dithranol and UVB. The latter has similar results to oral PUVA in terms of clearance rates and lengths of remission: approximately 75% in 6 weeks.

**Flexural psoriasis**
This is usually treated with mild steroid and/or tar topical creams. Calcitriol and 0.1% tacrolimus ointment are also useful for treating flexural (facial and genital) psoriasis, where irritation can be a problem.

**Guttate psoriasis**
This is usually treated with topical therapies and/or UVB phototherapy.

**Palmoplantar psoriasis**
Treatment is with very potent topical steroids, coal tar paste or local hand and foot PUVA.

**Systemic therapy**
Agents such as methotrexate, acitretin, mycophenolate, ciclosporin or hydroxycarbamide (hydroxyurea) are used for moderate to severe psoriasis. *Erythrodermic psoriasis* usually requires systemic therapy (but not phototherapy), as well as general supportive measures (see p. 1363).

All systemic treatments must be monitored for toxicity.

**Methotrexate**
Low-dose methotrexate is given once a week for severe psoriasis and psoriatic arthritis. Additional treatment with folic acid may improve gastrointestinal tolerance. Both men and women should avoid conception during, and for 3 months after, therapy. Regular blood tests need to be carried out to monitor for bone marrow suppression and liver damage. Alcohol should be avoided, as this can increase the risk of hepatotoxicity. Non-steroidal anti-inflammatory drugs (NSAIDs) should also be avoided, as these impair renal excretion of methotrexate. Lower doses of methotrexate should be used in the elderly. Long-term use can cause hepatic fibrosis, and serial monitoring of serum pro-collagen III peptide level or elastography (see p. 446) is increasingly being used as a non-invasive alternative to liver biopsy.

**Ciclosporin**
Ciclosporin is a selective immunosuppressant that inhibits IL-2 production by T lymphocytes. It is used for the long-term treatment of severe psoriasis. The main adverse effects are renal damage and hypertension, and so close monitoring of blood pressure and renal function (estimated glomerular filtration rate) is required throughout treatment. Ciclosporin interacts with many drugs (e.g. erythromycin, NSAIDs), which should be avoided.
Cytokine modulators

In the UK, the use of cytokine modulators (‘biologics’; see Fig. 31.19) is restricted to patients who have severe disease (Psoriasis Area Severity Index (PASI) >10, Dermatology Life Quality Index (DLQI) >10) and in whom phototherapy and conventional systemic treatment (ciclosporin, methotrexate, acitretin) have failed or cannot be tolerated due to toxicity.

- **Etanercept, infliximab and adalimumab** (TNF-α blockers). These are highly effective and tend to be used as first-line treatments in the UK, as they have the longest safety data. There is about 7% attrition per year (‘tachyphylaxis’).

- **Ustekinumab** (a human IL-12/23 monoclonal antibody). This is also highly effective but its safety data are limited so it is most commonly used in those patients in whom a TNF-α blocker has failed. There appears to be less tachyphylaxis than with TNF-α blockers and it has a favourable dosage schedule (four injections a year for maintenance therapy). Secukinumab, an IL-17A blocker, is also effective.

Both TNF-α blockers and anti-IL-12/23 drugs are also effective in treating psoriatic arthritis. Apremilast, an oral PDE4 inhibitor, has been shown to be effective in psoriatic arthritis.

New drugs

A number of anti-IL-17 monoclonal antibody drugs have been developed. Brodalumab (an anti-IL-17 receptor), ixekizumab (anti-IL-17) and secukinumab (anti-IL-17A) are all highly effective in psoriasis. Other anti IL-23 drugs are also in development.

All these new injectable biologic drugs are very expensive. Long-term side-effects of these new agents are unknown. The side-effects of TNF-α blockers are discussed on pages 680–682. One biologic drug (efalizumab) has been withdrawn due to the risk of prion brain disease.

Two new but somewhat less effective oral drugs are on the horizon. The small-molecule kinase inhibitors apremilast (a phosphodiesterase-4 blocker) and tofacitinib (a Janus kinase inhibitor) have also shown effectiveness in psoriasis.

Prognosis

Most individuals who develop chronic plaque psoriasis will have the condition for life but 80% will experience remission at times. Disease fluctuates in severity and there are no available tests to predict outcome. Guttate psoriasis resolves spontaneously and in up to one-third of individuals does not recur. However, two-thirds will go on to have recurrent guttate attacks or will progress to chronic plaque psoriasis.

Other papulo-squamous/inflammatory rashes

**Urticaria and angio-oedema**

Urticaria (hives, ‘nettle rash’) is a common skin condition characterized by short-lived, itchy
swellings –‘weals’ – which usually clear within minutes to hours without residual dryness of the skin (Fig. 31.22). Angio-oedema is a similar disorder involving deeper tissues and usually affecting the lips, tongue and eyelids. Urticaria and angioedema may occur together or separately, and have a range of causes.

Aetiology and clinical features

Both conditions are caused by degranulation of dermal mast cells, which leads to the release of a range of inflammatory mediators (including histamine and/or bradykinin) that cause vasodilatation and increased capillary permeability. Mast cell degranulation may be triggered by various different stimuli, including drugs (opiates, aspirin), physical triggers (friction, pressure, sweating), allergens and autoantibodies. Urticaria is classified as acute or chronic (>6 weeks' duration); the latter is divided into spontaneous (or idiopathic) and inducible types (Fig. 31.23).
Acute urticaria may be triggered by infections or can be a manifestation of immediate (type 1) allergy, especially in young children with atopic eczema. Common causes include food (nuts, egg, milk), drugs (penicillin) and natural rubber latex. It may be localized, as in contact urticaria, or part of a more widespread allergic reaction that can progress to anaphylaxis (see pp. 143–144). Measurement of allergen-specific IgE and/or skin prick tests and allergen challenge tests are used to confirm an allergic cause.

Chronic inducible urticaria has a range of causes, including friction (symptomatic dermographism), pressure (delayed pressure urticaria), cold (cold urticaria), sunshine (solar urticaria) and sweating (cholinergic urticaria). Physical tests, such as lightly scratching the skin for dermographism or an ice cube test for cold urticaria, are helpful in demonstrating the nature of the problem.

Chronic spontaneous urticaria (CSU). The underlying cause may be autoimmune; in some individuals, functional autoantibodies against the high-affinity IgE receptor on mast cells and basophils or against IgE antibodies can be identified. There is also an association with autoimmune thyroid disease. Chronic urticaria is seldom caused by food allergy, and so food allergy testing is not routinely indicated.

Angio-oedema without urticaria is classified into hereditary and acquired variants. Hereditary angioedema (HAE) (Box 31.8) is a rare autosomal dominant condition that can cause recurrent severe swellings of the skin, upper airways and intestinal tract. Laryngeal involvement may be life-threatening. Attacks usually start in childhood and can be spontaneous or triggered by minor trauma. Skin swellings are not itchy and usually last for several days. They may be preceded by a non-specific erythema (erythema marginatum). HAE types I and II are caused by mutations in the SERPING1 gene that result in decreased plasma levels of functional C1 esterase inhibitor (C1INH). This allows unchecked activation of the complement cascade. Measurement of serum complement C4 can be used as a screening test. HAE type III is the rarest type and is caused by increased kininogenase activity. All lead to increased levels of bradykinin. HAE usually presents in childhood; severity is highly variable and is influenced by factors such as hormones, trauma, stress and infection.

AD, autosomal dominant; C1-INH, C1 esterase inhibitor; SLE, systemic lupus erythematosus; XLD, X-linked dominant.

**Acquired angioedema** may be idiopathic or associated with lymphoproliferative or autoimmune disorders. Drugs can also cause angioedema, especially angiotensin-converting enzyme (ACE) inhibitors, and black people are more commonly affected. The onset can be delayed by months or years after starting therapy and so a careful drug history is necessary.

### Management

**Acute urticaria** is usually self-resolving. Acute allergic urticaria and angioedema may require emergency treatment with intramuscular adrenaline (epinephrine) and intravenous steroids (see **Box 8.24**). **Chronic urticaria** is managed with non-sedating antihistamines such as loratadine 10 mg daily, which may be ‘up-dosed’ to four times the usual daily dose if needed for symptom control. Montelukast may also be helpful in those with aspirin sensitivity. NSAIDs and opiate analgesics should be avoided, as they can aggravate urticaria. Some physicians advocate low-salicylate, low-histamine and pseudoallergen-free diets for CSU, but these are difficult to follow in the long term. IgE therapy with omalizumab is used for treatment of severe CSU in addition to allergic asthma.

Management of **HAE** used to be limited to prophylaxis with attenuated androgens (stanozolol, danazol), which were poorly tolerated, and treatment of acute attacks was with
fresh frozen plasma. Newer selective therapies include C1-inhibitor – both human plasma-derived and recombinant – a kallikrein inhibitor (ecallantide) and a specific antagonist of bradykinin B2 receptors (icatibant). These newer products can be used for treatment of acute attacks of HAE, and C1-inhibitors can also be used for prophylaxis.

### Urticarial vasculitis

If urticular weals are painful and persist for more than 12–24 hours with residual bruising or skin staining, this may indicate an underlying cutaneous or systemic vasculitis. It requires thorough assessment with a vasculitis screen of blood tests, skin biopsy and urinalysis.

### Pityriasis rosea

Pityriasis rosea is an acute, self-limiting exanthem, which is thought to be caused by a viral infection, possibly human herpesvirus (HHV)-6 and HHV-7. It usually affects older children or young adults and there is an increased incidence in spring and autumn.

The rash is most prominent on the torso and proximal limbs, and consists of circular or oval pink macules with a collarette of fine scale. It is usually preceded by a larger solitary patch – the ‘herald patch’. Lesions tend to run along dermatomal lines of the back, giving a ‘Christmas tree’ pattern. The rash is usually asymptomatic or mildly itchy and resolves within 4–8 weeks. Treatment is not usually required but emollients and a mild steroid cream may be used for pruritus.

### Lichen planus

Lichen planus (LP) is a chronic inflammatory rash of unknown cause. It is speculated that a viral infection triggers an autoimmune attack on keratinocytes by cytotoxic T cells. Conflicting results have been reported for an association with hepatitis viruses (HBV and HCV). Mucosal involvement may be seen in about 50% of patients with cutaneous LP and the oral mucosa may also be affected in isolation. Less commonly, LP may involve the scalp or nails, causing scarring. LP-like (lichenoid) rashes may be triggered by drugs (e.g. beta-blockers, gold, levamisole, ACE inhibitors and antimalarials) and are rarely due to sunlight. A widespread lichenoid eruption is also a feature of chronic graft-versus-host disease.

The rash of LP usually consists of clusters of intensely pruritic, purple–pink, polygonal papules ([Fig. 31.24](#)). It is most common on the flexors of the wrists and the lower legs but can be widespread. Close inspection of the papules shows fine, lacy white streaks (Wickham's striae). Lesions can fuse into plaques, especially on the lower legs, where they can become hyperkeratotic. After resolution, post-inflammatory hyperpigmentation may be prominent, especially in people with darker skin. Atrophic, hypertrophic and annular variants can occur. LP may köbnerize: that is, localize to areas of superficial trauma. Involvement of the scalp causes scarring alopecia, and nail involvement can cause permanent dystrophy with wing-like
scars (pterygion) and loss of the nail plate.

**Mucosal involvement** is common. Changes range from asymptomatic, reticulate, white streaks on the buccal mucosa and lateral tongue to a severe, painful, erosive gingivitis and glossitis. Delayed-type hypersensitivity to metals in amalgam fillings may cause localized LP-like changes on the oral mucosa, which resolve on removal of the filling. The anogenital mucosa may be affected by LP and lesions on the penis are often annular. A rare chronic, severe, erosive form with vulval, vaginal and oral involvement is recognized in women.

Histology of LP usually shows diagnostic features of a dense infiltrate of T lymphocytes along the dermo-epidermal junction, which becomes damaged and ‘saw-toothed’, and degenerate basal keratinocytes (liquefaction degeneration). Apoptotic keratinocytes may also be identified as densely eosinophilic colloid bodies.

Cutaneous LP usually resolves within 1–2 years, though it may relapse at intervals. Hypertrophic and mucosal disease may be more persistent. Malignant change and development of squamous cell carcinoma may rarely complicate chronic ulcerated LP. Skin and mucosal lesions usually show some response to potent or superpotent topical corticosteroids. Topical calcineurin inhibitors (TCIs) may also be of benefit. Widespread skin disease or scalp disease may require tapering courses of oral steroids. Other therapies for recalcitrant disease include PUVA, methotrexate, oral retinoids, azathioprine and thalidomide.

### Granuloma annulare

Granuloma annulare (GA) is seen most commonly in children and young adults. It is usually asymptomatic and characterized by clusters of small flesh-coloured or slightly erythematous papules (with no surface change), which tend to form rings or part of a ring with a dusky centre. They typically affect the dorsal hands and/or feet. Generalized papular and annular
variants also exist. The cause of GA is unknown; several systemic associations have been proposed but not proven, including diabetes mellitus and thyroid disease. Histological features include a granulomatous dermal infiltrate and focal degeneration of collagen (necrobiosis). Localized GA is often self-limiting, resolving within 2 years. Papules may respond to intralesional corticosteroids or cryotherapy. Generalized disease can be persistent and many interventions have been proposed, but there is no clearly effective therapy.

**Lichen sclerosus**

Lichen sclerosus (LS) is a common inflammatory dermatosis that usually affects the genital area. The cause is unknown but may be autoimmune, and preceding infection or trauma and an occluded, moist environment may act as triggers. In females, the usual age of onset is before puberty or after the menopause. Males may develop LS at any age. Lesions are intensely pruritic or sore, and appear as shiny, ivory–white, fissured patches on the vulva, or on the glans penis (ballanitis xerotica obliterans) and distal foreskin or penile shaft. Perianal involvement is common in females, giving a ‘figure-of-eight’ distribution. Telangiectasia may be evident. Early lesions in girls may present with haemorrhagic blisters and these are occasionally mistaken for signs of sexual abuse.

The scarring and atrophy that accompany longstanding LS cause change in the vulval architecture, with loss and fusion of the labia minora and scarring of the clitoral hood. Involvement of the foreskin can cause phimosis, and urethral disease may cause strictures and impaired micturition. Profound sexual dysfunction can result from LS in both men and women. Perianal lesions may fissure and cause constipation. Rarely, LS may involve non-anogenital sites, especially in women, and lesions are typically more hyperkeratotic with plugged follicles. The diagnosis is usually made by the clinical appearance. The dominant feature on histology is condensation ‘hyalinization’ of the dermal collagen.

**Management**

Short-term courses of potent or superpotent topical corticosteroids improve the signs and symptoms of LS. TCIs may also be helpful. The condition may remit spontaneously after several years, especially in children. Male patients may require circumcision if phimosis does not respond to topical therapy. Longstanding anogenital LS is associated with an increased risk of squamous cell carcinoma of the penis and vulva.

**Hidradenitis suppurativa (acne inversa)**

This chronic inflammatory disorder affects the apocrine pilosebaceous follicles of the axillae, the inguinal area and around the breasts. It is characterized by recurrent abscesses, draining sinuses and scarring, and is associated with the metabolic syndrome, obesity and smoking. Patients often struggle with debilitating pain, odour and discharging lesions; there is no definitive treatment. Bacterial biofilms within the occluded follicles may explain the
disappointing results of treatment with acne antibiotics. Other options include acitretin, combined rifampicin and clindamycin, TNF-α and IL-1 inhibitors and laser therapy. Surgery may be required to drain abscesses and to excise the affected areas of skin.

Facial Rashes
Facial rashes often cause diagnostic confusion but a close examination of the clinical signs should help differentiate the underlying cause (Box 31.9). All facial rashes, by virtue of their visibility, can cause significant distress to the patient.

Box 31.9
Causes of facial rashes
- Acne vulgaris
Acne vulgaris

Acne is one of the most common skin complaints and affects over 85% of adolescents. It may persist into adulthood and, in women, a late-onset chronic variant starting in the twenties is increasingly recognized. Acne can have a significant effect on self-esteem and mood, leading to anxiety, depression and an increased risk of suicide. Lesions arise in the pilosebaceous follicle, which becomes blocked due to abnormal keratinization and increased production of sebum. This leads to overgrowth of *Propionibacterium acnes*, which triggers an inflammatory response by activation of Toll-like receptors and induction of pro-inflammatory cytokines *(Fig. 31.25A)*. The hallmark of acne is the comedo or blocked pore. Early microscopic comedones – microcomedones – can be seen in acne-prone skin. Comedones may be obscured in moderate to severe acne where inflammatory lesions predominate. Release of elastase by activated neutrophils causes connective tissue damage and scarring, which has long-lasting psychological sequelae. Post-inflammatory hyperpigmentation is common in dark-skinned patients.
Acne occurs on the face and upper torso, where the sebaceous glands are very dense and affected areas are usually greasy (seborrhoea). Lesions are classified as:

- **non-inflammatory** – open comedones (blackheads) or closed comedones (whiteheads)
- **inflammatory** – papules, pustules (*Fig. 31.25B*), nodules and cysts
- **scars** – raised (hypertrophic) or depressed/pitted (box, rolling and ice-pick).

A number of clinical variants exist:

- **Infantile acne** is occasionally seen in infants and is sometimes cystic. It is thought to be triggered by maternal androgens and resolves spontaneously.
- **Acneiform eruptions** may be caused by systemic steroid therapy, which cause a pustular
folliculitis without comedones, and by epidermal growth factor receptor (EGFR) inhibitors.

- **Oil acne** is an occupational skin complaint caused by prolonged contact with oils or other hydrocarbons, and is common on the legs.

- ‘**Acne conglobata**’ is a severe form of cystic acne with abscesses and interconnecting sinuses.

- **Acne fulminans** is a rare form of severe acne with systemic upset, seen mostly in male adolescents. Deeply inflamed, ulcerated nodules occur in association with fever, weight loss and musculoskeletal pain. Systemic steroids and oral isotretinoin are required.

- **SAPHO syndrome** (synovitis, acne, pustulosis, hyperostosis, osteitis) also features acne, but skin and osteoarticular changes do not often occur simultaneously and it may affect older individuals.

- ‘**Acne excoriée**’ is a chronic form of acne typically affecting women, in which minor lesions are repeatedly picked/excoriated and there is underlying psychological upset.

- ‘**Follicular occlusion triad**’ is a rare disorder most commonly seen in black Africans. It is characterized by the presence of severe nodulocystic acne, dissecting cellulitis of the scalp (see p. 1381) and hidradenitis suppurativa (pp. 1358–1359). This may be caused by a problem of follicular occlusion.

## Management

Acne treatment should include therapy to target the primary pathogenic lesion: the **microcomedo**. The choice of agents broadly depends on the predominant acne lesions, severity and response to earlier treatment (**Box 31.10**).

### Box 31.10

BPO, benzoyl peroxide.

(Adapted from Cunliffe WJ, Gollnick H. *J Am Acad Dermatol* 2003; 49:S1–S37.)
Patients should be told that topical retinoids, azelaic acid, salicylic acid and benzoyl peroxide (BPO) cause dryness and flaking of the skin due to their keratolytic effects. Tetracyclines and erythromycin are licensed for oral use in acne. Treatment may need to be continued for up to 6 months for maximum benefit. They should not be prescribed for non-inflammatory acne and should be used in conjunction with a non-antibiotic topical agent, as this improves effectiveness and reduces bacterial resistance. In females, the **combined oral contraceptive pill** and a formulation containing additional **cyproterone acetate** (a mild antiandrogen) may be of benefit, primarily due to a reduction in sebum excretion. **Oral isotretinoin** is a highly effective treatment for inflammatory acne; it is indicated for severe or unresponsive acne and where there is scarring or psychological upset. It is a potent teratogen, and females of child-bearing potential must use effective contraception and be carefully monitored with monthly pregnancy tests if at risk of pregnancy. All patients should be monitored for mood change but this usually improves as the acne clears. Several forms of high-energy light therapy have recently been advocated for treatment of acne, including blue light, intense pulsed light and photodynamic therapy. Ablative laser therapy and physical treatment, such as dermabrasion, may improve the appearance of scars.

## Rosacea

Rosacea (**Fig. 31.26**) is a common inflammatory facial rash. The onset is usually in mid-adult life and it is more common in women.

![Rosacea. Papules and pustules on background erythema. There are no comedones.](image)

The cause is unknown. Recent attention has turned to abnormalities in the innate immune system, including cathelicidin antimicrobial peptides and the proteases that convert them into pro-angiogenic and pro-inflammatory mediators. The commensal mite *Demodex folliculorum* is speculated to be one of the primary triggers of this abnormal immune response.
Clinical features

The main features are diffuse erythema and inflammatory papules and pustules affecting the convexities of the central face: that is, nose, forehead and cheeks. Flushing and blushing are often the earliest sign and can be triggered by hot drinks, alcohol, sunlight and changes in temperature. As the disease progresses, fixed erythema occurs due to dilated blood vessels (telangiectatic rosacea). This is followed by papules and pustules (papulopustular rosacea) but, unlike in acne, there are no comedones. Ocular involvement can lead to blepharitis, keratitis and conjunctivitis. Later complications include sebaceous gland and soft tissue overgrowth, especially of the nose in men, causing rhinophyma and facial lymphoedema. Prolonged use of topical steroids can exacerbate or trigger rosacea.

Management

Treatment is suppressive rather than curative. Metronidazole or azelaic acid cream or gel may be used for long-term control, with intermittent courses of oral tetracyclines for more resistant inflammatory disease. Sub-antimicrobial doses of doxycycline are effective due to their anti-inflammatory effects. The flushing and erythema do not respond to antibacterial drugs; treatment options include cosmetic concealers, topical brimonidine and vascular laser therapy. Rhinophyma can be debulked surgically or with the CO₂ laser.

Perioral dermatitis

Perioral dermatitis is a distinctive rosacea-like rash that typically affects the area around the mouth in young women. It is characterized by small inflammatory papules and pustules with overlying scaling and often runs along the nasolabial folds. Topical steroids may trigger the complaint in susceptible individuals and are often continued inadvertently as they appear to help temporarily. Treatment is with an oral tetracycline as for rosacea and weaning off topical steroids.

Flushing

Facial flushing in response to emotional stimuli (blushing) is a normal physiological response that can cause embarrassment and may be associated with social phobia. Non-emotional causes should be excluded, such as menopause, drugs, carcinoid syndrome and mastocytosis. Management includes cognitive behavioural therapy, cosmetic camouflage, beta-blockers and clonidine. Selective serotonin reuptake inhibitors may help associated depression and anxiety. Other rarer causes of facial rashes include autoimmune rheumatic diseases and granulomatous infiltrates (see Box 31.9).

Further reading
Photodermatology

The solar spectrum includes visible light and UV radiation, which is divided into short, medium and long wavelengths (UVC, UVB and UVA, respectively; **Box 31.11**). UVB and UVA penetrate the Earth's atmosphere and reach the skin, where they are potentially mutagenic and carcinogenic. They cause premature ageing (photodamage) and skin cancer, but can also suppress cutaneous inflammation. Sunburn is caused by UVB and photosensitive drug rashes are predominantly caused by UVA (**Box 31.11**).

**Photosensitive rashes** arise on sun-exposed sites, such as the face, the ‘V’ of the chest, the ears and the dorsa of the hands and forearms. Shaded areas, such as under the chin, the upper eyelid and between the fingers, are characteristically spared. Porphyria, drug sensitivity and lupus erythematosus should be excluded in all photosensitive patients.

Photosensitive rashes may be divided into photo-exacerbated/provoked rashes and the idiopathic photodermatoses (**Box 31.12**). Examples of this include systemic lupus erythematosus (see pp. 692–695), pellagra (pp. 199–200) and porphyria (pp. 1289–1291). The only common photodermatosis is polymorphic light eruption. Very rarely, eczema and urticaria can be light-induced.

**Box 31.12**

**Differential diagnosis of photosensitive rashes**
Photoexacerbated/provoked rashes

Systemic disease
- Systemic lupus erythematosus (see pp. 692–695)
- Chronic discoid lupus erythematosus (see p. 1366)
- Subacute cutaneous lupus erythematosus (see p. 1367)

Metabolic disease
- Porphyrias (see pp. 1289–1291)
- Pellagra (see pp. 199–200)

Drugs
- Thiazides
- Phenothiazines
- Tetracyclines
- Amiodarone

Plant phototoxins
- Phytophotodermatitis (photosensitivity induced by contact of the skin with certain plants, e.g. celery, hogweed, rue, lime, fig tree)

Skin disease
- Rosacea
- Rarely, atopic eczema, psoriasis, lichen planus (these usually improve in sunlight)

Idiopathic photodermatoses
- Polymorphic light eruption
- Chronic actinic dermatitis
- Solar urticaria

Polymorphic light eruption
Polymorphic light eruption (PLE) is a very common photosensitive rash that affects up to 10–20% of the population in temperate regions. It is most common in young women. In many cases, it is mild and undiagnosed, and simply a nuisance on tropical holidays. Typically, an itchy papular rash develops several hours after sun exposure and is confined to the exposed sites. Vesicles or plaques may occur: hence ‘polymorphic’. These last for several days. A minority of patients are also affected in temperate zones; the rash appears in spring, but may improve during the summer because of acquired UV tolerance (‘skin hardening’). PLE is thought to be an immunologically mediated condition where there is a failure of UV-induced immunosuppression, which allows a delayed-type hypersensitivity response to an as yet unidentified endogenous photoantigen.
Management

Mild cases can be managed by avoiding sun exposure with clothing and sunscreens. Topical steroids are of limited effectiveness, and individuals who are troubled by more severe PLE after intense sun exposure can be given prophylaxis or treatment with a short course of oral prednisolone (e.g. 30 mg daily for 7 days). Resistant cases can be managed with a short course of phototherapy (narrow-band UVB or PUVA) in early spring to induce photo-tolerance. Regular natural sunlight exposure is needed to maintain this effect over the summer season.

Phototherapy and photoprotection

Phototherapy

UVB and UVA have localized immunosuppressive effects in the skin and there is increasing evidence that they can also suppress systemic immunoreactivity: hence their use in the treatment of several inflammatory dermatoses. However, they also cause skin ageing and predispose to skin malignancy especially in fair-skinned individuals. UVB is less carcinogenic than UVA and is the preferred treatment for most dermatoses. Sunbeds are used for tanning and predominantly deliver UVA; they are of limited effectiveness in treating skin disease. If used frequently, there is an increased risk of skin cancer and premature ageing. The following types of phototherapy are used therapeutically:

- broad-band UVB
- narrow-band UVB (311 nm or TL01)
- psoralen and UVA (PUVA)
- high-intensity long wave UVA (UVA-1).

Narrow-band UVB therapy is widely employed in the treatment of eczema and psoriasis, and is usually given three times a week for 6–10 weeks. It has superseded broad-band UVB, as it is more effective. UVA is relatively ineffective alone, and so is used with a psoralen photosensitizer, which may be applied topically or taken orally (PUVA therapy). PUVA is usually given twice a week, and if the psoralen is taken orally, UV-protective glasses must be worn for the day of treatment to protect the retina. The use of PUVA is limited because long-term treatment increases the risk of skin cancer development, especially squamous cell carcinoma.

The maximum recommended lifetime dose is 1000 joules (approximately 200 treatments).

Unaffected regions of skin or high-risk areas like the scrotum can be screened during phototherapy. High-intensity UVA-1 penetrates more deeply into the dermis and can be of benefit in autoimmune rheumatic diseases such as morphea, but it is not widely available.

Photoprotection

Sunscreens protect against UVA and UVB irradiation but they are no substitute for covering the
skin and restricting exposure, especially in young children. They work by absorbing/filtering UV radiation (e.g. benzophenones, cinnamates, salicylates) or reflecting it (zinc/titanium dioxide). New sunscreen chemicals have been developed to give better protection, and the particle size of reflective sunscreens can be reduced (micronized) to improve their cosmetic acceptability. Modern creams are formulated to give broad-spectrum protection against UVA and UVB. The sun protection factor (SPF) is a measure of UVB protection and the degree to which exposure can be prolonged before burning. However, in many cases, sunscreens are not applied in adequate amounts so do not provide the SPF as labelled. UV-absorbing chemicals may occasionally cause allergic contact dermatitis and, in rare instances, photoallergic contact dermatitis (where the sunscreen becomes allergenic with UV exposure).

Sunlight is the main source of vitamin D and individuals who do not have photosensitivity benefit from short-term sun exposure (without burning) to maintain levels, particularly in those with darker skins living in temperate climates; advice about sun protection therefore needs to take into account the individual’s skin type.

Further reading

Erythroderma
Erythroderma (literally, ‘red skin’) is a term applied to inflammatory complaints that cause redness of 90% or more of the body surface.

Aetiology and clinical features
There are a number of causes (Box 31.13), of which underlying skin disease and drugs are the most common. It is more frequently found in males and older people. The skin may feel ‘tight’ and itchy. Systemic symptoms are common and include malaise, fever or chills; there may be generalized lymphadenopathy. Because the normal functions of the skin are disturbed (see below) – that is, there is skin failure – erythroderma may be life-threatening and is regarded as a medical emergency. Longstanding erythroderma may be associated with hair loss, ectropion of the eyelids and nail shedding.
Causes of erythroderma

Common
- Atopic eczema
- Psoriasis
- Drugs (e.g. sulphonamides, gold, sulphonylureas, penicillin, allopurinol, captopril)
- Seborrhoeic eczema
- Idiopathic

Rare
- Chronic actinic dermatitis
- Cutaneous T-cell lymphoma (Sézary syndrome)
- Malignancy (especially leukaemias)
- Pemphigus foliaceus
- Pityriasis rubra pilaris (a hereditary disorder of keratinization)
- HIV infection
- Toxic shock syndrome

Examination should look for features of an underlying dermatosis, such as pustules and nail changes suggestive of psoriasis. A skin biopsy may help with diagnosis, especially in cutaneous lymphoma. Lymph node biopsy and T-cell receptor gene rearrangement studies (seeking evidence of clonal T cell expansion in the skin and blood) are also useful in the diagnosis of lymphoma. In non-malignant disease, enlarged lymph nodes usually show non-specific, reactive (dermatopathic) changes.

Complications

The skin is the largest organ of the body and, given its essential role in regulating body temperature and water loss, it is no surprise that extensive inflammation causes metabolic and haemodynamic problems. These may include:
- high-output cardiac failure from increased blood flow
- hypothermia from heat loss
- pre-acute kidney injury from fluid depletion
- hypoalbuminaemia
- catabolism and increased basal metabolic rate
- ‘capillary leak syndrome’.

Capillary leak syndrome is the most severe complication and has been responsible for a fatal outcome in some cases of psoriasis, although this is extremely rare. It is thought that the
inflamed skin releases large quantities of cytokines that cause generalized vascular leakage. This can lead to cutaneous oedema, hypovolaemic shock and acute respiratory distress syndrome (ARDS) (see pp. 1167–1169).

**Management**

Supportive treatment includes maintaining body temperature (with space blankets and heaters) and close monitoring of vital signs and of fluid and electrolyte balance. Skin swabs should be taken if secondary infection is suspected. All non-essential medication should be stopped. Topical therapy with a bland emollient or mild topical steroid can be initiated until the underlying cause is established, when systemic therapy may be indicated: for example, ciclosporin for psoriasis.

**Cutaneous Signs of Systemic Disease**

Some dermatoses are associated with a variety of underlying systemic diseases. Furthermore, some medical conditions may present with cutaneous features.

**Erythema nodosum**

Erythema nodosum (see also p. 705) has a number of underlying causes (*Box 31.14*). It presents as painful or tender dusky blue–red nodules, commonly over the shins or lower limbs, which fade over 2–3 weeks, leaving a bruised appearance (see *Fig. 31.52*). It is most common in young adults, especially females. It may be associated with arthralgia, malaise and fever. Inflammation occurs in the dermis and the subcutaneous layer (panniculitis).

---

*Box 31.14*

**Causes of erythema nodosum**

- Streptococcal infection
- Drugs (e.g. sulphonamides, oral contraceptive)
- Sarcoidosis
- Idiopathic
- Bacterial gastroenteritides, e.g. *Salmonella, Shigella, Yersinia*
- Fungal infection (histoplasmosis, blastomycosis)
- Tuberculosis
- Leprosy
- Inflammatory bowel disease
- *Chlamydia* infection
Common causes.

Management consists of treatment of the symptoms with NSAIDs (avoid in pregnancy), light compression bandaging and bed rest, as the condition resolves spontaneously. The underlying cause should be treated. In very persistent cases, dapsone (100 mg daily), colchicine (500 µg twice daily) or prednisolone (up to 30 mg daily) can be useful.

Erythema multiforme

Erythema multiforme is a self-limiting, symmetrical rash characterized by target lesions on the distal limbs, palms and soles. These are concentric rings of erythema with a dusky centre, which may occasionally blister. The mucous membranes may be involved, with oro-genital ulceration, erosions and conjunctivitis – so-called ‘erythema multiforme major’ (Fig. 31.27). The most common trigger is herpes simplex virus. Erythema multiforme may occasionally be a recurrent problem, in which case prophylactic aciclovir can be used. Other causes include orf (see p. 1345), Mycoplasma and drugs (sulphonamides, anticonvulsants). In 50% of cases, there is no identifiable cause.

Management is supportive, with analgesia and short-term parenteral fluids if there is dysphagia. The role of systemic steroids in erythema multiforme major remains controversial. The clinical features of ‘erythema multiforme major’ – Stevens–Johnson syndrome – are show in Box 31.15.

Box 31.15

**Pyoderma gangrenosum**

Pyoderma gangrenosum is a condition of unknown aetiology. It presents with painful erythematous nodules or pustules that rapidly evolve into large ulcers *(Fig. 31.28)*. The ulcer often has a purple margin, undermined edge and a purulent surface (‘pyoderma’). Lesions may occasionally be triggered by trauma or surgery, and debridement is contraindicated, as it worsens the condition. Biopsy of the ulcer edge shows an intense neutrophilic infiltrate but the diagnosis is based largely on clinical appearance. Most cases occur in association with:

- inflammatory bowel disease
- rheumatoid arthritis
- haematological malignancy – myeloma, monoclonal gammopathy, leukaemia, lymphoma
- liver disease (e.g. primary biliary cholangitis).

![Pyoderma gangrenosum](image)
Very potent topical steroids or tacrolimus ointment may help mild disease, but high-dose oral steroids are usually needed to halt rapidly progressive ulceration. Systemic immunosuppressants or dapsone may be required for long-term control, and any underlying disease should be treated.

**Endocrine disease**

**Acanthosis nigricans**

Acanthosis nigricans presents as thickened, hyperpigmented, velvet-textured skin around the large flexures ([Fig. 31.29](#)). It can appear warty when advanced. The commonest and mildest form is associated with obesity and insulin resistance (‘pseudo-acanthosis nigricans’, [Fig. 31.29](#)). Late onset and severe disease is usually a paraneoplastic phenomenon caused by underlying malignancy (especially gastrointestinal tumours). Rarely it is associated with hyperandrogenism in females.

![FIGURE 31.29 Acanthosis nigricans in axilla of an obese individual.](image)

**Diabetes mellitus**

Diabetes mellitus (see also p. 1241) can have a number of cutaneous manifestations and complications, including:

- fungal infection (e.g. *Candidiasis*; see p. 295)
- bacterial infections (e.g. recurrent boils; see p. 1342)
• xanthomas
• arterial disease (ulcers, gangrene)
• neuropathic ulcers.

Specific dermatoses of diabetes include:
• necrobiosis lipoidica (a patch of spreading erythema over the shin, which becomes yellowish and atrophic in the centre and may ulcerate; *Fig. 31.30*)

*FIGURE 31.30* Necrobiosis lipoidica on the shin in type 1 diabetes mellitus.

• diffuse granuloma annulare (see p. 1358)
• diabetic dermopathy (red–brown, flat-topped papules)
• diabetic stiff skin (tight, waxy skin over the fingers with limitation of joint movement owing to thickened collagen; also called cheiroarthropathy).

**Thyroid disease**

(See also pp. 1199–1212.) Hypothyroidism may cause dry, firm, gelatinous (myxoedematous) skin with diffuse hair thinning and loss of the outer third of the eyebrows. Hyperthyroidism may be associated with warm, sweaty skin and a diffuse alopecia. Graves' disease is rarely associated with thyroid acropachy (‘clubbing’ with underlying bone changes) and pretibial myxoedema (a red–brown mucinous infiltration of the shins, which can become lumpy and tender).
Cushing syndrome
(See also pp. 1197–1199.) Skin manifestations include hirsutism, a moon face, a buffalo hump, striae, telangiectasia and folliculitis (often called steroid acne; see p. 1342).

Metabolic disease

Hyperlipidaemias

Hyperlipidaemias (see also pp. 1279–1284) can present with xanthomas, which are abnormal collections of lipid in the skin. All people with xanthomas should be investigated for hyperlipidaemia, although the most common type, called xanthelasmas (yellow plaques around the eyes), are usually associated with normal lipids. There are a number of other clinical variants of xanthomas, such as:

• tuberous xanthoma (firm orange–yellow nodules and plaques on extensor surfaces)
• tendon xanthoma (firm subcutaneous swellings attached to tendons)
• plane xanthoma (orange–yellow macules often affecting palmar creases)
• eruptive xanthoma (numerous small, yellowish papules commonly on the buttocks).

Amyloidosis

Macular amyloid is a common, purely cutaneous variant seen in Asians. It is characterized by itchy brown, rippled macules on the upper back.

Systemic amyloid may be associated with reddish-brown papules, nodules or plaques, especially around the eyes, the flexural areas and mucosal surfaces. Distinctive periorbital bruising and macroglossia may also be present.

Porphyria cutanea tarda

Porphyria cutanea tarda (PCT; see p. 1290) is a rare metabolic disorder associated with liver disease; it is usually precipitated by alcohol excess or hepatitis C virus (HCV) infection and 20% of cases have underlying haemochromatosis (see pp. 477–479). Approximately 75% of cases are sporadic and 25% familial. PCT presents with sun-induced blisters, skin fragility, scarring, milia, especially on the dorsal hands, and hypertrichosis.

Management is with repeated venesection to reduce iron load, alcohol avoidance and low-dose chloroquine. Antiviral therapy for HCV may also help the skin, presumably by improving liver function. All people with PCT are at risk of hepatic carcinoma.

Pruritus

The pathophysiology of pruritus (itch) is complex and incompletely understood. It may be
caused by peripheral mechanisms (as in skin disease), central or neuropathic mechanisms (as in multiple sclerosis), neurogenic mechanisms (as in cholestasis/μ-opioid receptor stimulation) or psychogenic mechanisms (e.g. parasitophobia). Evidence suggests that low stimulation of unmyelinated C-fibres in the skin is associated with the sensation of itch (high stimulation produces pain). Histamine, tachykinins (e.g. substance P) and cytokines (e.g. IL-31) may also play a role peripherally in the skin. The major nerve pathways for itch and the influence of the central nervous system are not well characterized but processes that are dependent on μ-opioid receptors can regulate the perception and intensity of itch.

Asteatotic eczema and cholinergic urticaria are common causes of pruritus in which the rash is often missed. The term idiopathic pruritus or ‘senile’ pruritus is often due to skin dryness (xerosis) and is common in the elderly.

Pruritus in the absence of a demonstrable rash can be caused by a number of different medical problems (Box 31.16).

### Box 31.16

**Medical conditions associated with pruritus**

- Iron deficiency anaemia
- Internal malignancy (especially lymphoma)
- Diabetes mellitus
- Chronic kidney disease
- Chronic liver disease (especially primary biliary cholangitis)
- Thyroid disease
- HIV infection
- Polycythaemia vera

Management involves avoidance of soaps and symptomatic measures (as for asteatotic eczema). Phototherapy, low-dose amitriptyline or gabapentin may help intractable cases. Any underlying medical problem should be treated.

### Haematological disease

Both anaemia (especially iron deficiency) and polycythaemia can cause pruritus. It can also be a feature of lymphoproliferative disease, such as lymphoma.

### Liver disease

#### Chronic liver disease
Chronic liver disease may present with jaundice, palmar erythema, spider naevi, white nails, hyperpigmentation and pruritus.

Renal disease

Chronic kidney disease

Chronic kidney disease (CKD; see also pp. 774–789) is commonly associated with intractable pruritus. Pallor, hyperpigmentation and ecchymoses are commonly seen. Rarely, it is associated with non-inflammatory blisters, pseudo-porphyria cutanea tarda and cutaneous calcification. Longstanding renal transplant recipients often suffer with recurrent viral warts and squamous cell carcinomas due to the immunosuppression.

‘Nephrogenic fibrosing dermopathy’ (also known as ‘nephrogenic systemic fibrosis’) is a severe scleroderma-like skin disease found in a subset of patients who have CKD (usually those on dialysis). The disease is rapid in onset (days to weeks) with skin discoloration and thickening, joint contractures, muscle weakness and generalized pain. Widespread tissue fibrosis may ensue, causing severely restricted mobility. The condition is strongly associated with the contrast medium, gadolinium, used in magnetic resonance imaging (MRI) scans, and such contrast agents are best avoided in people with low glomerular filtration rates. There is no accepted treatment but some advocate PUVA and extracorporeal photophoresis. No spontaneous remissions have been recorded. Rapid correction of renal function generally stops the condition progressing.

Calciphylaxis is discussed on page 780.

Autoimmune rheumatic diseases

Dermatomyositis

The rash of dermatomyositis (see also pp. 697–698) is distinctive and often photosensitive. There is facial erythema and a magenta rash with oedema around the eyes. There may be areas of poikiloderma (reticulate pigmentation, atrophy and telangiectasia). Bluish-red nodules or plaques may be present over the knuckles (Gottron's papules; see Fig. 18.37) and extensor surfaces. The nail folds are frequently ragged with dilated capillaries. The diagnosis is made from the clinical appearance, muscle biopsy, electromyography and a serum creatine phosphokinase. Skin biopsy is not diagnostic. MRI scanning is useful to assess myositis. Newer antibody tests are of use in diagnosis and prediction of complications; they include anti-Mi-2 antibodies (highly specific for dermatomyositis), anti-MDA-5 antibody (interstitial lung disease) and anti-TIF1-gamma antibodies (associated malignancy) (see p. 698).

Juvenile dermatomyositis usually starts before the age of 10 and eventually resolves. This variant is associated with cutaneous calcinosis and muscle contractures. The adult form usually occurs after the age of 40. Some cases are associated with malignancy, especially
gynaecological, and this requires thorough investigation. Other cases are linked with autoimmune rheumatic diseases and may share overlapping features with scleroderma and lupus erythematosus.

**Management**

Skin disease may respond to sunscreens and hydroxychloroquine (200 mg twice daily). Myositis usually requires high-dose corticosteroids and immunosuppressant drugs, such as azathioprine or ciclosporin.

**Scleroderma**

The term scleroderma refers to a thickening or hardening of the skin owing to abnormal dermal collagen. It is not a diagnostic entity in itself. Systemic sclerosis and morphea both show sclerodermatous changes but are separate conditions.

*Systemic sclerosis* (often called scleroderma) has cutaneous and systemic features, and is discussed fully on pages 695–697.

*Morphea* (localized cutaneous scleroderma) is confined to the skin and usually presents in children or young adults. It is more common in females and the cause is unknown. Lesions are usually on the trunk and appear as bluish-red plaques, which progress to induration and then central white atrophy (*Fig. 31.31*). A linear variant exists in childhood, which is more severe as it can cause atrophy of underlying deep tissues and thus lead to unequal limb growth or scarring alopecia.

![Morphea. Hyperpigmentation and scarring on the trunk.](image)

Rarely, sclerodermatous skin changes may be seen in Lyme disease (acrodermatitis chronica atrophicans), chronic graft-versus-host disease, polyvinyl chloride disease, eosinophilic myalgia syndrome (due to tryptophan therapy) and bleomycin therapy.

**Management**

Potent topical steroids, oral (or pulsed intravenous) steroids and phototherapy can be used. Treatment needs to be more aggressive if there is deep cutaneous involvement, as scarring is
irreversible once it has occurred. Methotrexate and mycophenolate have also been used.

Lupus erythematosus

Lupus is a chronic autoimmune disease characterized by acute and chronic inflammation in various body tissues (see pp. 692–695). Skin involvement falls into three broad categories:

• chronic discoid lupus erythematosus (CDLE)
• subacute cutaneous lupus erythematosus (SCLE)
• systemic lupus erythematosus (SLE).

The cause is unknown but inherited factors, drugs and UV exposure may be relevant. All forms of lupus erythematosus are more common in women.

Chronic discoid lupus erythematosus

Chronic discoid lupus erythematosus (CDLE) is characterized by erythematous, scaly, atrophic plaques with telangiectasia, especially on the face or other sun-exposed sites (Fig. 31.32). Hypopigmentation is common and follicular plugging may be apparent. Scalp involvement may lead to a scarring alopecia. Oral involvement (erythematous patches or ulceration) occurs in 25% of cases. A minority of patients also suffer with Raynaud's phenomenon or chilblain-like lesions (chilblain lupus). Disease is usually localized to the skin and fewer than 5% of cases will go on to develop systemic disease, but this is more common in children. Serum anti-nuclear factor (ANF) is positive in 30% of cases.

Skin biopsy shows a dense patchy, lymphocytic infiltrate around the dermal appendages. Epidermal basal layer damage, follicular plugging and hyperkeratosis may be present. Direct
immunofluorescence of lesional skin may show IgM and C3 deposition in a granular band at the dermo-epidermal junction (‘lupus band’).

First-line treatment is with sunscreens and potent topical steroids. Unresponsive disease may require antimalarial therapy (hydroxychloroquine 100–200 mg twice daily and mepacrine 100 mg daily). Smoking reduces their effectiveness. Systemic steroids and immunosuppressants may be required for resistant disease or associated arthritis. Thalidomide has been used for recalcitrant CDLE.

The disease is usually chronic, with fluctuations in severity, and eventually undergoes remission in up to 50% of cases after many years.

**Subacute cutaneous lupus erythematosus**

Subacute cutaneous lupus erythematosus (SCLE) is a rare variant that presents with widespread annular, papulosquamous lesions and plaques on the upper torso and upper limbs. Photosensitivity is often a prominent feature. Complications, such as arthralgia and mouth ulceration, are seen but significant organ involvement is rare. ANF and extractable nuclear antibodies (anti-Ro and anti-La) are usually positive (see p. 694).

Treatment is with oral dapsone, antimalarials or systemic immunosuppression (prednisolone and ciclosporin).

**Systemic lupus erythematosus**

The cutaneous manifestations of systemic lupus erythematosus (SLE; see also p. 693) are not usually the presenting complaint, as other organ involvement such as joints or kidneys predominates. The classical ‘butterfly’ rash affects the cheeks, nose and forehead (Fig. 31.33). Palmar erythema, dilated nail-fold capillaries, splinter haemorrhages and digital infarcts of the fingertips may also be seen; livedo reticularis and purpura are occasionally present. Rarely, SLE can be complicated by an atypical erythema multiforme-like rash (‘Rowell syndrome’).
**Treatment** is described on pages 694–695.

**Livedo reticularis**

This is also seen in non-autoimmune rheumatic disorders. It is a disorder of blood vessels. Livedo reticularis is the term used to describe a bluish-red discoloration of the skin in a network or lacy pattern. It occurs on the limbs (especially the legs) and sometimes the trunk. It looks worse in the cold but does not disappear on rewarming (unlike cutis marmorata in babies). The colour change is due to dilatation of capillaries and small venules in the affected areas. When biopsying livedo reticularis, the sample should be taken from the middle of the ‘mesh’ and not through the visibly apparent vessels or the pathology is often missed. If the network/mesh pattern is broken, it is more likely that there will be an underlying secondary cause.

There are many causes of livedo reticularis:

- idiopathic livedo reticularis (young adults and middle-aged females, rarely with leg ulceration)
- systemic disease (rheumatoid arteritis, lupus erythematosus, antiphospholipid syndrome, dermatomyositis, cryoglobulinaemia)
- livedoid vasculopathy (associated with painful leg ulcers, atrophie blanche and venous insufficiency)
- polyarteritis nodosa (cutaneous or systemic; see p. 701)
- Sneddon syndrome (associated with widespread evidence of arterial disease involving cerebral, ocular, coronary and peripheral arteries)
- calciphylaxis (chronic kidney disease)
• cutis marmorata telangiectatica (fixed livedo reticularis in neonates – may associate with abnormal limb growth or skin ulceration)
• post-cosmetic ‘filler’ (hyaluronic acid) injections.

There is no specific treatment for livedo reticularis but any underlying cause that is identified should be treated.

Miscellaneous systemic disorders

**Behçet's disease**

Behçet's disease (see p. 702) is a syndrome characterized by oral ulcers combined with two of the following: eye lesions, genital ulcers or skin lesions.

Cutaneous features include erythema nodosum/panniculitis, acneiform papulopustular lesions, thrombophlebitis or skin pathergy (blistering at the site of needleprick or other skin injuries). The syndrome is probably a vasculitis and many organs can be involved. Whilst systemic disease is usually treated with immunosuppression, skin disease may respond well to oral colchicine or dapsone.

**Sarcoidosis**

Sarcoidosis (see also pp. 1118–1120) is a multisystem granulomatous disorder of unknown aetiology. Cutaneous infiltrates usually present with reddish-brown dermal papules and nodules, especially around the eyelid margins and the rim of the nostrils. Extensive infiltration around the nose is called lupus pernio. Lesions on the body may be polymorphic (papules, nodules and plaques) and accompanied by hypo- or hyperpigmentation, especially in dark skin. Swollen fingers from a dactylitis may also be present. Erythema nodosum (see p. 1363) is sometimes seen in acute sarcoidosis. Although sarcoidosis may be confined to the skin, all patients should be investigated for evidence of systemic disease (see p. 1120).  

*Treatment* of cutaneous lesions includes very potent topical steroids (0.05% clobetasol propionate), intralesional steroids or oral steroids; methotrexate or an antimalarial is also used.

**Neurofibromatosis type 1 (von Recklinghausen's disease)**

Type 1 neurofibromatosis is an autosomal dominant condition with high levels of penetrance. It often presents in childhood with a variety of cutaneous features. Many cases are new mutations in the *NF1* gene. Early signs include café-au-lait spots (brown macules, >5 mm in diameter, and more than five lesions) and axillary freckling. Lisch nodules (hyperpigmented iris hamartomas) may be seen in the eyes by slit-lamp examination. Learning difficulties and skeletal dysplasia occur. Later on, fleshy skin tags and deeper soft tumours (neurofibromas) appear and they can progress to cover the skin completely, causing significant cosmetic
disability. A number of endocrine disorders are rarely associated, including phaeochromocytoma, acromegaly and Addison's disease.

## Tuberous sclerosis

The tuberous sclerosis complex (TSC) is an autosomal dominant condition of variable severity, which may not present until later childhood. It is characterized by a variety of hamartomatous growths. The three cardinal features are:

- mental retardation
- epilepsy
- cutaneous abnormalities

but not all have to be present. In most cases, it is due to a mutation in either the \( TSC1 \) gene (encodes hamartin) or the \( TSC2 \) gene (encodes tuberin). Genetic testing is available but the diagnosis still remains clinical, requiring two major features or one major and two minor features. The **skin signs** include:

- adenoma sebaceum (reddish papules/fibromas around the nose)
- periungual fibroma (nodules arising from the nail bed)
- shagreen patches (firm, flesh-coloured plaques on the trunk)
- ash-leaf hypopigmentation (pale macules best seen with Wood's UV lamp)
- forehead plaque (indurated, flesh-coloured patch)
- café-au-lait patches
- pitting of dental enamel.

Internal hamartomas can arise in the heart, lung, kidney, retina and central nervous system. Parents of a suspected case should be examined (under UV light), as they may have a ‘forme fruste’ of the condition, which can manifest just as hypopigmented patches. This and gonadal mosaicism can have genetic implications for future offspring. A large contiguous gene defect may involve \( TSC2 \) and \( PKD1 \) genes, causing tuberous sclerosis and polycystic kidney disease together in the same patient. A recent major advance in treatment has been the use of mTOR inhibitor drugs, such as rapamycin. This has useful effects against various hamartomas, including skin angiofibromas, cardiac rhabdomyomas and renal angiomyolipomas.

## Systemic malignant disease

Certain rashes may be a non-metastatic manifestation of an underlying malignancy: paraneoplastic dermatoses (*Box 31.17*). Rarely, internal malignancies can metastasize to the skin, where they usually present as papules or nodules that may ulcerate.

**Bullous Disease**
There are many causes of skin blisters; the most common are infection (herpes simplex virus, chickenpox, impetigo, tinea pedis, cellulitis), insect bites – especially on the lower legs – and trauma (burns and friction). Blistering may also be a feature of eczema, especially on the hands and feet (‘pompholyx’).

More rarely, blistering is due to skin fragility secondary to a genetically determined abnormality in the structural proteins of the skin (mechanobullous diseases) or an autoimmune disease targeting antigens in keratinocytes or the basement membrane zone of the dermo-epidermal junction (immunobullous). The level of the skin where fragility and blistering occur varies according to disease and will influence the clinical presentation and prognosis. The level can be identified by light and electron microscopy and by immunofluorescence (IMF) studies (Fig. 31.34). Direct immunofluorescence investigates the presence of antibody (with or without complement) deposition in affected (perilesional) skin; indirect immunofluorescence identifies the presence of circulating skin autoantibodies.

## Immunobullous disease

### Pemphigus vulgaris and pemphigus foliaceus

**Pemphigus vulgaris** is a rare and potentially life-threatening blistering disease. It is more common in Ashkenazi Jews and people from the Indian subcontinent. It may affect all ages but usually starts in mid-adult life. Pathogenic IgG4 antibodies against desmosomal proteins (desmoglein 1 and 3) cause loss of keratinocyte adhesion in the skin and mucous membranes, leading to superficial blisters (intraepidermal), erosions and oral ulceration. The cause of pemphigus is unknown but viral triggers have been speculated.
Pemphigus foliaceus is a rarer variant of pemphigus, in which the target antigen is desmoglein 1. This antigen is not expressed in the oral mucosa, which is therefore unaffected. Histology of pemphigus vulgaris shows intraepidermal cleavage above the basal cell layer with separation of individual keratinocytes (acantholysis). The split occurs higher in the epidermis in pemphigus foliaceus where there is greater target antigen expression.

An endemic form of pemphigus foliaceus occurs in the Limão Verde area of Brazil and is thought to be triggered by an infectious agent carried by the black fly and other biting insects. A pemphigus foliaceus-like rash can also be induced by drugs (e.g. captopril, penicillamine).

Direct immunofluorescence of perilesional skin in pemphigus demonstrates intercellular IgG deposition. Circulating anti-epidermal antibodies can also be detected and their titre correlates with disease activity.

### Clinical features

Mucosal involvement (especially oral ulceration) is common and is the presenting sign in up to 50% of patients with pemphigus vulgaris. Development of non-itchy, flaccid blisters may follow, especially on the torso. Large areas may be involved, but as blisters are fragile (intraepidermal), they rupture easily, leaving erythematous, weeping erosions. Blisters can be extended with gentle lateral pressure (Nikolsky's sign). Flexural lesions often have a vegetative appearance. In pemphigus foliaceus, blisters are rarely seen and the rash has a crusted appearance, often affecting the seborrhoeic areas (scalp, face and upper chest) before becoming more widespread.

### Management

High-dose systemic corticosteroids are usually effective in controlling pemphigus, but due to their long-term adverse effects, immunosuppressive drugs are usually introduced for a steroid-sparing effect. These include azathioprine, cyclophosphamide, methotrexate, ciclosporin, mycophenolate mofetil, dapsone and, more recently, rituximab (an anti-CD20 monoclonal antibody). High-dose intravenous immunoglobulin may also be of benefit in severe, unresponsive pemphigus vulgaris.

### Paraneoplastic pemphigus

This is a rare pemphigus-like disorder that occurs in association with neoplasms, especially lymphoproliferative malignancy. Features include severe oral erosions and the rash may show additional changes resembling pemphigoid, erythema multiforme and lichen planus. Autoantibodies can be demonstrated against a range of desmosomal proteins and a broad-range protease inhibitor. Therapy includes immunosuppressants and treatment of the underlying malignancy.
Bullous pemphigoid

Bullous pemphigoid is more common than pemphigus and usually affects those over the age of 60 years. Autoantibodies against a 230 kDa or 180 kDa hemidesmosomal protein (‘bullous pemphigoid antigen 1’ and ‘type XVII collagen’) play a pathogenic role and cause a split through the basement membrane zone. This can be demonstrated on routine histology as a sub-epidermal split, and direct IMF shows deposition of IgG and complement at the dermo-epidermal junction.

Clinical features

Large, tense, serous or haemorrhagic blisters (bullae) appear anywhere on the body, especially the limbs and torso (Fig. 31.35). The underlying skin is usually inflamed; early lesions may resemble urticaria but persist for days or weeks. Pemphigoid can be very itchy. Mucosal ulceration is uncommon except in a rare variant of pemphigoid – mucous membrane pemphigoid (formerly called cicatricial pemphigoid) – in which erosions and ulceration of the mucosal surfaces lead to scarring. Ocular involvement in mucous membrane pemphigoid can cause fusion of the eyelids, corneal damage and visual loss. Pemphigoid gestationis is rarely seen in pregnancy (p. 1309).
Management

Oral corticosteroids in moderate to high dose are used initially for disease control, with introduction of a steroid-sparing agent such as azathioprine or mycophenolate mofetil for long-term disease control. This requires monitoring, as the elderly are at increased risk of the adverse effects of steroids and immunosuppressant agents, and these drugs contribute to the increased mortality associated with pemphigoid. In mild, localized pemphigoid, use of a very potent topical steroid and minocycline may provide adequate disease control. Treatment can sometimes be withdrawn within a few years but relapses occur.

Dermatitis herpetiformis

Dermatitis herpetiformis is a rare blistering disorder associated with gluten-sensitive
enteropathy (coeliac disease; see p. 398). Dermatitis herpetiformis and coeliac disease are associated with other organ-specific autoimmune disorders.

Skin biopsy shows a sub-epidermal blister with neutrophil microabscesses in the dermal papillae. Direct immunofluorescent studies of uninvolved skin show IgA deposits in the dermal papillae and patchy granular IgA along the basement membrane. The small bowel mucosa shows a partial villous atrophy in most cases but a total villous atrophy in a small percentage.

Clinical features

Dermatitis herpetiformis is more common in males; it can present at any age but is most likely to appear for the first time in young adult life. It presents with small, intensely itchy blisters and papules on the elbows, extensor forearms, scalp and buttocks. Intact blisters may not be evident because their roofs are removed by scratching, leaving crusted erosions.

Management

Patients should avoid all dietary forms of gluten (see p. 397). Treatment with dapsone or sulphonamides usually gives rapid relief from itch and blistering. The dose can be titrated according to symptoms. If a strict gluten-free diet is followed, oral medication can usually be withdrawn after 2 years.

Dapsone usually causes mild dose-related haemolysis, which is well tolerated except in those with cardiorespiratory disease. Screening for glucose-6-phosphate dihydrogenase deficiency is performed to identify individuals who are at risk of severe haemolysis. Other rare adverse effects of dapsone include hepatitis, which may be associated with a hypersensitivity syndrome including rash and fever (see p. 1384), and peripheral neuropathy. Treatment requires regular monitoring of the full blood count and liver function tests.

Linear IgA disease (chronic bullous dermatosis of childhood)

Linear IgA disease is a rare sub-epidermal blistering disorder of adults and children. Pathogenic IgA autoantibodies bind to several basement membrane proteins, including type XVII collagen and laminin-332 (see Fig. 31.34). The cause is unknown but disease may be induced by drugs, especially vancomycin.

Clinical features

Linear IgA disease characteristically presents with circular clusters of blisters, described as a ‘string of jewels’ (Fig. 31.36). The oral, vulval and ocular mucosa may be involved and can be scarred. Direct IMF of skin shows linear IgA deposition along the dermo-epidermal junction.
Management

There is usually a good response to dapsone or sulphonamides, with disease resolution after several years.

Mechanobullous disease (epidermolysis bullosa)

This rare group of genodermatoses are disorders caused by defective or absent structural skin proteins, leading to ‘skin fragility’. This causes trauma-induced blisters and erosions that often appear at or shortly after birth. The degree of blistering varies considerably between diseases, ranging from mild friction blisters to severe extensive skin loss, with life-threatening complications. There are three broad groups of disorders:

- **Epidermolysis bulosa simplex** is characterized by ‘superficial’ localized blistering of the hands and feet, especially in hot weather. Scarring is absent and the nails and teeth are normal. It is inherited as an autosomal dominant trait and caused by abnormal synthesis of cytoskeleton proteins within the basal layer of the epidermis, e.g. keratins 5 and 14.

- **Epidermolysis bulosa dystrophica** is characterized by deeper blistering within the basement membrane and scarring. The underlying abnormalities are mutations in the \(\text{COL-7A1}\) gene, which cause a reduction or absence of collagen VII in the anchoring fibrils. Nails and mucosae, including the larynx, may be involved. The autosomal dominant form usually manifests as mild disease, but the autosomal recessive form usually causes widespread, painful erosions that heal with scarring, leading to fusion of digits, joint contractures and dysphagia. Life expectancy is significantly reduced and this is usually due to an associated high risk of developing multiple aggressive squamous cell carcinomas within areas of chronically inflamed skin. There is no curative therapy at present and management is supportive.

- **Junctional epidermolysis bullosa** is the most severe form of epidermolysis bullosa and is characterized by a split in the lamina lucida of the basement membranes due to mutations in various proteins (laminin-332, \(\alpha_6\beta_4\) integrin, type XVII collagen). It presents at birth with widespread blistering and areas of absent skin. Erosions of the central face and hoarseness from laryngeal involvement are common. Nail and teeth abnormalities are also frequently present. Both a lethal and a rarer non-lethal form of junctional epidermolysis bullosa exist.
and they show an autosomal recessive inheritance. The lethal form causes death in infancy or early childhood.

### Investigations and management

Investigation and treatment of epidermolysis bullosa should be carried out in a specialist centre. The precise diagnosis depends on ultrastructural analysis of the skin and immunohistochemistry, which can be further confirmed with genetic testing. This enables a more accurate prognosis and genetic counselling of parents. Prenatal diagnosis and pre-implantation diagnosis are available for the more severe forms of epidermolysis bullosa. Gene therapy and bone marrow transplantation are two new approaches that are currently undergoing clinical trials.

### Further reading

### Skin Tumours

#### Benign cutaneous tumours

##### Melanocytic naevi (moles)

Moles are benign proliferations of overgrowth of melanocytes and are common in fair-skinned people. Congenital melanocytic naevi are present at birth. Acquired naevi appear in childhood, adolescence and early adult life, increasing in size and number. Benign naevi usually have even pigmentation and regular borders. They start as flat brown macules with proliferation of melanocytes at the dermo-epidermal junction (junctional naevi). With later downward growth of melanocytes into the dermis (compound naevi), the mole becomes raised and palpable, eventually maturing into an intradermal naevus with loss of pigment.

*Blue naevus* is an acquired asymptomatic blue–grey mole caused by a deeper proliferation of melanocytes in the mid-dermis.

##### Basal cell papilloma (seborrhoeic keratosis/wart)

This is an extremely common, harmless growth that affects older adults and is caused by
overgrowth of the basal keratinocytes. Lesions range from flesh-coloured to very dark brown, and have a greasy ‘stuck-on’ appearance (*Fig. 31.37*). The surface is rough and warty and may contain tiny keratin cysts. They can be removed under local anaesthetic with curettage or treated with cryotherapy or electrodesiccation.

*FIGURE 31.37* Seborrhoeic warts (basal cell papillomas).

---

**Dermatofibroma (histiocytoma)**

Dermatofibromas are pink–beige, firm dermal nodules, which may be surrounded by a peripheral ring of hyperpigmentation. They are often found on the leg and are more common in females. There is sometimes a history of trauma or an insect bite. The lesion consists of histiocytes, blood vessels and varying degrees of fibrosis. Excision is not needed unless lesions are symptomatic or there is diagnostic uncertainty.

**Epidermoid cyst (‘sebaceous cyst’)**

Epidermoid cysts are cystic swellings derived from an occluded follicle. They have a central punctum and contain ‘cheesy’ keratinous matter. Cysts may enlarge and can become secondarily infected and inflamed.

**Pilar cyst (trichilemmal cyst)**

Pilar cysts are smooth cysts without a punctum, usually found on the scalp. They may be multiple and familial.

**Pyogenic granuloma (granuloma telangiectaticum)**

Pyogenic granulomas are benign vascular proliferations that present as rapidly growing, friable red nodules. They may follow minor trauma and often occur on the face or fingers.
Excision is advisable and lesions should be sent for histology to exclude amelanotic malignant melanoma.

**Cherry angioma (Campbell de Morgan spots)**

Cherry angiomas are benign angiokeratomas that appear as tiny, pinpoint, red papules, especially on the trunk, and increase with age. No treatment is required.

**Dysplastic/pre-malignant cutaneous lesions**

**Solar keratoses (actinic keratoses)**

These are common on the sun-exposed areas of fair-skinned individuals in later life, especially bald scalps. They appear as rough, scaly, erythematous papules or patches and the surrounding skin usually shows signs of chronic sun damage (*Fig. 31.38*), with wrinkles and solar lentigines. A small minority (<1%) of lesions may undergo malignant transformation into squamous cell carcinoma after many years. Lesion-based treatments include cryotherapy and curettage. Field treatments, aimed at removing early and subclinical lesions in a larger area, include topical 5-fluorouracil cream, imiquimod cream, diclofenac gel and ingenol mebutate gel. Topical photodynamic therapy (PDT) using aminolaevulinic acid or its methyl ester is another option, but is painful and requires special expertise.

![Solar keratoses with background actinic damage.](image)

**Bowen's disease**

This is an indolent form of intraepidermal carcinoma-in-situ, which rarely progresses to invasive squamous cell carcinoma. It typically affects the lower legs in fair-skinned women or the torso in men, and is thought to be caused by chronic UV exposure. Lesions appear as a
slowly enlarging, well-demarcated, scaly red patch or plaque resembling psoriasis but lacking thick silvery scale. A variant of Bowen's disease can affect the mucosal sites of the genital area and is referred to as vulval-, penile- or anal-intraepithelial neoplasia (Fig. 31.39). This presents with non-specific erythematous patches (‘erythroplasia’) or warty areas. There is a strong link with oncogenic infection, and genital Bowen's disease probably has a greater malignant potential than non-mucosal disease. It is more common in immunosuppressed individuals, including those with HIV. The anal form is increasingly reported in HIV-positive patients (as, indeed, is anal carcinoma) and extension into the rectum may occur. Treatment is with topical 5-fluorouracil, 5% imiquimod cream, cryotherapy, curettage, topical photodynamic therapy or a tissue-destructive laser.

**FIGURE 31.39** Erythroplasia of glans penis (penile intraepithelial neoplasia).

---

**Keratoacanthoma**

Keratoacanthomas are rapidly growing epidermal tumours that develop central necrosis and ulceration (Fig. 31.40). They occur on sun-exposed skin in later life and often reach 2–3 cm in diameter. Although they resolve spontaneously after several months, they are usually excised to exclude a squamous cell carcinoma (which they can closely resemble.)
Familial atypical multiple mole melanoma (FAMMM)

This is often familial. A large number of melanocytic naevi begin to appear in childhood, even on unexposed sites. Individual lesions may be large with irregular pigmentation and border; histologically, they may show cytological and architectural atypia but no frank malignant change. Individuals with this condition have an increased risk of developing malignant melanoma, pancreatic and other malignancies. They should have their moles photographed and be regularly reviewed. Suspicious lesions should be excised.

Giant congenital melanocytic naevi

These are very large moles present at birth. Very large lesions (>20 cm across) show an increased risk of developing malignant melanoma (up to 5%). Excision may be considered but is rarely possible without multiple operations and marked disfigurement, so regular monitoring is advised. There have been a number of reports showing that a few of these lesions improve spontaneously and partially resolve during childhood.

Lentigo maligna

This is a slow-growing macular area of pigmentation seen in elderly people, commonly on the face. The border and pigmentation are often irregular. Some people regard this lesion as a melanoma-in-situ. There is an increased risk of developing invasive malignant melanoma. Treatment is by excision if possible but 5% imiquimod cream is currently being tried in the very large lesions where surgery would be disfiguring.

Malignant cutaneous tumours
Basal cell carcinoma (‘rodent ulcer’)  

Basal cell carcinomas (BCCs) are the most common malignant skin tumour and are increasingly prevalent in ageing populations. The exact aetiology of BCCs is unknown, but it is thought that they arise from pluripotential cells in the basal epidermis or follicular structures. Mutations in PTCH1, the human homolog of the ‘Patched’ gene that regulates the Hedgehog intracellular signalling pathway (see p. 98), have been detected in sporadic BCCs and Gorlin syndrome (hereditary BCC syndrome). BCCs typically appear as a slowly enlarging, shiny nodule on the head and neck area, which bleeds following minor trauma and does not heal (nodulocystic BCC). The border of ulcerated lesions is raised with a pearly appearance (Fig. 31.41) and overlying telangiectasia. Pigmented, superficial and morpheic (scar-like) variants exist. BCCs can cause significant morbidity by eroding into adjacent tissues but have minimal metastatic potential.

![Ulcerating basal cell carcinoma.](image)

**Management**

In most cases, the treatment of choice is a wide excision with histology to ensure clear and adequate tumour margins. Mohs micrographic surgery is preferred for morpheic BCCs and lesions involving the nasal creases, as these are more likely to recur. Superficial BCCs can be managed with non-surgical treatment, including cryotherapy, photodynamic therapy and topical imiquimod. Radiotherapy remains an option in those who are unable to tolerate surgery. Vismodegib is a new oral therapy for advanced/inoperable BCC that inhibits the Hedgehog signalling pathway by binding to Smoothened transmembrane protein, thereby normalizing basal keratinocyte proliferation. The majority of tumours respond (60%) and a small number
may actually clear.

**Squamous cell carcinoma**

Squamous cell carcinoma (SCC) is a more aggressive tumour than BCC and has a higher metastatic potential. There is a clearer correlation with chronic UV damage than for BCC and sun protection measures reduces its incidence. SCC can arise in pre-existing solar keratoses or Bowen's disease and can also complicate areas of chronic inflammation, as in lupus vulgaris. Rarely, multiple tumours may arise due to arsenic ingestion in early life. Multiple tumours also occur in people who have had prolonged periods of immunosuppression, such as renal transplant patients, where certain HPV subtypes may be involved in malignant transformation.

Clinically, the lesions are often keratotic, rather ill-defined nodules that may ulcerate (Fig. 31.42). They can grow very rapidly. They are most common on sun-exposed sites in later life. Ulcerated lesions on the lower lip or ear are often more aggressive. Examination of regional lymph nodes is essential.

![Squamous cell carcinoma](image)

**FIGURE 31.42** Squamous cell carcinoma.

**Management**

Treatment is complete surgical excision with a minimal margin of 5 mm. Radiotherapy is also used.

**Malignant melanoma**
Malignant melanoma is the most serious form of skin cancer, as metastasis can occur early; it causes a number of deaths, even in young people. The increasing incidence in recent years is thought to be due to excessive exposure to sunlight, especially intermittent intense exposure and sunburn in childhood. Other risk factors include pale skin, multiple melanocytic naevi (>50), sun sensitivity, immunosuppression, atypical mole syndrome, giant congenital melanocytic naevi, lentigo maligna and a positive family history of malignant melanoma. Malignant melanoma is more common in later life but many young adults are also affected. A number of oncogenes and tumour suppressor proteins have been implicated in the pathogenesis of melanoma. Some 60% of human melanomas have an activating mutation (V600E) in the serine protein kinase B-RAF, which has now become a target for ‘personalized’ therapy (see p. 1374).

**Diagnosis** of melanoma is not always easy but the clinical signs listed in **Box 31.18** help distinguish malignant from benign moles. Examination with a dermatoscope (a hand-held polarized light source with magnification) can aid clinical diagnosis.

### Box 31.18

**Clinical criteria for the diagnosis of malignant melanoma**

**ABCDE criteria (USA)**
- Asymmetry of mole
- Border irregularity
- Colour variegation
- Diameter >6 mm
- Elevation

**The Glasgow seven-point checklist**

**Major criteria**
- Change in size
- Change in shape
- Change in colour

**Minor criteria**
- Diameter >6 mm
- Inflammation
- Oozing or bleeding
- Mild itch or altered sensation

Four clinical types exist:
• **Lentigo maligna melanoma** is a patch of lentigo maligna that develops a papule or nodule, signalling invasive tumour.

• **Superficial spreading malignant melanoma** is a large, flat, irregularly pigmented lesion that grows laterally before vertical invasion develops.

• **Nodular malignant melanoma** ([Fig. 31.43](#)) is the most aggressive type. It presents as a rapidly growing pigmented nodule, which bleeds or ulcerates. Rarely, it is amelanotic (non-pigmented) and can mimic pyogenic granuloma.

![FIGURE 31.43 Nodular malignant melanoma.](#)

• **Acral lentiginous malignant melanomas** arise as pigmented lesions on the palm or sole or under the nail, and usually present late. They may not be related to sun exposure.

### Management

In the UK, all people with melanoma >1 mm thick should be referred to their regional multidisciplinary team for expert management. Surgery is the only curative treatment: urgent wide excision with a 1 cm margin for thin melanomas (<1 mm), increasing to a 3 cm margin for thicker melanomas (>2 mm). Histological analysis will determine the depth of invasion (‘Clark’s level’) and the thickness of the tumour (‘Breslow thickness’). People with thick melanomas are staged according to the **American Joint Committee on Cancer (AJCC) 2009 criteria** (tumour, nodes, metastases – TNM), which help predict prognosis and 5-year survival rates. Sentinel node biopsy for people with thicker lesions remains under assessment as a tool for predicting prognosis, determining therapy (e.g. lymph node dissection) and improving survival.

**Treatment** for metastatic disease includes removal of regional lymph nodes, isolated limb perfusion, radiotherapy, immunotherapy and chemotherapy. Until recently, none of these altered the disease outcome. However, a variety of new treatments have been developed over the last 5 years, which are now beginning to improve survival. The first was the selective mitogen-
activated protein (MAP) kinase inhibitor, BRAF inhibitors (vemurafenib) and MEK inhibitors (trametinib). These drugs proved better than conventional chemotherapy, but early resistance and toxicity were limitations. The second major advance is the development of immune checkpoint-blocking agents, including CTLA4 antibody (ipilimumab) and programmed death 1 protein antibody (PD-1 antibody – pembrolizumab, nivolumab).

Results from combination treatments with ipilimumab and nivolumab have shown good results with acceptable toxicity.

Primary cutaneous T-cell lymphoma (mycosis fungoides)

Mycosis fungoides is a rare lymphoproliferative disease that usually follows an indolent course. It presents with pruritic, scaly patches, which typically start on the buttocks and can resemble eczema or psoriasis; asymmetry and atrophy are useful clues (Fig. 31.44). Skin biopsy shows invasion of the epidermis by atypical T lymphocytes (exocytosis), and T-cell receptor gene rearrangement studies show that the infiltrate is clonal.

Occasionally, patches evolve into nodules or tumours, which may metastasize to lymph nodes and internal organs. Sézary syndrome (see p. 625) is a rare erythrodermic variant of cutaneous T-cell lymphoma with peripheral lymphadenopathy and peripheral blood involvement; it is seen mostly in elderly men. Mycosis fungoides and Sézary syndrome usually run chronic relapsing courses. Treatment choices depend on disease stage and extent. Patch and plaque-stage mycosis fungoides usually responds to potent topical corticosteroids, topical
nitrogen mustard or low-dose PUVA. Radiotherapy and systemic therapy are used for aggressive/recalcitrant early-stage disease and advanced-stage disease; options include IFN-α, oral retinoids (acitretin) and bexarotene (an agonist of the retinoid x receptor), histone deacetylase inhibitors and chemotherapy drugs. However, evidence of their effectiveness is lacking.

Kaposi's sarcoma

This is a tumour of vascular and lymphatic endothelium that presents as purplish nodules and plaques. There are three types:

• The ‘classic’ or ‘sporadic’ form (as described by Kaposi) occurs in elderly males, especially Jewish people from Eastern Europe. It presents as slow-growing, purple tumours in the foot and lower leg, which rarely cause any significant problem.

• The ‘endemic’ form occurs in males from Central Africa and shows more widespread cutaneous involvement, as well as lymph node (or occasionally systemic) involvement. Oedema is a prominent feature.

• The immunosuppression-related form is more severe and is most common in HIV-positive men who have sex with men. Lesions are widespread and often affect the skin, bowel, oral cavity and lungs.

All three types have a strong association with human herpesvirus-8 (HHV-8) but other factors must be involved, as HHV-8 seroprevalence is up to 10% in the USA and 50% in some African countries. Anti-retroviral therapy (ART; see pp. 341–346) has significantly reduced the incidence of Kaposi’s sarcoma in HIV infection, although the prevalence has started to increase again over the last few years for as yet unexplained reasons.

Management

Treatment of advanced Kaposi's sarcoma is with radiotherapy, immunotherapy or chemotherapy.

Disorders of Blood Vessels and Lymphatics

Leg ulcers

Leg ulcers are common and can have many causes (Box 31.19). Venous ulcers are the most common type in developed countries.

Box 31.19

Causes of leg ulceration

• Venous hypertension
• Arterial disease (e.g. atherosclerosis)
• Neuropathic (e.g. diabetes, leprosy)
• Neoplastic (e.g. squamous or basal cell carcinoma)
• Vasculitis (e.g. rheumatoid arthritis, systemic lupus erythematosus, pyoderma gangrenosum)
• Infection (e.g. ecthyma, tuberculosis, deep mycoses, Buruli ulcer, syphilis, yaws)
• Haematological (e.g. sickle cell disease, spherocytosis)
• Drug (e.g. hydroxycarbamide (hydroxyurea))
• Other (e.g. necrobiosis lipoidica, trauma, artefact)

Venous ulcers

Venous ulcers are the result of sustained venous hypertension in the superficial veins, owing to incompetent valves in the deep or perforating veins or to previous deep vein thrombosis. The increased pressure causes extravasation of fibrinogen through the capillary walls, giving rise to perivascular fibrin deposition, which leads to poor oxygenation of the surrounding skin.

Venous ulcers are common in later life and constitute a significant drain on healthcare budgets, as they are often chronic and recurrent; they affect 1% of the population over the age of 70 years. They are most commonly found on the lower leg in a triangle above the ankles.
and may be associated with:

- oedema of the lower legs
- venous eczema (see p. 1352)
- brown pigmentation from haemosiderin
- varicose veins
- lipodermatosclerosis (the combination of induration, reddish-brown pigmentation and inflammation) – a fibrosing panniculitis of the subcutaneous tissue
- scarring white atrophy with telangiectasia (atrophie blanche).

**Management** is with high-compression bandaging (e.g. four-layer bandaging) and leg elevation to reduce venous hypertension. Similar healing results can be obtained with a two-layer support hosiery technique, although more dressing changes are needed. Doppler studies should be done before compression to exclude significant arterial disease. This treatment can be delivered effectively in the community by appropriately trained nurses. Ulcer dressings are used to keep the ulcer moist and free of slough and exudates. Up to 80% of ulcers can be healed within 6 months. Slower healing rates occur in patients who have decreased mobility and in those with ulcers that are very large, present for longer than 6 months or bilateral. Diuretics are sometimes helpful to reduce the oedema. Antibiotics are necessary only for overt bacterial infection.

Venous leg ulcers can be painful so adequate analgesia should be given, including opiates if required. Split-thickness skin grafting is used in resistant cases. Support stockings (individually fitted) should be worn for life after healing, as this lessens recurrence.

Underlying venous disease is best investigated with duplex ultrasound or plethysmography. Therapeutic ultrasound is now proven not to help ulcer healing. Surgery for purely superficial venous disease does not assist ulcer healing but it is proven to help prevent ulcer recurrence (ESCHAR study).
Arterial ulcers

Arterial ulcers present as punched-out, painful ulcers higher up the leg or on the feet. There may be a history of claudication, hypertension, angina or smoking. Clinically, the leg is cold and pale. Absent peripheral pulses, arterial bruits and loss of hair may be present. Doppler ultrasound studies will confirm arterial disease.

Management depends on keeping the ulcer clean and covered, adequate analgesia and vascular reconstruction if appropriate. Compression bandaging must not be used.

Neuropathic ulcers

Neuropathic ulcers tend to be seen over pressure areas of the feet, such as the metatarsal heads, owing to repeated trauma. They are most commonly found in diabetics due to peripheral neuropathy. In some developing countries, leprosy is a common cause.

Management depends on keeping the ulcer clean and removing pressure or trauma from the affected area. Diabetics should pay particular attention to foot care and correctly fitting shoes with the help of a specialist podiatrist (see pp. 1272–1273).

Pressure ulcers (decubitus ulcers, bedsores)

These occur in elderly, immobile, unconscious or paralysed patients. They are due to skin ischaemia from sustained pressure over a bony prominence: most commonly, the heel and sacrum. Normal individuals feel the pain of continued pressure, and even during sleep movement takes place to change position continually. Pressure ulcers may be graded:

- Stage I: non-blanchable erythema of intact skin.
- Stage II: partial-thickness skin loss of epidermis/dermis (blister or shallow ulcer).
- Stage III: full-thickness skin loss involving subcutaneous tissue but not fascia.
- Stage IV: full-thickness skin loss with involvement of muscle/bone/tendon/joint capsule.

There are numerous risk factors for the development of pressure ulcers (Box 31.20).

Box 31.20

Risk factors for the development of pressure ulcers

**Prolonged immobility**

- Paraplegia
- Arthritis
- Severe physical disease
- Apathy
Operation and postoperative states
- Plaster casts
- Intensive care

**Decreased sensation**
- Coma, neurological disease, diabetes mellitus
- Drug-induced sleep

**Vascular disease**
- Atherosclerosis, diabetes mellitus, scleroderma, vasculitis

**Poor nutrition**
- Anaemia
- Hypoalbuminaemia
- Vitamin C or zinc deficiency

The majority of pressure ulcers occur in hospital. Some 70% appear in the first 2 weeks of hospitalization; 70% are in orthopaedic patients, especially those on traction. Between 20% and 30% of pressure ulcers occur in the community. Some 80% of patients who have deep ulcers involving the subcutaneous tissue die in the first 4 months.

The early sign of red/blue discoloration of the skin can lead rapidly to ulcers in 1–2 hours. Leaving patients on hard emergency room trolleys or sitting them in chairs for prolonged periods must be avoided.

**Management**
- Bed rest with pillows and fleeces to keep pressure off bony areas (e.g. sacrum and heels) and prevent friction.
- Air-filled cushions for patients in wheelchairs.
- Special pressure-relieving mattresses and beds.
- Regular turning but avoidance of pressure on hips.
- Adequate nutrition.
- Non-irritant occlusive moist dressings (e.g. hydrocolloid).
- Adequate analgesia (may need opiates).
- Plastic surgery (debridement and grafting in selected cases).
- Treatment of underlying condition.

**Prevention**
Prevention is better than cure. Specialist ‘tissue-viability nurses’ help identify at-risk patients and train other clinical staff. Several risk assessment tools have been devised for the immobile patient, based on the known risk factors. The ‘Norton scale’ and Waterlow Pressure Ulcer Risk Assessment (Box 31.21) are two such validated systems; they produce a numerical score, enabling staff to identify those at most risk. Braden, Walsall and Maelor scales are also used.

*Low scores carry a high risk.
Vasculitis

Vasculitis (see also pp. 699–702) is an inflammatory disorder of blood vessels that causes endothelial damage. Cutaneous vasculitis (confirmed by skin biopsy) may be an isolated problem or part of a systemic disease with involvement of other organs. The most commonly used classification is based on the size of blood vessel involved (see Boxes 18.37 and 18.38).

The cutaneous features are haemorrhagic papules, pustules, nodules or plaques, which may erode and ulcerate. These purpuric lesions do not blanch with pressure from a glass slide (‘diascopy’). Occasionally, a fixed livedo reticularis pattern may appear, which does not disappear on warming. Pyrexia and arthralgia are common associations, even in the absence of significant systemic involvement. Other clinical features depend on the underlying cause.

**Leucocytoclastic vasculitis** (LCV) or angiitis is the most common cutaneous vasculitis affecting small vessels. This usually appears on the lower legs as a symmetrical palpable purpura. It is rarely associated with systemic involvement. It can be caused by drugs (15%), infection (15%), inflammatory disease (10%) or malignant disease (<5%) but often no cause is found (55–60%). Investigations are only necessary with persistent lesions or associated signs and symptoms. Whilst LCV often settles spontaneously, treatment with analgesia, support stockings, dapsone or prednisolone may be needed to control the pain and to heal any ulceration. *Urticarial vasculitis* is discussed on page 1357.

*Calciphylaxis (calcific uraemic arteriopathy)* is described on page 780.

Lymphatics

**Lymphoedema**

Lymphoedema refers to a chronic, non-pitting oedema caused by lymphatic insufficiency. It most commonly affects the legs and tends to progress with age. The legs can become enormous and prevent normal shoes being worn. Chronic disease may cause a secondary ‘cobblestone’ thickening of the skin. Lymphoedema can be primary (and present early in life) due to an inherited deficiency of lymphatic vessels (e.g. Milroy's disease) or can be secondary due to obstruction of lymphatic vessels (e.g. filarial infection or malignant disease).

*Management* is with compression stockings and physical massage. If there is recurrent cellulitis, long-term antibiotics are advisable, as each episode of cellulitis will further damage the lymph vessels. Surgery should be avoided.

**Lymphangioma circumscriptum**

This is a rare hamartoma of lymphatic tissue. It usually presents in childhood with multiple small vesicles in the skin, which weep lymphatic fluid and sometimes blood. They reflect deeper vessel involvement and so surgery should be avoided. Cryotherapy or CO₂ laser treatment may help the superficial lesions.
Further reading

Disorders of Collagen and Elastic Tissue

**Ehlers–Danlos syndrome**

Ehlers–Danlos syndrome (see also pp. 666–667) is a term that refers to a group of inherited autoimmune rheumatic diseases that manifest with abnormalities in the skin, ligament, joints, blood vessels and internal organs. The underlying defects are varied and involve abnormalities of synthesis of collagen fibrils and extracellular matrix molecules (see p. 94). Cutaneous features include hyper-extensible skin, tissue paper scarring and pseudo-tumours at the sites of scars. Skin biopsy with electron microscopy can be helpful in guiding the need for genetic testing. The beta-blocker celiprolol significantly decreases the severe arterial complications of the vascular form of type IV Ehlers–Danlos syndrome.

**Pseudoxanthoma elasticum**

Pseudoxanthoma elasticum is a rare disease involving abnormal mineralization of connective tissue, characterized by changes in the skin, eye and blood vessels. It is caused by mutations in the cell transporter gene *ABCC6*. The skin may be slack and wrinkled with a yellow, papular,
‘plucked chicken’ appearance. These changes are best seen in the flexures, especially the sides of the neck. Non-cutaneous features include recurrent gastrointestinal bleeding, early myocardial infarction, claudication and angioid streaks on the retina.

**Striae distensae (stretch marks)**

Striae are linear scars caused by dermal collagen damage and fragmentation of elastic tissue. They occur commonly over the abdomen and breasts in pregnancy, and on the thighs and trunk in adolescents and obese individuals. Striae are usually red–blue then fade to white atrophic lines. The cause is unknown but excessive skin tension, high levels of cortisol (as in Cushing syndrome) and genetics may play a role. Striae are also seen in Marfan syndrome.

**Keloids and hypertrophic scars**

Abnormal wound healing with excessive dermal fibrosis leads to hypertrophic scars and keloid formation. Hypertrophic scars remain confined to the borders of the original wound and usually regress spontaneously. Keloids *(Fig. 31.46)* can arise spontaneously or after trauma and continue to proliferate and enlarge beyond the wound margins. They are often itchy and tend to affect young, dark-skinned adults. Sites of predilection include the shoulders, upper back and chest, earlobes and chin. Treatment options include silicone gel or dressings, cryotherapy and intralesional triamcinolone. Newer agents include intralesional chemotherapeutic agents (5-fluorouracil or bleomycin) and laser therapy (pulsed dye laser, non-ablative fractional lasers).

**Further reading**

Disorders of Pigmentation

Hypopigmentation

Vitiligo

Vitiligo is chronic depigmenting skin disorder that affects 1–2% of the world population; about a third of all cases start in childhood. Vitiligo has features of an autoimmune disorder with an aberrant T-cell response against melanocytes, and is associated with other organ-specific autoimmune diseases. It presents with asymptomatic, symmetrical, well-demarcated macules of complete pigment loss and typically affects the face, genitalia and bony prominences (Fig. 31.47). Pigment may be lost from overlying hair. There is no history of preceding inflammation. Treatment is often unsatisfactory and has no impact on the long-term outcome. Potent topical corticosteroids, topical tacrolimus and phototherapy (UVB, PUVA or excimer laser) may stimulate repigmentation, and this usually starts around hair follicles, giving a speckled appearance. Repigmentation is less likely in established lesions and acral sites. Sunblocks should be used to prevent burning. Patients may benefit from psychological support and skin camouflage advice. If vitiligo is extensive and fixed, the remaining pigment can be removed with monobenzone.
**Post-inflammatory hypopigmentation**

This phenomenon is sometimes noticeable in dark-skinned individuals when inflammatory rashes such as eczema and psoriasis clear. It may be mistaken for vitiligo, but lesions are usually hypopigmented rather than depigmented, and recover spontaneously over several months, as long as the underlying disease is controlled.

**Oculocutaneous albinism**

This group of rare autosomal recessive disorders are caused by reduced or absent pigment synthesis in the skin, hair and eyes. It can affect all races. Affected individuals have pale skin, white or yellow hair, and a pink iris. Ocular manifestations include photophobia, nystagmus and a squint. Meticulous UV protection is required to prevent sunburn and reduce the risk of skin cancer.

**Idiopathic guttate hypomelanosis**

This occurs most commonly in black African people and is of unknown aetiology. It presents with small (2–4 mm), asymptomatic, porcelain-white macules, often on skin exposed to sunlight. The borders are frequently sharply defined and angular. There is no effective treatment.

**Leprosy**

Both tuberculoid leprosy and indeterminate leprosy (see also pp. 285–286) can present with anaesthetic hypopigmented patches and should always be considered in people from endemic
regions. Lesions may also show hair loss and decreased sweating.

**Hyperpigmentation**

---

**Freckles (ephelides)**

These appear in childhood as small brown macules after sun exposure. They fade in the winter.

---

**Lentigines**

These are persistent pigmented macules that look similar to freckles. They may rarely be associated with systemic syndromes (e.g. Peutz–Jeghers (see p. 403), LEOPARD/Noonan (Lentigines, ECG abnormalities, Ocular hypertension, Pulmonary stenosis, Abnormalities of genitalia, Retardation of growth and Deafness). Solar lentigines (‘age spots’, ‘liver spots’) are common on the dorsal hands and face and on bald scalps in older, fair-skinned people.

---

**Café-au-lait macules**

These may occur as an isolated abnormality. Multiple lesions are also a feature of neurofibromatosis types 1 and 2, tuberous sclerosis, ataxia telangiectasia, Fanconi's anaemia, multiple endocrine neoplasia type 1 and McCune–Albright syndrome.

---

**Chloasma (melasma)**

This is a common complaint in pregnancy and women taking hormonal contraception. Asymptomatic beige–brown patches develop on the forehead, temples and cheeks. Topical treatment with azelaic acid or retinoic acid (which should be avoided in pregnancy) and 2–5% hydroquinone may help. High-factor sunscreens are needed to prevent relapse.

---

**Post-inflammatory hyperpigmentation**

This phenomenon occurs in dark-skinned individuals at the sites of skin trauma or inflammatory rashes, such as acne, lichen planus and eczema. It improves slowly over many months.

---

**Metabolic/endocrine effects**

Generalized skin darkening can occur with chronic liver disease, especially haemochromatosis. It is also seen sometimes in Cushing syndrome, Addison's disease (more marked in palmar creases and buccal mucosa) and Nelson syndrome.
**Urticaria pigmentosa (cutaneous mastocytosis)**

This disorder is caused by a benign proliferation of cutaneous mast cells. It presents most commonly in childhood as multiple pigmented macules that become red, itchy and urticated if they are rubbed (Darier's sign). Occasionally, lesions may blister. Extensive mast cell degranulation can lead to systemic symptoms, such as wheeze, flushing, syncope or diarrhoea and, very rarely, anaphylaxis. This may be triggered by drugs, including aspirin and opiates. Childhood urticaria pigmentosa usually resolves spontaneously but adult-onset disease is often persistent. Histology of skin lesions shows increased numbers of mast cells. Most cases are due to somatically acquired activating mutations of the *KIT* receptor that controls mast cell proliferation and apoptosis. Rarely, in adult and neonatal disease, urticaria pigmentosa may progress with mast cell infiltration of internal organs (bone, gastrointestinal tract, liver, spleen – systemic mastocytosis). There is a small risk of developing leukaemia if the bone marrow is heavily infiltrated. Therapy of cutaneous mastocytosis is aimed at controlling the symptoms of mast cell mediator release with antihistamines and cromoglicate, and minimizing the risk of anaphylaxis.

**Further reading**

**Disorders of the Nails**

- *Psoriasis* (see pp. 1353–1356), *fungal infection* (pp. 1345–1347) and *trauma* are the most common causes of abnormal nail growth (dystrophy).
- *Pitting* can be caused by psoriasis, alopecia areata, atopic eczema and trauma.
- *Onycholysis* (distal nail plate separation) is caused by psoriasis, thyrotoxicosis, trauma and, rarely, a phototoxic drug reaction (e.g. with tetracyclines).
- *Koilonychia* (thin, spoon-shaped nails) can be caused by iron deficiency anaemia.
- *Leuconychia* (white nails) is seen in hypoalbuminaemia.
- *Beau’s lines* (transverse lines) are horizontal grooves that grow distally with the nail over several months. They are associated with an acute severe illness that causes a temporary arrest in nail growth.
- *Yellow-nail syndrome* is a rare disorder of lymphatic drainage. It presents with thickened, slow-growing, yellow nails, which may be associated with pleural effusions, bronchiectasis and lymphoedema of the legs.
- *Sub-ungual hyperkeratosis* is thickening of the nail plate – usually due to tinea infection (see p. 1346), psoriasis, trauma or a combination of these.
• **Onychogryphosis** is severe nail thickening and curvature (ram's horn), which is common in the elderly, especially in the big toe-nail, where trauma from ill-fitting footwear may be relevant.

• **Longitudinal melanonychia** (brown streaks) of multiple nails is a common finding in dark-skinned people. An acquired solitary pigmented streak may be caused by a melanocytic naevus and needs to be differentiated from subungual melanoma (see pp. 1373–1374), especially if the pigmentation spreads on to the adjacent nail fold (‘Hutchinson’s sign’).

• **Sub-ungual haemorrhage** is common in the great toe-nails after trauma (football, running downhill). The red–brown pigmentation grows out with the nail over several months with clear proximal growth.

• **Clubbing** is discussed on page 1067.

  Nail dystrophy is also a feature of various genodermatoses including *nail patellar syndrome* (triangular lunulae, dystrophic nails and absent or hypoplastic patellae; *ectodermal dysplasias* (abnormal hair, teeth and nail) and *pachyonychia congenita* (‘hoof’ nails and keratoderma).

---

**Further reading**

---

**Disorders of Hair**

**Hair loss**

Hair loss can be due to either a disorder of the hair follicle in which the scalp skin looks normal (non-scarring alopecia), or a disorder within the scalp skin that causes permanent loss of the follicle (scarring or cicatricial alopecia). This latter form causes shiny, atrophic bald areas in the scalp, which are devoid of follicular openings. There are many causes of alopecia (*Box 31.22*).

---

**Box 31.22**

**Causes of alopecia**

**Scarring alopecia**

• Discoid lupus erythematosus
• Kerion (tinea capitis)
• Lichen planus
- Dissecting cellulitis
- X-irradiation
- Idiopathic (‘pseudopelade’)

**Non-scarring alopecia**
- Androgenic alopecia
- Telogen effluvium
- Alopecia areata
- Trichotillomania (self-induced hair-pulling)
- Tinea capitis
- Traction alopecia
- Metabolic (iron deficiency, hypothyroidism)
- Drugs (e.g. heparin, isotretinoin, chemotherapy)

---

**Androgenic alopecia**

Androgenic alopecia (male-pattern baldness) is the most common type of non-scarring hair loss and depends on genetic factors and an abnormal sensitivity to androgens. It presents in young men with frontal receding followed by thinning of the crown, and there is often a positive family history. It also occurs in females but tends to occur at a later age, be milder and show little in the way of frontal recession. If acne and menstrual disturbance are also present, the cause may be polycystic ovary syndrome or another endocrine disorder of androgens.

*Treatment* may not be required. Topical 5% minoxidil lotion or oral 5-alpha-reductase inhibitors (finasteride or dutasteride) can help arrest progression and may induce modest regrowth, providing they are used early in disease, but the treatment needs to be continued indefinitely. Approximately one-third of patients will not respond to either therapy. Finasteride is well tolerated but causes sexual adverse effects, such as loss of libido in about 1% of men. It should not be used in females, as it can affect the sexual development of a male fetus. However, antiandrogen therapy (e.g. cyproterone acetate or spironolactone) may help some women.

---

**Alopecia areata**

Alopecia areata is thought to be an autoimmune disease, as it is often associated with other organ-specific autoimmune diseases. Recent genome-wide association studies have implicated ligands for the NKG2D receptor (the product of the *KLRK1* gene) in disease pathogenesis.

Alopecia areata presents in children or young adults with patches of baldness (*Fig. 31.48*). These may regrow, to be followed by new patches of hair loss. The presence of broken exclamation mark hairs (narrow at the scalp and wider and more pigmented at the tip) at the
edge of a bald area is diagnostic. Regrowth may initially be with white hairs and often occurs slowly over months. Occasionally, all of the scalp hair is lost (alopecia totalis) and, rarely, all body hair is lost (alopecia universalis). The nails may be pitted or roughened.

**Figure 31.48**  Alopecia areata.

*Management* has no effect on the long-term progression. Potent topical or injected steroids may trigger regrowth of localized patchy hair loss. Topical immunotherapy with diphencyprone can be helpful in more extensive disease. There is insufficient evidence to justify using PUVA, topical minoxidil or tacrolimus ointment. Oral ruxolitinib (a JAK1 and 2 inhibitor) has recently been shown to be highly effective in a mouse model of alopecia, as well as in three patients with alopecia areata. Larger studies are currently under way. Wigs can be provided for severe cases and patient support groups are often beneficial.

**Traction alopecia**

This refers to the ‘mechanical damage’ type of hair loss that arises from pulling the hair back into a bun or tight plaits. It is more common in black Africans.

**Telogen effluvium**

Telogen effluvium refers to the pattern of diffuse hair loss that occurs some 3 months after pregnancy or a severe illness. It occurs because ‘stress’ puts all the hairs into the telogen phase of hair shedding at the same time. The hair fully recovers and the normal staggered hair growth/hair shedding cycle resumes within a few months.

**Dissecting cellulitis**

This is a chronic folliculitis of the scalp that predominantly affects young black men. Papules and pustules occur over the back of the scalp with scarring hair loss, and the skin may become
chronically swollen and purulent with a boggy texture (Fig. 31.49). Prolonged courses of oral antibiotics, including a combination of rifampicin and clindamycin, may be helpful.

**Increased hair growth**

**Hirsutism**

Hirsutism (see p. 1220) refers to the male pattern of hair growth seen in females. The racial variation in hair growth must be considered. Certain races (e.g. Mediterranean and Asian) have more male-pattern hair growth than Northern European females. This is not due to excess androgens but may reflect a genetically determined altered sensitivity to them. If virilizing features (deep voice, clitoromegaly, dysmenorrhoea, acne) are present, a full endocrine assessment is necessary. Hirsutism can cause severe psychological distress in some individuals.

**Management** involves physical methods, such as bleaching, waxing, electrolysis, intense pulsed light (IPL) and laser therapy. Oral anti-androgen therapy is occasionally helpful.

**Hypertrichosis**

Hypertrichosis refers to the state of excessive hair growth at any site and occurs in both sexes. It can be seen in anorexia nervosa, porphyria cutanea tarda and underlying malignancy, and is caused by certain drugs (e.g. ciclosporin, minoxidil).

Birth Marks/Neonatal Rashes

**Infantile haemangioma (strawberry naevus, cavernous haemangioma)**

Infantile haemangioma affects up to 1% of infants *(Fig. 31.50)*. It presents at, or shortly after, birth as a single red, lumpy nodule that grows rapidly for the first few months. Multiple lesions can be present. They will spontaneously resolve with good cosmesis but complete resolution may take up to 7 years. Occasionally, plastic surgery is needed after resolution to remove residual slack skin. Reassurance of parents is usually all that is required.

![Figure 31.50: Strawberry naevus (cavernous haemangioma).](image)

Urgent treatment is indicated if the lesion:

- interferes with feeding or vision
- ulcerates or bleeds frequently
- is associated with high-output cardiac failure from shunting of large volumes of blood
- consumes platelets and/or clotting factors, causing potentially life-threatening haemorrhage (‘Kasabach–Merritt syndrome’).

The last two complications are very rare and tend to occur only in large lesions with significant deep-vessel involvement.

*Treatment* has been revolutionized by the discovery that oral propranolol (3 mg/kg per day in 3 divided doses) rapidly shrinks infantile haemangiomas, even the deep or sub-glottic lesions. The mechanism of action is unclear. Treatment may need to be continued for up to a year. Side-effects (acrocyanosis, disturbed sleep, hypotension) are usually mild. In life-
threatening cases, high-dose systemic steroids, vincristine or embolization may be used.

**Port-wine stain (naevus flammeus)**

Port-wine stain is also called a capillary haemangioma but, strictly speaking, it is not a haemangioma, just an abnormal dilatation of dermal capillaries. It presents at birth as a flat, red, macular area and is commonly found on the face. It does not improve spontaneously and may become thickened with time. If the lesion is found in the distribution of the first division of the trigeminal nerve, it may be associated with ipsilateral meningeal vascular anomalies that can cause epilepsy and even hemiplegia (Sturge–Weber syndrome). Periocular lesions may be associated with glaucoma and so ophthalmological follow-up is required.

*Management* of port-wine stains is ideally with a vascular selective laser, such as the tunable dye (pulsed dye) laser. Facial lesions respond best but lesions can darken after several years and require retreatment.

**Milia**

‘Milk spots’ are small follicular epidermal cysts. These small, pinhead, white papules are commonly found on the face of infants. They resolve spontaneously, unlike in adults.

**Congenital melanocytic naevi**

Some children are born with small melanocytic naevi (<2 cm in diameter). In later life, they are usually larger than acquired naevi and often have coarse hair. They may display some irregularity in colour and border but malignant change is extremely rare, so prophylactic excision is not necessary. It is only the giant congenital melanocytic naevus (>20 cm) that has a high risk for malignant transformation (see p. 1373).

**Mongolian blue spot**

This appears in infants as a deep blue–grey, bruise-like area, usually over the sacrum or back (*Fig. 31.51*); it is occasionally mistaken for a sign of child abuse. Mongolian blue spot is due to presence of melanocytes in the deeper dermis. It is very common in Oriental children, less common in black Africans and rare in Caucasians. It usually disappears by the age of 7 years.
Toxic erythema of the newborn (erythema neonatorum)

Toxic erythema of the newborn is a term used to describe a common transient, blotchy, maculopapular rash in newborns. The rash is occasionally pustular but the child is not toxic or unwell. It disappears spontaneously within a few days.

Nappy rash (‘diaper dermatitis’)

This is a form of irritant contact dermatitis caused by prolonged skin contact with faeces and urine. It is much less common nowadays due to the high absorbency of disposable nappies. The flexures are usually spared, which is a useful differentiating feature from atopic eczema. Satellite lesions around the edge may indicate a superimposed candidal infection. A recalcitrant purpuric nappy rash in the groins and axillae should be biopsied to exclude rarer pathology such as Langerhans cell histiocytosis.

Management involves frequent changing of the nappy and regular application of a barrier cream.

Acrodermatitis enteropathica

This rare but distinctive rash (see p. 203) is a manifestation of zinc deficiency, which can occur in three settings:

- an inherited defect in zinc transporter protein in the gastrointestinal tract (presents after breast-feeding finishes)
- low levels in breast milk in breast-fed infants (presents during breast-feeding)
- patients on total parenteral nutrition without adequate zinc replacement.

There is an erythematous, sometimes blistering, rash around the perineum, mouth, hands and feet. It may be associated with photophobia, diarrhoea and alopecia.
In the inherited form the rash presents when breast-feeding finishes, as breast milk usually has high levels of zinc that override the poor absorption. These cases will need life-long oral zinc replacement therapy, not just to improve the skin but also to ensure normal neurological development. The second type needs replacement only until breast-feeding finishes. The response to zinc is rapid and dramatic.

**Further reading**

**Drug Eruptions**
Drugs can cause predictable, dose-related adverse effects in the skin, such as phototoxicity from doxycycline or mucocutaneous dryness from oral isotretinoin. They may also cause hypersensitivity rashes ranging from mild exanthems to severe, life-threatening eruptions (severe cutaneous adverse drug reactions). These are idiopathic and can be difficult to diagnose because individual drugs can lead to different rashes, and these sometimes mimic constitutional dermatoses such as dermatitis or viral rashes. A high index of suspicion and a detailed drug history are essential. Underlying viral infection, especially HIV, and systemic disease, such as systemic lupus and leukaemia, may also increase the risk of drug rashes (*Fig. 31.52*). Allergy tests (prick tests and patch tests) have a limited role, especially in the acute setting, and drug challenge tests are time-consuming and potentially risky.
Maculopapular (morbilliform) exanthems

These are the most common type of hypersensitivity rash (Fig 31.53). They start on the torso and spread to the face and limbs, but spare the mucosae. They are self-limiting and usually clear within 1–2 weeks.
Fixed drug eruptions

These are inflamed patches that recur at the same site each time a drug is taken. They may blister, and often resolve with hyperpigmentation.

Drug-induced and drug-exacerbated dermatoses

Drugs may exacerbate pre-existing skin disease and can also trigger/induce skin disease that resembles a constitutional dermatosis. Examples are shown in Box 31.23.

Severe cutaneous adverse drug reactions

Severe drug rashes are listed below (Box 31.24). Common causes include antibiotics, NSAIDs, anticonvulsants, allopurinol, Dapsone and nevirapine. Early recognition and drug
withdrawal can minimize morbidity and mortality. Recent advances in pharmacogenetics have identified HLA associations, and cytochrome P450 polymorphisms which are associated with an increased risk of reaction to certain drugs.

### Box 31.24

**Severe cutaneous adverse drug reactions**
- Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN)
- Drug reaction with eosinophilia and systemic symptoms (DRESS)
- Acute generalized exanthematous pustulosis (AGEP)
- Erythroderma/exfoliative dermatitis
- Serum sickness-like reactions

### Stevens–Johnson syndrome and toxic epidermal necrolysis

Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are severe mucocutaneous disorders, which are considered variants of a disease spectrum. They are characterized by varying extents of blistering/epidermal detachment and mucosal ulceration:

- **SJS**: <10% skin detachment; one or two mucosal sites involved (oral, genital, ocular)
- **SJS–TEN overlap**: 10–30% skin detachment
- **TEN**: >30% skin detachment: all mucosal sites involved in most cases.

The onset is usually 1–2 weeks after drug exposure. Initial symptoms are non-specific (malaise, myalgia, fever and cough). These are followed by very tender areas of maculopapular erythema on the torso with inflammation of mucosal surfaces. Target lesions may occur on the hands and feet in SJS. In TEN there is widespread flaccid blistering with skin that wrinkles like wet wallpaper on gentle pressure (Nikolsky's sign). Features of ‘skin failure’ can ensue, with defective fluid and temperature regulation leading to hypotension and renal impairment. Respiratory mucosal and pulmonary involvement may require ventilation, and upper gastrointestinal involvement can cause haemorrhage. Patients are at high risk of sepsis and require expert intensive supportive care, as for extensive burns. Multiorgan failure may occur and the mortality for TEN ranges from 30% to 50%. ‘SCORTEN’ is a clinical severity score that can help assess prognosis (**Box 31.25**). All potential drug causes should be stopped.

### Box 31.25

**SCORTEN prognostic score in toxic epidermal necrolysis**
**Risk factor** | 0 | 1
---|---|---
**Age** | <40 years | >40 years
**Associated malignancy** | No | Yes
**Heart rate (b.p.m.)** | <120 | >120
**Serum urea (mmol/L)** | <9.6 | >9.6
**Detached or compromised body surface** | <10% | >10%
**Serum bicarbonate (mmol/L)** | >20 | <20
**Serum glucose (mmol/L)** | <13.9 | >13.9

The more risk factors present, the higher the SCORTEN score, and the higher the mortality rate:
- 0–1 risk factors: 3.2% mortality
- 2: 12.1%
- 3: 35.3%
- 4: 58.3%
- ≥5: >90%

**Treatment** with high-dose steroids, ciclosporin and intravenous immunoglobulin therapy remains controversial, as high-quality clinical trials are lacking.

### Drug reaction with eosinophilia and systemic symptoms/drug hypersensitivity syndrome
Drug reaction with eosinophilia and systemic symptoms (DRESS)/drug hypersensitivity syndrome usually starts 2–6 weeks after initial exposure and is characterized by widespread erythema, facial oedema, fever, lymphadenopathy and hepatosplenomegaly. Blood eosinophilia is usual with elevated hepatic transferases. Pneumonia and nephritis can develop and a mortality rate of 10% has been reported. Treatment is with oral steroids tapered over at least 3 months. Aromatic anticonvulsants are one of the most common causes of DRESS and, as they cross-react, all drugs of this group must be avoided in the future. Sodium valproate is a suitable alternative.

### Acute generalized exanthematous pustulosis/toxic pustuloderma
Acute generalized exanthematous pustulosis (AGEP)/toxic pustuloderma is an exanthem with numerous small, non-follicular, sterile pustules that usually develop around the neck, axillae and groin. It usually starts a few days after drug exposure and resolves with peeling. There may be mild systemic upset but internal organs are not involved. Topical steroids and emollients can be used to relieve symptoms.

**Further reading**
Dodiuk-Gad RP, Laws PM, Shear NH. Epidemiology of severe drug hypersensitivity. *Semin*
Human Immunodeficiency Virus and the Skin

HIV infection (see pp. 331–355) commonly causes significant dermatological problems and a rash may even be the presenting feature of HIV infection. Rashes may be severe or atypical and difficult to diagnose; histology or culture of skin biopsies is sometimes required for diagnosis. Prior to anti-retroviral therapy (ART; see pp. 341–346), many dermatoses associated with advanced HIV infection were recalcitrant, but this treatment has considerably reduced their prevalence.

### Seroconversion rash

This is a non-specific maculopapular exanthem that occurs in up to 75% of individuals a few weeks after contracting the virus as they start to make an anti-HIV antibody response. There may be an associated fever, malaise, myalgia, lymphadenopathy and mouth ulceration (or oral candidiasis). Symptoms usually resolve within a few weeks. This episode is often dismissed as influenza and the diagnosis missed. Patients are extremely infectious at this time due to very high viral loads.

### Cutaneous infection and opportunistic infection

These are increased due to HIV-induced immune deficiency. *Molluscum contagiosum* is particularly common, especially on the face. Lesions are often multiple and of a ‘giant’ size, measuring over 1 cm across. Molluscum is rarely seen in immunocompetent adults but can be the presenting feature of HIV. Other viral infections, such as extensive ulcerative herpes or widespread viral warts, are seen. Bacterial infections (e.g. staphylococcal boils) and fungal infections (e.g. ringworm and *Candida*) are also common. Recalcitrant and recurrent oropharyngeal candidiasis is a particular problem.

*Opportunistic infections*, such as cutaneous cytomegalovirus (pustules or necrotic ulcers), sporotrichosis (linear nodules) or *Cryptococcus* (red papules, psoriasiform or molluscum-like lesions), can pose diagnostic difficulties, stressing the need for skin biopsy and culture.

### Inflammatory dermatoses
These show an increased incidence with HIV infection, probably due to an immune dysfunction or imbalance. Severe, extensive seborrheoeic eczema is very common and is often a presenting sign of HIV. Ichthyosis (dry, scaly skin), nodular prurigo, pruritus and psoriasis are all more common in HIV infection and can be very severe. The treatment of these conditions can be difficult in patients who have low CD4 counts (<200/mm³), as oral immunosuppressive therapies (e.g. prednisolone, ciclosporin) are best avoided. Topical therapies and phototherapy seem relatively safe and oral retinoids are a safe option for psoriasis.

‘Autoimmune dermatoses’

Dermatoses such as bullous pemphigoid, thrombocytopenic purpura and vitiligo seem to increase in incidence. The aetiology is related to polyclonal stimulation of B lymphocytes by HIV with a resulting abnormal antibody production. Erythroderma is sometimes seen in HIV disease where skin biopsy suggests a 'graft-versus-host disease’ mechanism. This presumably reflects a severe underlying immune dysfunction of T-lymphocyte control.

Drug rashes

These are much more common in HIV patients. Reactions (maculopapular rash) to co-trimoxazole, dapsone (used in Pneumocystis prophylaxis) and anti-retroviral drugs appear particularly common. Drug rashes may be severe (especially with nevirapine and efavirenz), resulting in erythroderma or toxic epidermal necrolysis. Other unusual rashes include a striking nail/mucosal pigmentation from zidovudine, paronychia from indinavir and lipodystrophy (of the face and abdomen/buttocks) from protease inhibitors. As protease inhibitors and zidovudine are now used much less often in first-line drug combinations, the latter side-effects are rare today.

Cutaneous tumours

Benign tumours, such as extensive persistent viral warts and melanocytic naevi, are more common with HIV infection. Pre-malignant conditions, such as the intraepithelial dysplasias (cervix – CIN, penis – PIN, anal – AIN), are all much increased, possibly due to persistent human papillomavirus infection. The risk of malignant transformation in all these three sites is high and should be assessed by screening.

Kaposi’s sarcoma (see pp. 1374–1375) is much more common in men who have sex with men with HIV than other groups. Basal and squamous cell carcinomas are also increased in incidence, presumably reflecting a loss of immune surveillance.

Interestingly, ART has had little impact on reducing rates of anal, penile or cervical cancer, and although Kaposi's sarcoma seemed almost to disappear early on when CD4 counts rose, it has recently shown a resurgence, even in those with high CD4 counts and fully suppressed virus.
‘Specific’ HIV dermatoses

‘Itchy folliculitis’ of HIV

Itchy folliculitis (also called papular pruritic eruption) is common in HIV as CD4 counts decline. Its aetiology is unknown. The previously described staphylococcal folliculitis, eosinophilic folliculitis, pityrosporum folliculitis and Demodex mite folliculitis are probably all part of a spectrum and the term ‘itchy folliculitis’ is useful to encompass these. It presents with intensely itchy papules centred on hair follicles and occurs most commonly over the upper trunk and upper arms (Fig. 31.54). The face is more commonly involved in black patients. Individual lesions frequently have the top scratched off, leaving a crateriform appearance.

![Itchy folliculitis of HIV infection on upper trunk and proximal limbs.](image)

Management with oral minocycline, potent topical steroids and emollients helps. Phototherapy or oral isotretinoin is useful in resistant cases.

Oral hairy leucoplakia

This is characterized by white plaques with vertical ridging on the sides of the tongue. Unlike in oral candidiasis, the lesions cannot be peeled off. It was first recognized in HIV disease but can rarely occur in other forms of immunosuppression. It is thought to be due to co-infection with Epstein–Barr virus.

Treatment is with aciclovir, ganciclovir or foscarnet.

Immune reconstitution inflammatory syndrome

Many infections can manifest 2–4 months after commencing ART as the CD4 lymphocyte count recovers – so-called immune reconstitution inflammatory syndrome (IRIS). Most commonly described are ano-genital herpes simplex virus infection, viral warts, tinea folliculitis,
molluscum and genital warts. IRIS affects up to 25% of patients on ART and may simply reflect the fact that the recovering immune system can now react against pathogens that were already present. IRIS may also be responsible for an increase in inflammatory rashes, such as folliculitis and subacute lupus erythematosus. It can affect internal organs, such as with an exacerbation of pulmonary tuberculosis or cytomegalovirus retinitis.

**Further reading**

**Principles of Topical Therapy**

The easy accessibility of the skin means that many dermatoses can be treated effectively with topical therapy. This reduces the likelihood of systemic adverse effects compared with oral therapy. Topical formulation consists of an **active ingredient**, in an appropriate **vehicle** or **base**, and **excipients** such as **preservatives** or **emulsifiers** to maintain the product’s shelf-life. Cosmetic acceptability and clear instructions are important in achieving good adherence and efficacy – creams do not work if they stay in the pot! Patients should be advised of common adverse effects, such as irritancy with topical retinoids, and risks, such as atrophy with potent corticosteroids. Clear information, such as the ‘fingertip unit’ for topical corticosteroids, helps guide correct dosage.

- **Creams are oil-in-water emulsions**, which are light and easily absorbed. They usually contain preservatives, such as parabens (hydroxybenzoates), which can cause sensitization. Aqueous cream is a popular and inexpensive soap substitute.

- **Ointments are greasy preparations based in vehicles** such as polyethylene glycol (water-soluble) or petrolatum (insoluble). They feel sticky and are used to treat dry, flaky skin disorders (*Box 31.26*).

**Box 31.26**

**Emollients commonly used in the UK**

**Greasy emollients**

- Epaderm ointment
- Oily cream
- Unguentum Merck
- 50 : 50 white soft paraffin/liquid paraffin
**Lighter creams**

- E45 cream
- Diprobase cream
- Aveeno cream
- Aqueous cream

*Trade names.*

- **Lotions** have a liquid vehicle, such as water or alcohol, which evaporates on contact with the skin, giving a cooling effect. They are useful for weeping skin conditions and hairy skin (e.g. the scalp), but alcohol based-lotions should be avoided on broken skin, as they sting.

- **Gels** are semi-solid preparations of high-molecular-weight polymers. They are non-greasy and liquefy on contact with the skin. They are used to treat oily or hairy areas (e.g. scalp).

- **Pastes** are thick, adherent preparations containing a high percentage (>40%) of powder in an ointment base: e.g. dithranol in Lassar's paste, used for plaque psoriasis. They are seldom used now due to poor cosmetic acceptability.

**Adverse effects of topical therapies**

- **Systemic absorption** may occur but is significant only if large areas of inflamed skin are treated topically, especially with occlusive bandages or dressings. Neonates are particularly susceptible due to their relatively high body surface area and immature stratum corneum.

- **Contact allergy** may develop to the active drug (e.g. hydrocortisone, neomycin) vehicle (e.g. lanolin, cetearyl alcohol) or excipient (e.g. chlorocresol, parabens). It should be suspected in patients with an unresponsive dermatitis or new dermatitis following application of topical treatment. Ointments contain fewer excipients and are therefore less likely to cause contact allergy.

- **Folliculitis** can occur due to blockage of hair follicles especially with use of ointments in hot weather and on occluded skin (bandages, tight clothing).

  **Corticosteroids** can cause a range of adverse effects (see p. 1350). However, they have a very good safety profile when used correctly under supervision.
